Initially, manual evacuation of the rectum may be necessary; however, once this is done, it is necessary to use chronic laxative therapy (Borowitz et al., 2005). Treatment with pharmacologic agents in children is controversial, and few well-designed placebo-controlled trials have been conducted on the use of osmotic laxatives, fiber, formula-switching, sorbitol-containing juices, rectal stimulation by thermometer, or glycerin suppositories. A Cochrane Review of osmotic and stimulant laxatives concluded that PEG preparations may be superior to placebo, lactulose, and milk of magnesia for childhood constipation (Gordon et al., 2012). Liquid paraffin (mineral oil) is also a good alternative. The use of sodium phosphate enemas in children under 2 years of age has been associated with electrolyte disturbances, dehydration, and cardiac arrest.

For infants, malt soup extract or corn syrup (Karo) may be used at a dosage of 5 to 10 mL twice daily. For children older than 6 months, milk of magnesia, lactulose, or sorbitol at a dosage of 1 to 3 mL/kg/d given in one to two doses may be used. Senna syrup at a dosage of 5 to 10 mL/d for children ages 1 to 5 and 10 to 20 mL/d for children ages 5 to 15 is another option.

Geriatric

The choice of a laxative preparation may depend on the patient's attitude or beliefs about normal bowel habits. Normal bowel frequency can range from two or three bowel movements per day to two or three per week. However, many people think that less than one bowel movement per day is abnormal. These patients may seek an OTC laxative to keep them "regular." This concern about regular bowel movements is particularly common

in the elderly. The self-reported incidence of constipation increases with advancing age, but the actual bowel movement frequency usually does not decline.

The overuse of laxatives in the elderly can be of particular concern because this population is more intolerant to the fluid and electrolyte abnormalities that accompany laxative abuse. In addition, many of the laxatives should be used with caution in elderly persons because they are more likely to have the disease states that some laxatives can exacerbate (e.g., heart failure, hypertension). Elderly patients are also more likely to take medications that may cause constipation, such as antipsychotics, tricyclic antidepressants, calcium supplements, and certain blood pressure medications.

Elderly patients should be carefully assessed to determine the cause of the constipation, and causative factors should be eliminated. Careful selection and judicious use of laxatives are necessary to avoid complications in this population.

Women

Girls and women with bulimia or anorexia nervosa may abuse laxatives as a means of reducing nutrient absorption to cause weight loss. Bulimia is 10 times more common in women than in men; it affects up to 3% of young women.

For the pregnant woman, the use of laxatives that are not absorbed into the systemic circulation, such as docusate and bulk-forming agents, should be considered as first-line therapy. Docusate sodium has not been found to be associated with fetal malformations and may be safe to use during pregnancy. Lactulose and sorbitol have not been found to be teratogenic in animals and may be safe to administer to pregnant women. Stimulant laxatives should be used only occasionally, if necessary. Cascara sagrada may cause loose stools in breast-fed infants. Castor oil should be avoided in pregnant women because of the risk of stimulation of uterine contractions. Mineral oil should be avoided because its use can reduce the absorption of necessary vitamins by the mother, which may result in deficiencies for the neonate.

Monitoring Patient Response

Monitoring the patient's response to laxative therapy usually is accomplished by asking the patient whether he or she has regained normal bowel patterns after using the laxative. Different patients have different perceptions of what "normal" bowel habits are. Depending on the factors affecting defecation, patients should be informed that the reason for treating with a laxative is not to increase the frequency of defecation but to promote comfortable defecation. Periodic use of laxatives can be safe as there is no substantial evidence of abuse potential.

Patient Education

In most cases, the occasional use of laxatives poses no major problems for the patient. Laxatives are relatively safe when used in moderation. However, the fact that many laxatives are available OTC may give consumers the false impression that constipation is a physiologic condition and there are no other alternatives for treatment. Understanding of constipation has expanded in recent years, and health care providers can provide other options for treatment.

Health care providers should work with patients who have constipation and guide them to the best treatment options. OTC laxatives carry a warning for the consumer not to use them for more than 7 days. For chronic constipation, use of a bulk-forming laxative may be a safer alternative, provided no contraindications exist. However, patients should be counseled that bulk-forming laxatives take time to work (up to 3 days). Because patients are usually looking for an immediate response, they may draw the conclusion that these agents are not effective if a bowel movement has not occurred within the first day.

Patient-Oriented Information Sources

Providing patients with information about constipation can help them understand constipation and their role in treatment. Patient education items are readily available on the Internet through the National Digestive Diseases Information Clearinghouse, which provides information to consumers on a wide variety of GI topics (see Box 30.11).

Nutrition/Lifestyle Changes

Patients should be educated on the lifestyle modifications discussed previously to reduce the need for a laxative. An increase in fluid intake improves the efficacy of most laxatives. Patients should also be educated on the potential for side effects of the laxative chosen as well as the appropriate method to administer the laxative.

Complementary and Alternative Medications

Little evidence exists that any specific herbal supplement or alternative treatment works to relieve constipation (Cherniak, 2013). However, probiotics found in yogurt and are relatively easy to obtain and worth trying.

Diarrhea

True diarrhea is an increase in frequency of loose, watery stools (three or more daily), usually over a period of 24 to 48 hours. It is a relatively common disorder of the GI tract that is experienced occasionally by most people. The organisms that cause diarrhea are easily transferred from person to person through food and water. Globalization and industrialization of the world has increased the ability of these organisms to spread. Experts of infectious diseases estimate that 211 million people experience acute diarrhea every year; an average of 16 million seek medical attention, resulting in 1.2 million hospitalizations and >5,000 deaths (Bushen & Guerrant, 2003; Jones et al., 2007). Children, the elderly, and those who are immunocompromised are most susceptible to the complications of diarrhea, and serious dehydration can result from the disorder. Proper hydration and symptomatic treatment as well as elimination of causative factors are necessary to prevent these complications. Ultimately, diarrhea can have a profound impact on public health, and proper diagnosis and treatment can prevent an epidemic.

Causes

Diarrhea may be caused by a host of different medications (Box 30.4), infective organisms (Box 30.5), or disease states or procedures (Box 30.6). Prompt attention to causative factors, as well as rehydration, prevents complications.

BOX 30.4 Medications Commonly Causing Diarrhea

Antacids (magnesium containing)
Antibiotics
Antidepressants (SSRIs)
Cholinergic agents
Colchicine
Digoxin
Gastrointestinal stimulants (metoclopramide)
Laxatives
Metformin
Prostaglandins (dinoprostone)
Prostaglandin analog (misoprostol)
Quinidine

BOX 30.5 Infective Organisms Associated with Diarrhea

Aeromonas species
Bacillus cereus
Campylobacter
Chlamydia trachomatis
Clostridium difficile
Cryptosporidium
Escherichia coli
Entamoeba histolytica
Giardia
Mycobacterium avium-intracellulare
Salmonella
Shigella
Staphylococcus aureus

Viral agents
Yersinia

BOX 30.6 Disorders and Procedures Associated with Diarrhea

Acquired immunodeficiency syndrome
Bowel resection
Colon cancer
Diverticulitis
Enteral feedings
Gastroenteritis
Hyperthyroidism
Inflammatory bowel disease
Irritable bowel syndrome
Lactose intolerance
Malabsorption
Pheochromocytoma

Medications

Antibiotics may cause diarrhea by direct irritation of the intestinal tract or disruption of the normal intestinal flora. The poor absorption of erythromycin (E-mycin) lends itself to irritation of the GI tract. Clarithromycin (Biaxin) and azithromycin (Zithromax) may cause less diarrhea than erythromycin. The clavulanic acid component of the combination of amoxicillin–clavulanic acid (Augmentin) is also a GI irritant, and diarrhea is a common side effect. Tetracycline and ceftriaxone (Rocephin) cause diarrhea by disrupting the normal balance of the gut flora.

Clostridium difficile, a normal part of the flora of the colon in up to 20% of hospitalized patients, normally does not cause disease unless chemotherapeutic medications or antibiotics trigger its toxins. Only certain antibiotics have been implicated in *C. difficile*–associated diarrhea. Less common causes of *C. difficile* diarrhea are vancomycin (Vancocin), erythromycin, tetracyclines, trimethoprim–sulfamethoxazole (TMP-SMZ), quinolones, and aztreonam (Azactam). The antibiotics most likely to cause *C. difficile* diarrhea are beta-lactam antibiotics (penicillins, cephalosporins, and carbapenems) and clindamycin (Cleocin). Box 30.7 gives more information.

BOX 30.7 Treating *Clostridium difficile* Diarrhea

C. difficile diarrhea may occur weeks after stopping antimicrobial therapy. The diarrhea may progress to colitis if left untreated. While awaiting the results of *C. difficile* toxin assay of the stool specimen, empiric therapy with metronidazole (Flagyl) 500 mg PO tid Vancomycin therapy should not be empirically initiated unless there is no clinical improvement within 5 to 7 days.

Because routine use of vancomycin (Vancocin) may contribute to the emergence of vancomycin-resistant *Enterococcus* species, even though oral vancomycin is no longer costly and may be easily prescribed, it should be reserved for cases that fail to respond to oral metronidazole or for patients who are not able to tolerate oral metronidazole. Institute oral doses of vancomycin; start at 125 mg qid and increase to 500 mg qid for lack of response.

For *C. difficile* diarrhea advancing to colitis, the preferred agent is intravenous metronidazole 1 g every 24 hours with oral vancomycin at 500 mg qid, for 10 days or until colitis has resolved on computed tomography scan. Patients should not be given bowel antispasmodics because this may reduce the elimination of the toxins from the body.

Surawicz et al. (2013)

Infectious Organisms

Patients traveling to a developing region may contract diarrhea from bacterial organisms. *Giardia* should be suspected if the patient travels to mountainous areas, recreational waters, or Russia. Pathogens transmitted by the fecal-to-oral route should be suspected in homosexual men (*Shigella*, *Salmonella*, *Campylobacter*, and intestinal protozoa) and in patients exposed to day care centers (*Shigella*, *Giardia*, *Cryptosporidium*).

Traveler's diarrhea is usually a self-limiting, non–life-threatening illness affecting 20% to 50% of individuals who visit developing countries; however, it can become chronic disease process (Connor, 2013). The cause of travelers' diarrhea is ingestion of fecally contaminated food products or water. High-risk areas include Latin America, Africa, Asia, and the Middle East. The typical duration is 2 to 3 days; symptoms include nausea and vomiting, cramps, and bloody stools. The most common pathogen is *Escherichia coli*; *Salmonella*, *Shigella*, and *Campylobacter* are the culprits less frequently.

Dietary restrictions are the main prevention for travelers' diarrhea. Travelers should avoid foods and beverages that are not steaming hot, raw vegetables, unpeeled fruit, tap water, and ice.

Pathophysiology

Diarrhea may be classified by duration and category. Acute diarrhea lasts 1 to 14 days and is considered self-limiting. Persistent diarrhea lasts longer than 14 days but less than 30 days, and chronic diarrhea last more than 30 days. Diarrhea may also be categorized as osmotic, secretory, or exudative (inflammatory), or the diarrhea may be related to altered intestinal motility (transit). Some diarrheal illnesses involve more than one of these mechanisms. Diarrhea may also be a defense mechanism against toxins and invading organisms.

Osmotic Diarrhea

Osmotic diarrhea occurs when nonabsorbed solutes are retained in the lumen of the intestinal tract. The result is a hyperosmolar state that pulls water and ions into the intestinal lumen. Poorly absorbed salts (magnesium sulfate), lactose (in lactase deficiency), and large amounts of sugar substitutes (sorbitol) found in candy or chewing gum, diet foods, and soft drinks draw fluid into the intestinal tract, resulting in an overload of the colon.

Secretory Diarrhea

In secretory diarrhea, colonic absorption of fluid is secondary to active transport of Na^+ through Na^+–K^+–adenosine triphosphatase activity in the colonic epithelium. The colon absorbs chloride by exchanging it for HCO_3^2 and by uptake of sodium chloride. Any agent that increases concentrations of cyclic adenosine 3, 5-monophosphate in the cells of the colon inhibits sodium chloride uptake and causes secretion of chloride. This results in secretion of fluid in the colon. Prostaglandins E2 and I2 and vasoactive intestinal peptide stimulate adenyl cyclase activity. Cholinergic agents and cholinesterase inhibitors cause secretion of sodium chloride and water. Secretory diarrhea can be classified as pure (e.g., cholera) or a part of a complex disease process (e.g., celiac disease, Crohn disease). Other stimuli that can cause secretory diarrhea include bacterial endotoxins, hormones from endocrine neoplasms, dihydroxy bile acids, hydroxylated fatty acids, and inflammatory mediators.

Exudative Diarrhea

Exudative (inflammatory) diarrhea may result from inflammatory diseases of the mucosa. Inflammation occurs due to the compromise of the tight junctions of the epithelial cells in the intestine. These diseases may cause an increase of blood, mucus, pus, and serum proteins that increase fluid and overload the colon, resulting in diarrhea. Enteritis, ulcerative colitis, and carcinoma are examples of inflammatory conditions that may result in exudative diarrhea.

Altered Intestinal Motility

Intestinal contents need to have sufficient time to be in contact with the lining of the intestinal tract for fluid, electrolytes, and nutrients to be absorbed adequately. Any factor that increases or decreases the motility of the intestinal tract may result in decreased absorption of fluid and electrolytes. Resection of the bowels, vagotomy, and certain agents (serotonin, laxatives, prostaglandins, prokinetic agents) can increase intestinal motility. Decreases in motility can result from autonomic injury or smooth muscle injury to the intestine and result in bacterial overgrowth, subsequently leading to diarrhea.

Diagnostic Criteria

A careful travel and social history is important to identify and treat specific causes, such as infection. Use of empiric antibiotic therapy is not recommended due to increasing resistance of many strains of bacteria. However, if a traveler is unable to comply with precautions, it may be prudent to prescribe a fluoroquinolone to hold in reserve. Selective testing of stool will be cost-effective while helping to guide the clinician in the use of specific therapy. According to the most recent guidelines of the Infectious Disease Society of America (Guerrant et al., 2001), diarrhea can be divided into three categories: community-acquired or traveler's diarrhea, nosocomial diarrhea, or persistent diarrhea. Each category can be specifically evaluated, leading to more precise therapy.

The fecal leukocyte, lactoferrin, or Hemoccult blood test is useful in patients with moderate to severe cases of acute infectious diarrhea because it supports the use of empiric antibiotic therapy in the febrile patient. However, measuring fecal leukocytes can be unreliable if specimens are transported, refrigerated, or frozen. Fecal lactoferrin, as a measure of polymorphonuclear neutrophils, has an advantage over fecal leukocytes as a highly sensitive and specific testing method for intestinal inflammation. Stool cultures have traditionally been used to identify the pathology of diarrhea, but the positive yields are very poor and incur high costs. Controversy exists regarding when to obtain stool cultures. The absence of vomiting with persistent diarrhea may also indicate the need for stool cultures. Hypotension, tachycardia, orthostasis, bloody stool, and abdominal pain and tenderness were not found to be good predictors of a positive stool culture.

Laboratory evaluation for ova and parasites should be performed in the following:

- A person not previously treated with empiric antiparasitic therapy
- A person with persistent diarrhea for more than 7 days
- A person who recently traveled to mountainous regions, Russia, or Nepal
- A person who was exposed to infants at day care centers or who was exposed through a community waterborne outbreak
- A person with bloody diarrhea with few or no fecal leukocytes
- Homosexual men or patients with acquired immunodeficiency syndrome (AIDS)

For food- or waterborne pathogens, the incubation period and clinical features can give clues as to the source of infection.

Diarrhea and vomiting 6 hours after exposure to a food item suggests exposure to *Staphylococcus aureus* or *Bacillus cereus*. An incubation period of 8 to 14 hours suggests *Clostridium perfringens*. With an incubation period greater than 14 hours, with vomiting as the predominant feature, viral agents are suspected. In patients with fever greater than 101.3°F (38.5°C) plus leukocyte-, lactoferrin-, or Hemoccult-positive stools, or acute dysentery (grossly bloody stools), the most common pathogens identified by normal stool

culture are *Shigella*, *Salmonella*, *Campylobacter*, *Aeromonas*, and *Yersinia*. Additionally, patients with grossly bloody stools should be tested for *E. coli* O157 or HUS.

Initiating Drug Therapy

Most cases of diarrhea are self-limiting and can be self-treated. However, patients with profuse, watery diarrhea with dehydration, passage of blood and mucus, and fever exceeding 101.3°F should be evaluated for an inflammation-producing pathogen. These patients may benefit from antimicrobial therapy. In addition, a good history helps to determine the cause of illness. In diarrhea caused by infectious organisms, the pathogen should be identified so that therapy may be initiated to eradicate the organism and to prevent exposure to unnecessary antibiotics.

For traveler's diarrhea (TD), prophylactic agents may be given to patients who should not, cannot, or will not comply with dietary restrictions. Chemoprophylaxis of TD is controversial and usually is not recommended for patients unless the patient has an underlying illness (AIDS, prior gastric surgery, other chronic disease process), the purpose of the trip is particularly important (politicians, honeymoon), or the patient cannot or will not comply with dietary restrictions. In such cases, the use of bismuth subsalicylate (BSS; Pepto-Bismol), 2 tablets four times daily, is recommended unless the reason for prophylaxis is a serious underlying illness. In these cases, a quinolone antibiotic or rifaximin should be used.

If prophylactic therapy is not prescribed, at the first symptoms of diarrhea, empiric therapy can be prescribed using a quinolone antibiotic, rifaximin, or azithromycin (Table 30.3). Patients should be properly hydrated, and BSS may be used to treat symptoms. Loperamide (Imodium) is a more effective option than BSS, but loperamide should be used with caution in the presence of fever or bloody stools because the antimotility effects of the drug may prolong disease by reducing the elimination of possible infectious pathogens. If an antidiarrheal medication is necessary, selection should be based on patient-specific variables, including potential side effects, convenience, efficacy, and the patient's symptoms. For patients with moderate or severe TD, empiric antimicrobial therapy with a quinolone antibiotic or rifaximin may be given (see Table 30.3). Patients with persistent diarrhea lasting 2 to 4 weeks without systemic symptoms or dysentery may be studied for the cause and treated or given metronidazole (Flagyl) for empiric anti-*Giardia* therapy.

TABLE 30.3 Indications for Empiric and Specific Antimicrobial Therapy in Infectious Diarrhea

Indication for Antimicrobial Therapy	Suggested Antimicrobial Therapy
Fever (oral temperature >101.3°F [38.5°C]) together with one of the following: dysentery (grossly bloody stools) or those with leukocyte-, lactoferrin-, or Hemoccult-positive stools	quinolone:*NF 400 mg, CF 500 mg (preferred), OF 300 mg bid for 3–5 d
Moderate to severe TD	quinolone:* CF 500 mg NF 400 mg, OF 300 mg bid for 1–5 d rifaximin 200 mg tid × 3 d if not complicated by above symptoms
Persistent diarrhea (possible *Giardia* infection)	metronidazole 250 mg qid for 7 d
Shigellosis	If acquired in the United States, give TMP-SMZ 160/800 mg bid for 3 d; if acquired during international travel, treat as febrile dysentery (above); check to be certain of susceptibility to drug used. If not from the United States, give third-generation cephalosporin.
Intestinal salmonellosis	If healthy host with mild or moderate symptoms, no therapy; for severe disease or that associated with fever and systemic toxicity or other important underlying conditions, use TMP-SMZ 160 mg/800 mg or quinolone:*NF 400 mg, CF 500 mg, OF mg bid for 5–7 d depending on speed of response
Campylobacteriosis	erythromycin stearate 500 mg bid for 5 d
Enteropathogenic *Escherichia coli* diarrhea (EPEC)	Treat as febrile dysentery
Enterotoxigenic *E. coli* diarrhea (ETEC)	Treat as moderate to severe TD
Enteroinvasive *E. coli* diarrhea (EIEC)	Treat as shigellosis
Enterohemorrhagic *E. coli* diarrhea (EHEC)	Antimicrobials are usually withheld except in particularly severe cases, in which usefulness of these drugs is uncertain.
Aeromonas diarrhea	Treat as febrile dysentery
Noncholera *Vibrio* diarrhea	Treat as febrile dysentery
Yersiniosis	For most cases, treat as febrile dysentery; for severe cases, give ceftriaxone 1 g qd IV for 5 d.
Giardiasis	metronidazole 250 mg qid for 7 d or (if available) tinidazole 2 g in a single dose or quinicine 100 mg tid for 7 d
Intestinal amebiasis	metronidazole 750 mg tid for 5–10 d plus a drug to treat cysts to prevent relapses: diiodohydroxyquin 650 mg tid for 20 d or paromomycin 500 mg tid for 10 d or diloxanide furoate 500 mg tid for 10 d
Cryptosporidium diarrhea	None; for severe cases, consider paromomycin 500 mg tid for 7 d
Isospora diarrhea	TMP-SMZ 160 mg/800 mg bid for 7 d
Cyclospora diarrhea	TMP-SMZ 160 mg/800 mg bid for 7 d

*Fluoroquinolones include norfloxacin (NF), ciprofloxacin (CF), and ofloxacin (OF).

TMP-SMZ, trimethoprim–sulfamethoxazole.

Goals of Drug Therapy

The goals of drug therapy are to reduce the symptoms of diarrhea and to make the patient as comfortable as possible. Causative factors should be identified and eradicated. Fluid and electrolyte replacement is particularly important to avoid serious complications from dehydration. Rehydration is discussed later in this chapter.

Antidiarrheal Agents

Several types of drugs are used for the symptomatic relief of diarrhea; they include antimotility agents, adsorbents and absorbents, and the atypical antisecretory agent BSS. Table 30.4 provides an overview of these drugs, and Table 30.5 covers the recommended order of prescription.

TABLE 30.4 Overview of Selected Antidiarrheals

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Antimotility Agents			
diphenoxylate/atropine (Lomotil) 2.5–5 mg qid	Dry mouth, dry eyes, urinary retention, blurred vision, drowsiness, dizziness	Caution in patients with liver disease, fever, bloody stool, or fecal leukocytes.	Drug Enforcement Administration Class V controlled substance
loperamide (Imodium) 4–16 mg/d in divided doses	Abdominal discomfort, constipation, drowsiness, dry mouth	Caution in patients with fever, bloody stools, or fecal leukocytes	May induce drowsiness; warn patients about driving or performing activities that require alertness.
Selected Antisecretory Agents			
bismuth subsalicylate (Pepto-Bismol) Start: two tablets or 30-mL range: two tablets or 30 mL every 30 min to 1 h up to eight doses	Black stools, darkening of tongue, tinnitus	Caution in patients who are aspirin sensitive or are taking medications that interact with warfarin.	Not recommended for children and adolescents due to the presence of salicylate component and potential Rye syndrome
polycarbophil (Fiber-Con) 1–6 g/d	Stomach upset, bloating, gas	Caution: Potential for drug interactions with tetracycline or quinolones	
kaolin and bismuth salicylate (Kaopectate) Start: 30–120 mL of liquid or two tablets after each bowel movement Range: Up to seven doses a day	Constipation, feeling of fullness, stomach bloating, gas	Do not use with children due to the salicylate component.	May adsorb nutrients and medications Separate administration time of adsorbents and other medications.
Semisynthetic Antibiotic			
rifaximin (Xifaxan) TD: 200 mg tablets tid × 3 d	Most common for TD—headache	Known hypersensitivity to rifaximin Bloody diarrhea	Discontinue for diarrhea that worsens or persists >48 h. Consider different antibiotics.

TABLE 30.5 Recommended Order of Treatment for Diarrhea

Order	Agents	Comments
First line	loperamide rifaximin (TD)	Easy to use, tablet or liquid Well tolerated, 3-day course
Second line	Adsorbents or antisecretory agent	Selection based on drug–drug interactions or allergies (e.g., aspirin sensitivity and BSS)
Third line	diphenoxylate	Side effect profile, especially with atropine added, lowers the utility of this agent

Antimotility Agents

The antimotility agent loperamide is an opioid receptor agonist that acts on the μ-opioid receptors of the myenteric plexus of the large intestine, similar to the action of morphine without action on the CNS. This slows GI motility within the circular and longitudinal muscles of the intestines. Initially, this drug was classified as a controlled substance but in 1982 was declassified. It is not well absorbed and does not provide analgesic or euphoric effects.

Another similar agent is diphenoxylate with atropine (Lomotil). It is also chemically related to the narcotic meperidine. As with loperamide, it acts on decreasing GI motility. However, unlike loperamide, it can cross the blood–brain barrier and cause a euphoric effect. Combining diphenoxylate with atropine causes anticholinergic side effects if too much of the drug is ingested, decreasing the potential for abuse. Due to the potential for abuse, diphenoxylate with atropine is a controlled substance, Schedule V.

Contraindications

The antimotility effects may exacerbate infectious diarrhea by preventing the excretion of the infecting organism, allowing the organism more contact time in the intestines. Caution should be observed in using loperamide in patients with fever, bloody stools, or fecal leukocytes. In nondysenteric forms of diarrhea caused by invasive pathogens, loperamide can be used, provided antimicrobial therapy is administered.

Because loperamide undergoes extensive first-pass metabolism, caution should be used in patients with hepatic dysfunction because excessive side effects (CNS toxicity) may occur in these patients.

Because of the antimotility effects of diphenoxylate, it should be used with caution in patients with infectious diarrhea associated with fever or bloody stools. Diphenoxylate provides euphoric and analgesic effects at high doses but not at therapeutic doses. As previously stated for this reason, diphenoxylate is combined with atropine to discourage abuse. Diphenoxylate should be used with caution in patients with liver impairment because it is extensively metabolized by the liver.

Adverse Events

Adverse effects of loperamide include abdominal discomfort, constipation, and dry mouth. Although loperamide does not cross the blood–brain barrier, it may still induce drowsiness in some patients. Patients should be warned of the potential for drowsiness before driving or performing activities that require alertness. Although loperamide is usually well tolerated, it is not recommended in children younger than age 4 because shock, enterocolitis, fatal intestinal obstruction, and CNS toxicity have occurred.

Atropine has anticholinergic effects such as dry mouth, dry eyes, urinary retention,

constipation, blurred vision, and tachycardia. Diphenoxylate may cause drowsiness or dizziness, and patients should be warned of these effects and should avoid activities that require alertness. The liquid formulation is recommended in children because the dose needs to be carefully tailored to the child based on age and weight. Diphenoxylate with atropine can cause respiratory depression in infants and young children and should be avoided in children younger than age 4.

Interactions

Diphenoxylate may potentiate the action of depressants such as alcohol, barbiturates, or benzodiazepines. In addition, atropine may potentiate the effects of other agents with anticholinergic properties such as tricyclic antidepressants, antipsychotics, and antihistamines. Diphenoxylate has a structure similar to that of meperidine, and when used concomitantly with monoamine oxidase inhibitors, it can induce a hypertensive crisis.

Atypical Antidiarrheals

Subsalicylate is the active ingredient found in Pepto-Bismol and Kaopectate. BSS includes the active ingredients bismuth, which stimulates prostaglandin, mucous, and bicarbonate secretion *in the stomach*, and salicylate inhibits prostaglandin and chloride secretion *in the large intestine.* The action of salicylic acid and bismuth on diarrhea is not well understood, but is thought to have anti-inflammatory action and antacid and mild antibiotic properties.

Kaopectate is now formulated with the active ingredients of subsalicylic acid and therefore has the same contraindications, adverse effects, and interactions. Further discussion of Kaopectate as an absorbent is found in the next section.

Contraindications

BSS and Kaopectate are broken down in the intestinal tract to salicylate; therefore, it should be used with caution in patients taking aspirin therapy or those hypersensitive to aspirin. In addition, caution should be used in children and adolescents with the flu or chickenpox because this population is at risk for aspirin-induced Reye syndrome.

Adverse Effects

Side effects of BSS and Kaopectate with subsalicylate include black stools, darkening of the tongue, and tinnitus, which can be a potential sign of salicylate toxicity.

Interactions

Because BSS and Kaopectate with subsalicylate have a salicylate component, it may interact with other medications that interact with aspirin (e.g., warfarin).

Adsorbents and Absorbents

Mechanism of Action

Kaolinite is a naturally occurring magnesium aluminum silicate and is used in Kaopectate. Previous formulations of Kaopectate included a combination of kaolinite and attapulgite, which was removed from the formulation by the FDA and replaced by subsalicylate (Kim-Jung et al., 2004). Another adsorbent, pectin, has also been removed from the market. The current formulation of Kaopectate adsorbs water along with bacteria and toxins as well as helps to solidify loose stools. As an adsorbent, it is usually given after each bowel movement until diarrhea is relieved or a maximum dose is reached. The dose for adults is 30 mL every 30 to 60 minutes if needed or maximum of eight doses daily. Kaopectate is not approved for children due to the subsalicylate component.

Polycarbophil (FiberCon, Fiberall), an absorbent, absorbs water in the GI tract and is used as an antidiarrheal. Its fiber content also makes it useful as a bulk-forming laxative when taken with plenty of water.

Adverse Events

The most common side effects of the adsorbents are constipation and a feeling of fullness. Absorbents may also produce upset stomach, bloating, and gas. Adsorbents and absorbents are generally considered safe because the medication works locally and is not absorbed systemically. However, adsorbents may not be as effective as antimotility agents at reducing the symptoms of diarrhea.

Interactions

Adsorbents are not selective and may adsorb nutrients and medications. This interaction must be taken into consideration because several doses may be necessary each day. Separating administration times of adsorbents and other medications is advised. Polycarbophil contains calcium and may interact with fluoroquinolone and tetracycline antibiotics.

Semisynthetic antibiotic

Rifaximin

Rifaximin (Xifaxan) is a semisynthetic antibiotic that is only effective against noninvasive strains of *Escherichia coli.* The drug is a derivative of rifampin and acts to block transcription of the bacteria; therefore, it inhibits bacterial protein synthesis and growth. This acts to suppress diarrhea by altering the growth of the bacteria. The recommended dose for traveler's diarrhea is 200 mg three times daily for 3 days and may be administered with or without meals.

Contraindications

History of hypersensitivity to rifaximin, rifamycin antimicrobial agents, or any of the components of rifaximin

Adverse Effects

The most common side effects are peripheral edema, nausea, dizziness, fatigue, and muscle spasms. For TD, the most common side effect was headache. Additional postmarketing side effects include exfoliative dermatitis, rash, angioneurotic edema (swelling of the face and tongue and difficulty swallowing), urticaria, flushing, pruritus, and anaphylaxis.

Interactions

Rifaximin has a low risk of drug interactions because it is poorly absorbed into the bloodstream, and it does not significantly affect the cytochrome P-450 system. Coadministration with cyclosporine in healthy subjects resulted in the increased availability of rifaximin, but overall clinical significance is unknown.

Selecting the Most Appropriate Agent

The choice of antidiarrheal agent should be based on several factors, including the patient's history, potential side effects of the medication, potential for drug interactions, and efficacy of available agents (Tables 30.3 and 30.5; Figure 30.2).

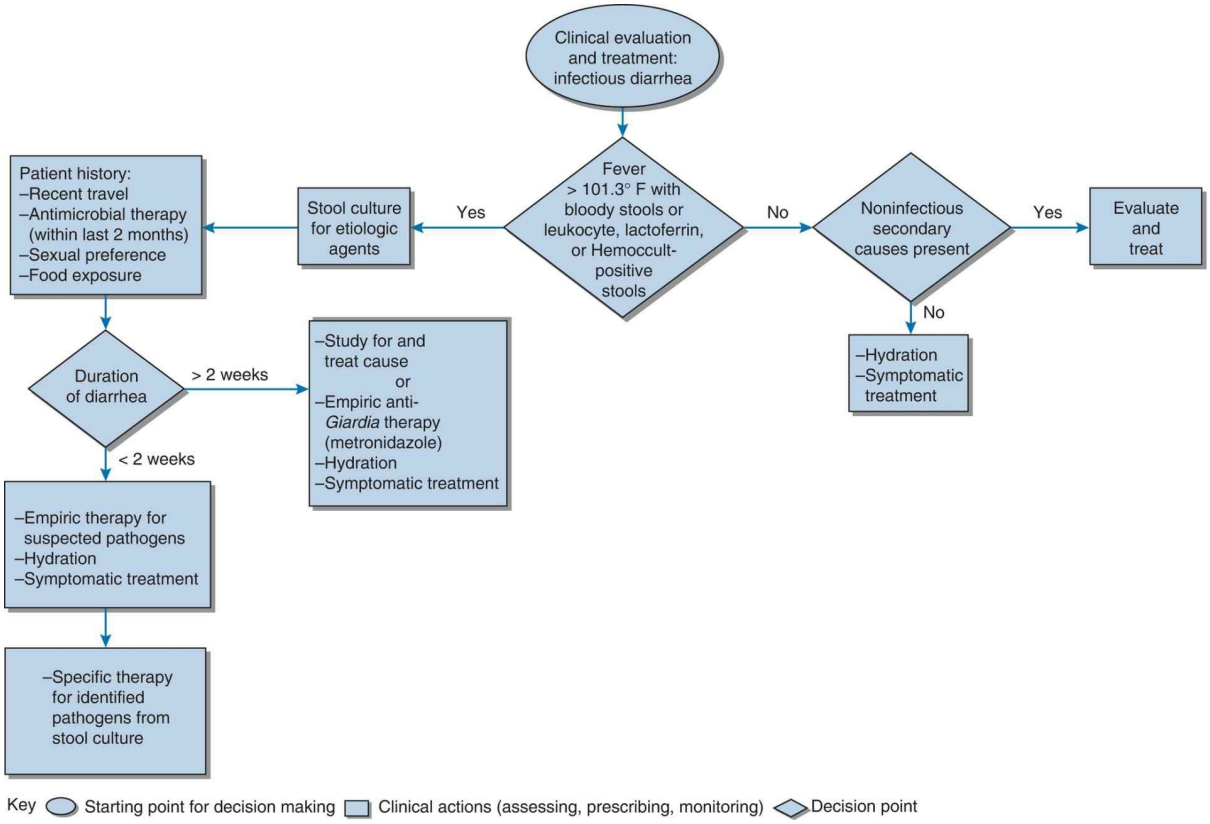

Figure 30.2 Treatment algorithm for diarrhea.

First-Line Therapy

Although the adsorbents are not absorbed into the systemic circulation and are usually safe and well tolerated, they are not as effective at controlling diarrhea as loperamide. Therefore, loperamide may be considered as first-line therapy secondary to its efficacy. Loperamide is also reasonably well tolerated and has few drug interactions. However, patients should be warned about the potential for loperamide to cause drowsiness (particularly patients who must stay alert).

Because loperamide is an antimotility agent, it should be used with caution in patients with fever or bloody stools to avoid exacerbation of any type of infectious diarrhea. In addition, caution should be used in patients with liver failure.

Appropriate antibiotic therapy should be considered for infectious diarrhea. First line for travelers' diarrhea is ciprofloxacin or levofloxacin (see Chapter 8 Antibiotics). Rifaximin can also be considered as a first-line choice.

Second-Line Therapy

For patients who cannot tolerate loperamide or for those with contraindications, an adsorbent or antisecretory agent may be chosen.

Antisecretory agents such as BSS or Kaopectate should be used with caution in patients

taking warfarin and should be avoided in children or adolescents with the flu. Antisecretory agents should also be avoided in patients with a documented hypersensitivity to salicylates. Black stools, darkening of the tongue, and tinnitus are side effects that may be disturbing to the patient. BSS may be useful for prophylaxis against TD and may be preferable over the adsorbents in a patient who also has indigestion or stomach upset that accompanies the diarrhea.

Although adsorbents may inhibit the absorption of nutrients from the diet and can cause some abdominal cramping, they are usually well tolerated.

Second-line antibiotic therapy is rifaximin, if the agent is known to be *Escherichia coli*, and has not responded to ciprofloxacin.

Third-Line Therapy

Although diphenoxylate with atropine is an effective agent for treating diarrhea, the atropine component can cause significant anticholinergic effects that may exacerbate certain conditions and interact with other agents with anticholinergic activity. In addition, diphenoxylate is a Drug Enforcement Administration Schedule V drug, and its potential for abuse limits this agent to third-line therapy. Third-line antibiotic therapy is azithromycin (see Chapter 8).

Special Populations

Pediatric

Recommendations for treatment of diarrhea in children have not changed since 1996 by the American Academy of Pediatrics, Provisional Committee on Quality Improvement, and Subcommittee on Acute Gastroenteritis. These recommendations apply to children ages 1 month to 5 years who have no previously diagnosed disorders. The main focus is on oral rehydration and zinc therapy (Lenters et al., 2013). Opiate and atropine combination drugs such as diphenoxylate with atropine should be avoided in acute diarrhea in children because of the potential for side effects and the limited scientific evidence for efficacy. Also, loperamide is not recommended based on limited scientific evidence, and BSS or Kaopectate is not appropriate due to the presence of subsalicylate. Adsorbents are also not recommended based on limited evidence. The committee recognized that major toxic effects from adsorbents are in general not a concern, but the potential for poor absorption of nutrients and antibiotics is a potential disadvantage. The final expert conclusion is that oral rehydration is the most important aspect of therapy, and routine use of antidiarrheal agents is not recommended based on lack of evidence or the potential for side effects.

If the health care provider still decides to choose diphenoxylate with atropine, the liquid formulation should be used because specific dosing is required based on the child's weight and age. In addition, diphenoxylate with atropine is contraindicated in children younger than age 2.

Geriatric

As with the pediatric population, rehydration is of paramount importance in the geriatric population. Elderly patients are likely to have multiple disease states that cause them to be intolerant of dehydration (e.g., congestive heart failure, diabetes, renal insufficiency). In addition, the antidiarrheal preparations may interact with agents that are commonly prescribed in the geriatric population. Diphenoxylate and loperamide may increase the sedative potential of benzodiazepines, antidepressants, anticholinergics, and antipsychotics. Adsorbents can reduce the absorption not only of important nutrients but also of other medications. BSS should be used with caution in elderly patients taking aspirin and agents that interact with aspirin.

Women

As with constipation, antidiarrheals such as the adsorbents that are not absorbed systemically should be considered as first-line therapy for pregnant women with diarrhea. However, adsorbents can inhibit the absorption of important nutrients. Iron supplementation may be particularly important in pregnant women taking adsorbents for diarrhea. Loperamide has not been shown to be teratogenic in animals but has been

inadequately studied in humans; therefore, the routine use of loperamide is not recommended. Diphenoxylate with atropine should be avoided because it has been shown to be teratogenic in animals. In addition, malformations in infants after first trimester exposure have been reported. Both Lomotil and loperamide are excreted in breast milk. Salicylates have been shown to be teratogenic in animals. Therefore, use of BSS in the pregnant woman should be avoided.

Monitoring Patient Response

For most cases of diarrhea, the major concern is dehydration. Fluid and electrolyte depletion can lead to hypotension, tachycardia, and vascular collapse. Vascular collapse may occur quickly in the very old or the very young. Severe dehydration may result in decreased plasma volume and a decrease in perfusion, which may be of clinical significance, particularly in patients with congestive heart failure or chronic renal disease. Bicarbonate loss from excessive diarrhea may result in metabolic acidosis. This may be of particular concern in patients with type 1 diabetes mellitus who may be prone to ketoacidosis.

Patients should be monitored for signs of dehydration, such as orthostatic hypotension and poor skin turgor. The body weight of an infant is mostly water, and therefore, infants may be weighed to determine significant fluid loss and dehydration from severe diarrhea. Monitoring serum electrolytes as well as intake of fluid and output of stools benefits patients who are hospitalized secondary to dehydration.

As stated earlier, the goal of therapy is not only to prevent dehydration but also to make the patient as comfortable as possible. Monitoring the effectiveness of an antidiarrheal preparation requires interviewing the patient to ensure a decrease in stool frequency and improved formation. Frequency and formation of stools vary from patient to patient, and determination of relief is subjective on the patient's part.

Patient Education

To avoid complications, patients should be educated about appropriate rehydration. In most cases, simple replacement of fluid and electrolytes with soda crackers, broths, and soups is all that is necessary in the nondehydrated adult with diarrhea. Oral rehydration therapy (ORT) solutions should also be considered because most sports drinks do not have enough sodium to replace losses from diarrhea (Centers for Disease Control and Prevention, 2005); however, the palatability of ORT product makes them difficult to administer especially to children. Additionally, food and drink high in sugar content should be avoided because it may increase the osmotic load and worsen the diarrhea. In the elderly or immunocompromised patient, solutions with sodium content in the range of 45 to 75 mEq/L are recommended. Boiled potatoes, noodles, rice, cereals, crackers, bananas, yogurt, soup, and boiled vegetables are recommended during the acute phase of diarrhea. The diet may return to normal as stools become formed.

Infants and children are particularly susceptible to dehydration with diarrhea. Oral replacement therapy is the preferred treatment to replace fluids and electrolytes in children with mild to moderate dehydration because it is less expensive than intravenous therapy and can be administered in many settings, including the home. Oral glucose–electrolyte solutions available in the United States (Table 30.6) are based on physiologic principles and should be recommended over commonly used nonphysiologic solutions such as colas, apple juice, chicken broth, and sports beverages.

TABLE 30.6 Commercially Available Oral Rehydration Solutions

Product	Carbohydrate (g/L)	Na^+ (mEq/L)	K^+ (mEq/L)	Cl^- (mEq/L)	Base (mEq/L)	Calories (kcal)
Infalyte* (Mead Johnson)	30 (rice syrup solids)	50	25	45	34 (citrate)	126
Pedialyte† (Ross Laboratories)	25 (dextrose)	45	20	35	30 (citrate)	100
Rehydralyte (Ross Laboratories)	25 (dextrose)	75‡	20	65	30 (citrate)	100
WHO Solution§ (Ianas Bros. Packing Co.)	20 (glucose)	90‡	20	80	10 (citrate)	80

*Available in hospitals as 6-ounce nursing bottle.

†Available in hospitals as 8-ounce nursing bottle.

‡The American Academy of Pediatrics recommends these solutions with sodium contents of 75–90 mEq/L for replacement of deficit during initial rehydration (*Pediatrics, 75*, 358, 1985).

§Must be mixed with 1 L of boiled or treated water; packets available in stores or pharmacies in all developing countries.

Currently, oral replacement solutions (ORSs) are recommended for children with mild to

moderate diarrhea (CDC, 2003). In addition, age-appropriate feeding should be continued and fluids encouraged. For children with mild to moderate dehydration (3% to 5% loss of total body weight), 50 to 100 mL/kg of ORS is recommended plus 10 mL/kg for each loose stool to replace continuing fluid losses. Severe dehydration (loss of 10% total body weight) can result in shock and is a medical emergency requiring intravenous therapy with normal saline or lactated Ringer solution. In all situations, age-appropriate feeding should begin after dehydration is corrected.

Drug Information

Patients need to be aware of the potential side effects of antidiarrheal medications. Constipation can occur if these agents are taken for too long. Antidiarrheal agents taken in the setting of infectious diseases can prolong or worsen the disease. It is always best to contact a health care provider if diarrhea lasts more than 2 days.

Patient-Oriented Information Sources

Providing patients with information about acute diarrhea and what to expect can help them understand diarrhea and their role in the treatment. Patient education items are readily available on the Internet through the National Digestive Diseases Information Clearinghouse (NDDIC), which provides information to consumers on a wide variety of GI topics. The CDC also has a wide array of patient information about diarrhea (see Box 30.11).

Nutrition/Lifestyle Changes

It is not recommended to rest the gut. Oral intake and breast-feeding should continue to replace lost calories during illness. Early feeding will stimulate enterocyte renewal, ultimately promoting a quicker recovery of the gut. Additionally, feeding decreases the potential risk of malnutrition.

Complementary and Alternative Medications

Probiotics have shown some efficacy in the treatment of diarrhea. The presumed mechanism of action is to alter the composition of the intestinal microflora and act against enteric pathogens (Guarino, 2009). Yogurt is a source of probiotics; however, not all brands have the active ingredients. Acidophilus capsules can be used to treat diarrhea resulting from antibiotic use. It restores the natural flora to the bowel. One to 10 billion viable organisms per day in three or four divided doses are appropriate.

Irritable Bowel Syndrome

IBS is a functional bowel disorder that presents with abdominal discomfort and an alteration in bowel pattern. The disorder is an international health problem that can be one of the most perplexing chronic abdominal complaints reported to primary care providers and gastroenterologists. Little has changed in the incidence of IBS with the rate continuing from 3% to 20% depending on the application of the Rome III criteria (Grundman & Yoon, 2010). Epidemiologic studies in North America suggest a prevalence of 10% to 15%, with a 4:1 female predominance, while 7% to 10% have IBS worldwide (Brandt et al., 2009; Lovell & Ford, 2012). Newer data also suggest that veterans of the Gulf War have a high prevalence of IBS compared to the general population, which increases the prevalence of IBS in men (Brandt et al., 2009). Work is currently being done on Rome IV criteria, but is not yet available. Future recommendations are going focusing on the use of evidence-based practice rather than consensus (http://www.romecriteria.org/romeiv_pub/romeiv_faqs.cfm).

Once thought to be associated primarily with psychological problems and stress, research is changing to an emphasis on motility of the gut, autonomic system imbalances, and increased visceral hypersensitivity (Akbar, 2009). A syndrome in childhood known as recurrent abdominal pain can be a hallmark of adult IBS. The majority of patients seeking care are ages 20 to 50, and symptoms can wax and wane over a lifetime.

Causes

For many years, the chief cause of IBS was thought to be primarily psychological. Now, however, research has identified physiologic but not pathologic causes that are accentuated by psychological stress. Symptoms generally are slow in onset, sometimes over weeks or months (Grundmann, 2010). Dysregulation occurs between the brain and the gut, leading to typical IBS symptoms. Commonly, the symptoms can be worse during times of physical and emotional stress, including sexual or physical abuse. In addition, some patients can identify foods that exacerbate the condition (e.g., lactose, caffeine, and fatty or spicy foods). Depending on the severity of the illness, pharmacotherapy may not be required and symptoms may respond solely to lifestyle changes. These lifestyle changes need to become incorporated into the patient's daily routines. Pharmacologic interventions may be required only intermittently to maintain symptom control.

Pathophysiology

In general, the syndrome is believed to have the components of motility and sensory abnormalities. This leads to dysregulation of the bowel as modulated by the CNS. Many neuroimmune and neuroendocrine modulators, such as serotonin (5-HT), substance P, CCK, neurotensin, cytokines, and others, contribute to the increase in visceral sensitivity, central mechanisms controlling pain and dysregulation of the brain–gut axis. Local reflex mechanisms can also be responsible for mechanical distention of the gut in response to short-chain fatty acids, affecting the emptying rate of the proximal colon. The prevailing theory is that the emptying rate of the proximal colon may be the key determination of overall colon function. The GI tract is innervated intrinsically and extrinsically by various neurohormonal agents from local or distant sources. Intrinsic factors include the neurons found in the enteric nervous system, which function similarly to the CNS. Bowel motor dysfunction can be associated with inflammation as well as changes in neurotransmitters, such as 5-hydroxytryptamine (5-HT3; serotonin). This neurotransmitter is found in the GI tract, and blocking it pharmacologically can decrease visceral pain, colonic transit, and GI secretions. External factors that can alter colonic activity are eating and drinking, stress, and endogenous hormones. Increased motility and abnormal contractions of the intestinal tract can result in either diarrhea or constipation-predominant IBS, due to either accelerated whole-gut transit times or delays in colonic transit. The IBS patient's sensory perception of colonic activity in response to balloon dilatation is more sensitive than that of patients with normal colonic activity. Sensory perception is also accentuated by external factors that lead to enhanced sensations that differ from those of healthy patients. However, evidence is increasing that IBS is not a psychological illness. This is supported by the fact that IBS exists in about 12% to 20% of the general adult population.

Diagnostic Criteria

The hallmark symptom of IBS is abdominal pain associated with a change in the consistency of stools that is relieved by defecation. Symptoms are usually first noticed in young adulthood and can be persistent or intermittent. Weight loss, rectal bleeding, fever, acute onset, and onset after age 50 are unusual in IBS and should raise suspicion of organic causes, not IBS. Diagnosis can be predominantly based on symptoms and appropriate treatment initiated, with reassessment in 3 to 6 weeks.

In 1978, the original Manning criteria proposed identifying IBS based on the presence of four symptoms: abdominal distention, pain relief with bowel action, more frequent stools with the onset of pain, and looser stools with the onset of pain. These criteria led to the establishment of an international group called the Multinational Working Teams for Diagnosis of Functional GI Disorders. This team identified key criteria for IBS, leading to the establishment of the Rome criteria (Box 30.8); the third revision focused on categorizing each type of IBS according to constipation, diarrhea, or mixed. However, the overall accuracy of the Rome criteria has led the American College of Gastroenterology (ACG) to simply define IBS as abdominal pain that occurs with altered bowel habits over a period of 3 months (Brandt et al., 2009). Therefore, for IBS to be considered as a diagnosis, the presenting clinical features may be sporadic, intermittent, or continuous but should be present for at least 3 months, as defined by the ACG. The Rome III criteria (Box 30.8) can be used to help verify the subtype, which can guide drug therapy.

BOX 30.8 Rome III Criteria for Irritable Bowel Syndrome (2006)

Diagnostic criterion must be fulfilled for the last 3 months with symptom onset at least 6 months prior to diagnosis.

Recurrent abdominal pain or discomfort at least 3 days/month in the last 3 months associated with two of the following:

- Improvement with defecation
- Onset associated with change in frequency of stool
- Onset associated with a change in form (appearance) of stool

The chief complaint most patients report is abdominal discomfort that can be relieved with defecation; however, symptom relief is often short-lived. Patients can also report abnormal bowel habits that alternate between diarrhea and constipation or are predominantly diarrhea or constipation; it is much more common to have bowel habits that are

predominantly one type. Associated components can be abdominal distention, bloating, and gassiness. Extreme urgency after a meal can be common and can possibly result in an "explosive" bowel movement that relieves the overall discomfort.

Organic symptoms of abdominal pain that do not suggest IBS are those that awaken the patient from sleep, initial onset in the elderly years, a change in abdominal pain that is not associated with bowel movements, significant weight loss, rectal bleeding, steatorrhea, and fever. In addition, steadily worsening symptoms should be considered atypical. These symptoms would suggest the need for additional studies. However, compared to the general population, IBS patients are not more likely to have organic causes for disease.

A key component of IBS treatment is a thorough history of symptoms, psychosocial stress, medications (because of GI symptoms from many drugs), and dietary habits (to identify nutritional patterns, gaps, and intolerances). Even in the general population, stress can result in GI symptoms. However, in the patient with IBS, these symptoms can become more pronounced. The relationship between psychological distress and GI symptoms has been well researched. Chronic and acute life stresses, including a history of verbal or sexual abuse, especially in childhood, may preclude early symptoms of IBS. These chronic stresses can contribute later in life to IBS symptoms.

Physical examination findings are often normal except for a slight diffuse abdominal tenderness with palpation, especially in the left lower quadrant near the sigmoid colon. Mild abdominal distention may also be present.

In 2009, the ACG Task Force, in an evidence-based position paper on the management of IBS in North America, reinforced the recommendation that minimal, if any, testing is necessary. Current treatments were evaluated, and the conclusion was reached that care is often based on nonrandomized, non–placebo-controlled trials. The best available data show that only 1% of IBS patients have alarming symptoms signifying serious organic disease. Therefore, for patients without alarming features of IBS, routine diagnostic studies are not necessary. However, patients who are classified as IBS-D (diarrhea) or IBS-M (mixed) should be routinely tested for celiac sprue disease. Other studies such as abdominal ultrasound, flexible sigmoidoscopy, barium enema, or colonoscopy do not lead to any change in the proposed treatment and are therefore not recommended. Additional testing may be indicated for patients with the key symptoms previously identified or if the patient is older than age 50.

Types of IBS

Once identified according to the Rome III criteria (Box 30.8), patient definition of further subtypes of constipation (IBS-C), diarrhea (IBS-D), mixed (IBS-M), or unspecified (IBS-U) (Box 30.9) can further refine the diagnosis and focus for treatment. Symptoms can also be stratified as *mild, intermittent, or continuous* according to the predominant features of the patient's stool (Longstreth, 2006). While patients can stay predominately in one category, there is often overlap in symptomatology.

BOX 30.9 Subtyping of IBS by Predominant Stool Pattern

1. IBS with constipation (IBS-C)—hard or lumpy stools ≥25% and loose (mushy) or watery stools ≤25 %
2. IBS with diarrhea (IBS-D)—loose (mushy) stools or watery stools ≥25% and hard or lumpy stools ≤25%
3. IBS mixed (IBS-M)—hard or lumpy stools ≥25% and loose (mushy) or watery stools ≥25%
4. IBS unclassified (IBS-U)—insufficient abnormality of stool, consistency to meet criteria for other classifications

Mild IBS usually shows a sporadic pattern. Symptoms are worsened by stress and dietary factors. There is no alteration in the patient's daily activities because of the symptoms.

In *intermittent* IBS, the symptoms are worse and begin to affect the patient's daily life. It is more difficult to relate symptoms to specific precipitants, and a psychological component to the syndrome may be developing.

In *continuous* IBS, the symptoms affect every aspect of the patient's daily routines. An inability to pinpoint precipitants still exists, and there is a definite psychological component to the syndrome.

Initiating Drug Therapy

Initial therapy is focused on establishing a therapeutic relationship and mapping out a long-term strategy. This provides the patient with knowledge regarding the disease process and lets the patient know that improvement may be a slow process, taking many months.

Patients with mild symptoms may be responsive to dietary and lifestyle changes (Box 30.10). Assessing the diet for potentially offending substances and removing those substances may improve symptoms. Hayes et al. (2014) found in a survey of patients with IBS that cereal products and spicy foods along with vegetables and fatty foods were a predominant cause of symptoms. These substances may be lactose, caffeine, beans, cabbage, fatty foods, or alcohol (Simren, 2001). In an earlier 1998 study, Versa and colleagues showed a positive correlation between IBS and lactose intolerance, female sex, and abdominal pain in childhood, and these early findings have been supported by additional research (Yang et al., 2014). A 2-week trial of a lactose-free diet is worth pursuing. Aspartame, an artificial sweetener found in many soft drinks and diet foods, may also provoke diarrhea. Trial elimination may also be worthwhile, especially in diarrhea-predominant IBS. However, with most IBS therapies, the placebo effect is often just as successful as the therapy itself.

BOX 30.10 Dietary and Lifestyle Changes

Avoid foods that exacerbate the symptoms (e.g., lactose, caffeine, fatty or spicy foods).
Incorporate routine exercise into daily activities.
Explore the life stressors that aggravate the symptoms.
Learn ways to deal with stress, such as meditation, counseling, and biofeedback.

Maintaining a daily diary of food intake, bowel patterns, and emotional stressors can be helpful in the treatment of IBS. It serves to identify factors that can be addressed and evaluates the effectiveness of treatment. Lifestyle modification requires the patient to understand the stressors in his or her life and the effect these stressors have on physiologic functions. Identifying ways to reduce stress can be critical to improving IBS symptoms. Biofeedback can be used to decrease gut sensitivity, along with relaxation tapes to decrease stressors. Daley et al. (2008) showed some benefit of regular exercise in reducing stress and improving bowel transit. However, as previously discussed in the section on constipation, exercise has little benefit on bowel transit time.

Goals of Drug Therapy

The pharmacologic agents used for IBS are the same as those discussed in the constipation and diarrhea sections of this chapter. The goal of pharmacotherapy for IBS is to alleviate or control the specific symptoms. Generally, clinical trials have been inadequate to establish a definite link between administration of specific drugs and relief of symptoms. In patients with IBS, between 50% and 75% still have symptoms after 10 years (Canavan et al., 2014). In an open-label placebo trial, response rates to a placebo were as high as 53% (Kaptchuk et al., 2010).

Bulk-Forming Laxatives

Previously, administration of dietary fiber in the form of a bulking agent was commonly the first agent prescribed in IBS (Table 30.7). However, administration of fiber to patients with IBS has become controversial. While the hypothesis exists that fiber increases colonic transit time and therefore lessens colon wall tension and ultimately abdominal pain, clinical trials on the use of fiber in IBS have had small sample sizes and have been short in duration. Also, fiber can exacerbate the diarrhea and bloating component of IBS. This led the ACG Task Force to conclude that fiber is no more effective than placebo and is not recommended for the treatment of IBS.

TABLE 30.7 Overview of Selected Agents Used to Treat Irritable Bowel Syndrome

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Selected Bulk-Forming Laxatives			
psyllium (Konsyl, Metamucil, Perdiem) Start: 1 tsp in 8 oz liquid bid–tid Range: 1–2 tsp in 8 oz liquid bid–tid	Abdominal fullness, increased flatus	Symptoms of acute surgical abdomen, intestinal obstruction, or perforation Inability to drink adequate amounts of water	Comes in granules, powder, or wafers Takes 12 h to 3 d to work
calcium polycarbophil (Equalactin, FiberCon, Mitrolan) Start: 500 mg tablets qd) Range: 500–1000 mg qid	Abdominal fullness, increased flatus	Same as above	Takes 12 h to 3 d to work
methylcellulose (Citrucel)) Start: 1 tsp in 8 oz liquid bid–tid) Range: 1–2 tsp in 8 oz liquid bid or tid	Nausea, abdominal cramps	Same as above	Takes 12 h to 3 d to work
Hyperosmotic Laxatives			
lactulose (Duphalac) syrup Start: 15–30 mL PO daily Range: 15–60 mg/d	Flatulence, intestinal cramps, diarrhea, nausea, vomiting, electrolyte imbalances	Galactose-restricted diets, appendicitis, acute surgical abdomen, fecal impaction, or intestinal obstruction Use with caution in diabetic patients.	
magnesium citrate (Citroma) oral solution Start: 5 oz qhs Range: 5–10 oz qhs magnesium hydroxide (Milk of Magnesia/MOM.)) Start: 15 mL qhs Range: 15–60 mL qhs	Abdominal cramping, nausea Abdominal cramping, nausea	End-stage renal disease End-stage renal disease	Can cause increased magnesium levels in patients with end-stage renal disease Same as above
Stimulant Laxatives			
bisacodyl (Dulcolax) Start: 10 mg PO in evening or before breakfast Range: 10–15 mg	Abdominal cramping, nausea, vomiting, burning sensation in rectum with suppositories		Oral: 6–8 h Rectal: 15–60 min
senna concentrates (Senokot) Start: 2 tabs or 1 level tsp at hs Range: 2–4 tabs or 1–2 tsp qhs	Abdominal cramping, nausea	Signs and symptoms of appendicitis, abdominal pain, nausea, vomiting	Elderly or debilitated, halve the dose
Surfactant Laxatives			
docusate calcium (Surfak) Start: 240 mg/d Range: 240 mg/d	None	None	May increase the systemic absorption of mineral oil
docusate sodium (Colace) Start: 50 mg/d Range: 50–200 mg/d	Bitter taste, throat irritation, nausea, rash	Signs and symptoms of appendicitis	Onset: 1–3 d Not to be used for acute relief of constipation

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Antidiarrheal Agents			
diphenoxylate HCl with atropine sulfate (Lomotil) Start: 5 mg qid Range: 5–10 mg qid; maintenance may be 10 mg qd	Sedation, dizziness, dry mouth, paralytic ileus	Pseudomembranous enterocolitis, obstructive jaundice, diarrhea caused by organisms that penetrate intestinal mucosa Under 2 y of age Pregnancy category C	Onset 45–60 min
loperamide HCl (Imodium) Start: 4 mg after first loose stool then 2 mg after each following stool Range: 4–16 mg/d	Constipation	Acute dysentery	Peak levels 2.5 h after liquid and 5 h after capsule
Selected Antispasmodics (Anticholinergic Agents)			
belladonna alkaloids (Donnatal) Start: 1 tab or capsule tid or qid Range: 1–2 tabs/capsules tid or qid	Drowsiness, anticholinergic effects, paradoxical excitement	Glaucoma, unstable coronary artery disease, GI or GU obstruction, paralytic ileus, severe ulcerative colitis	Antacids may inhibit absorption. Additive anticholinergic effects with other anticholinergics, antihistamines, narcotics, tricyclic antidepressants
dicyclomine HCl (Bentyl) Start: 20 mg qid Range: 20–40 mg qid if tolerated	Same as above	Same as above	Same as above
clidinium (Librax) Start: 1 capsule qid—ac and qhs Range: 1–2 capsules qid—ac and qhs	Drowsiness, anticholinergic effects, paradoxical excitement, ataxia, confusion, jaundice	Glaucoma, GI or GU obstruction	Same as above
hyoscyamine sulfate (Levsin, Levbid, Levsin SL) *Levsin* Start: 1 tab q4h prn Range: 1–2 tabs q4h prn; max 12 tabs/d *Levbid* Start: 1 tab q12h Range: 1–2 tabs q12h; max 4 tabs/d *Levsin SL* Start: 1 tab swallowed or chewed q4h prn Range: max 12 tabs/d	Same as above	Same as above	Same as above
Secretagogues—Chloride Channel Activators			
lubiprostone (Amitiza) IBS-C: 8 mcg capsules bid	Nausea, diarrhea, abdominal pain, dyspepsia	Known or suspected mechanical GI obstructions	Pregnancy category C Not approved for children For IBS only approved for women Must take medication with food and water, swallow whole
Semi-synthetic Antibiotic			
rifaximin (Xifaxan) IBS-D: 500 mg tablets tid × 14 d	Peripheral edema, nausea, dizziness, fatigue, and muscles spasms. Additional post-marketing side effects include exfoliative dermatitis, rash, angioneurotic edema (swelling of face and tongue and difficulty swallowing), urticaria, flushing, pruritus and anaphylaxis.	Known hypersensitivity to rifaximin Bloody diarrhea	If diarrhea continues consider evaluation for *C-Difficile* May repeat treatment up to two times for recurrent diarrhea at the same dose. Can be taken with or without food

Hyperosmotic Laxatives

When the patient requires a laxative, it is preferable to administer one that is osmotic (see Table 30.7). These agents can work either as a disaccharide sugar, which produces an osmotic effect in the colon, resulting in colonic distention and promotion of peristalsis, or by an osmotic effect in the small intestine, drawing water into the lumen and softening the stool. Lactulose or sorbitol, disaccharide sugars, can be used for patients with predominant constipation. PEG 3350 (MiraLAX) is a glycolated laxative that can be safely used for a long period without adverse pharmacologic effects.

Contraindications

The same contraindications exist as when using these agents to treat chronic constipation. Lactulose is contraindicated in patients who must restrict their galactose intake and in patients with appendicitis, acute surgical abdomen, fecal impaction, or intestinal obstruction. Caution must be used with administration to diabetic patients because of sugar content.

Other osmotic agents such as magnesium hydroxide (milk of magnesia) or magnesium citrate (Citroma) can be used to promote defecation. Approximately 15% to 30% of the magnesium in these agents may be absorbed systemically; therefore, caution needs to be used in patients who have renal failure and a decreased ability to excrete magnesium.

Adverse Events

When taken appropriately, these agents are well tolerated. The most common adverse events are abdominal cramping or nausea. Extensive, long-term use of these agents can lead to laxative dependence.

Stimulant Laxatives

These laxatives vary in effects but act by increasing peristalsis through a direct effect on the smooth muscle of the intestines and by simultaneously promoting fluid accumulation in the colon and small intestine. The recommendation is to use these agents intermittently due to the irritating effect of the agents on the musculature. Stimulant laxatives include bisacodyl (Dulcolax) and senna concentrates (Senokot, Senokot S). As with other laxatives, stimulants are contraindicated in patients with appendicitis, acute surgical abdomen, fecal impaction, or intestinal obstruction. Rectal fissures and hemorrhoids can be exacerbated by stimulation of defecation. Action begins 6 to 10 hours after oral administration and 15 minutes to 2 hours after rectal administration (see Table 30.7).

These agents are not as well tolerated as osmotic laxatives or bulking agents because of their side effects, which include nausea, vomiting, and abdominal cramping. These side effects can be more severe with cases of severe constipation. Several OTC products use the brand name of Dulcolax. One has the main ingredient of bisacodyl and another is docusate sodium, which is a stool softener. This could be important, especially when the patient has been instructed to use the drug as bowel preparation for a GI study.

Surfactant Laxatives

This class of laxatives reduces the surface tension of the liquid contents of the bowel. Ultimately, this promotes incorporation of additional liquid into the stool, forming a softer mass, and promotes easier defecation. Examples of this class include docusate sodium (Colace, Dulcolax) and docusate calcium (Surfak). This is the laxative of choice for patients who should not strain during defecation. However, emollient laxatives only prevent constipation; they do not treat it. Administration of emollient laxatives concomitantly with mineral oil is contraindicated because of increased absorption of the mineral oil. Action with these agents usually occurs in 1 to 3 days. The practitioner should consider this class for prevention purposes, not for acute treatment (see Table 30.7). These agents are extremely well tolerated when used to prevent constipation. Side effects include mild abdominal cramping, diarrhea, and throat irritation, but these are infrequent.

Antidiarrheal Agents

Antidiarrheal agents for patients with IBS with predominant diarrhea can be used on an occasional basis (see Table 30.7). Loperamide HCl (Imodium) inhibits peristaltic activity, thereby prolonging transit time, and it can increase anal sphincter tone. Approximately 40% of the drug is absorbed from the GI tract and 75% is metabolized in the hepatic system; excretion is primarily in the feces. As previously discussed, the drug does not cross the blood–brain barrier into the CNS. Because of these properties, it is the preferred agent for treating diarrhea. Conversely, diphenoxylate hydrochloride with atropine (Lomotil) is an opiate similar to meperidine that increases smooth muscle tone in the GI tract, inhibits motility and propulsion, and diminishes gut secretions. It is absorbed orally and extensively metabolized by the liver. It can affect the CNS, and atropine has been added to discourage abuse.

Neither of these antidiarrheal agents should be used in a patient suspected of having diarrhea from pseudomembranous colitis or ulcerative colitis or diarrhea resulting from poisoning or microbial infection. Diphenoxylate hydrochloride is contraindicated in patients who are hypersensitive to atropine or meperidine and patients with hepatic impairment. The atropine in Lomotil may aggravate glaucoma in patients with this disease. For additional discussion of contraindications and adverse events, see the diarrhea section.

Antispasmodic Agents

Treatment for patients with postprandial abdominal pain may require the use of antispasmodics (see Table 30.7). However, the efficacy of these medications remains unproven in controlled studies. The presumed desired action is by direct relaxation of the smooth muscle component of the GI tract. These agents competitively block the effects of acetylcholine at muscarinic cholinergic receptors that mediate the effects of parasympathetic postganglionic impulses. Examples of commonly used anticholinergics are dicyclomine hydrochloride (Bentyl) and hyoscyamine sulfate (Levbid, Levsin SL). Less commonly used are the belladonna alkaloids/phenobarbital (Donnatal) and clidinium/chlordiazepoxide (Librax); while both are still on the market, they can be difficult to find and expensive. These drugs are a combination of older benzodiazepines, antispasmodics, and/or antiepileptics. Dosing of the anticholinergics is variable, and general side effects are associated with the anticholinergic actions.

Contraindications

These agents are contraindicated in patients who have glaucoma, stenosing peptic ulcer, chronic obstructive pulmonary disease, cardiac arrhythmias, impaired liver or kidney function, and myasthenia gravis. Caution should be used in patients with hypertension, hyperthyroidism, and benign prostatic hyperplasia.

Adverse Events

Side effects include dry mouth, altered taste perception, nausea, vomiting, dysphagia, blurred vision, palpitations, and urinary hesitancy and retention. Anticholinergic side effects can be used as a measure of titration to achieve the desired pharmacologic end. It is important to monitor for signs of drug toxicity: CNS signs resembling psychosis, accompanied by peripheral effects that include dilated, nonreactive pupils; blurred vision; hot, dry, flushed skin; dry mucous membranes; dysphagia; decreased or absent bowel sounds; urinary retention; hyperthermia; tachycardia; hypertension; and increased respiration.

Antidepressants

Antidepressants as a class have also been used in the treatment of IBS. It is not clear whether these agents work by improving a concomitant depression or by improving the anxiety and stress often associated with IBS. Initial work was done with use of the tricyclic agents such as imipramine (Tofranil), desipramine (Norpramin), and amitriptyline (Elavil) in patients with severe symptoms. Careful monitoring is important when tricyclic antidepressants are given to patients with IBS in which constipation predominates, because these agents can cause constipation. Newer agents in the selective serotonin reuptake inhibitor (SSRI) class may also prove beneficial. It has been suggested based on current investigations that antidepressants alter perceived pain thresholds, which are often abnormal in patients with IBS. See Chapter 40 for further discussion of these drugs.

Serotonin-3 Receptor Antagonists

A newer class of drugs has evolved to address the brain–gut–neurotransmitter (5-HT3) connection with regard to colonic transit time. Currently, there is only one drug in this class.

In animal models, serotonin-3 receptor antagonist has been shown to decrease abdominal pain, slow colonic transit time, increase rectal compliance, and improve stool consistency. Indication for use of alosetron is for patients who have severe diarrhea and no constipation. The drug was first released in 1999, but later pulled from the market in 2000 due to concerns about ischemic colitis and severe constipation. In 2002, alosetron once again became available with special provisions by the FDA for provider education and distribution. The American Gastroenterology Association (2014) recommends *conditional* use of alosetron for IBS-D reflecting additional limitations based on FDA requirements.

Secretagogues

Chloride Channel Activators

As previously discussed in the constipation section, lubiprostone (Amitiza) is approved for CIC and OIC for both men and women; however, for treatment of IBS, it is only approved for use in women ≥ 18 years old. Lubiprostone is the only drug in this class. Lubiprostone became approved for IBS in 2008 and is prescribed at a lower strength starting at 0.5 mg twice a day.

Contraindications

Lubiprostone is contraindicated in patients with potential mechanical obstruction or hypersensitivity to components of the product.

Adverse Events

The side effect profile is similar to usage in chronic constipation; however, only GI effects are noted. Nausea is the most common side effect of lubiprostone. The rate of nausea is dose dependent and was experienced by approximately 8% of patients. Other common GI side effects include diarrhea, abdominal pain, and abdominal distention.

Interactions

No drug–drug interactions have been discovered with lubiprostone. In vitro studies showed the cytochrome P-450 isoenzymes are not inhibited by the drug.

Guanylate Cyclase-C Agonist

This class has been previously discussed in the constipation section. The mechanism of action for linaclotide (Linzess) is topical rather than systemic, elevating intracellular cGMP, which stimulates secretion of chloride and bicarbonate into the intestinal lumen. Along with the increased fluid, stool transit time is accelerated. Linzess is approved for 18 years and older with IBS. The recommended dosage for IBS is substantially increased to 290 mcg orally once a day, 30 minutes prior to the first meal of the day.

Semisynthetic antibiotic

Rifaximin

Rifaximin (Xifaxan) is a semisynthetic antibiotic also approved for treatment of IBS-D. It is only effective against noninvasive strains of *Escherichia coli.* The drug is a derivative of rifampin and acts to block transcription of the bacteria; therefore, it inhibits bacterial protein synthesis and growth. Additionally, rifaximin improves IBS-D symptoms of

abdominal pain after a 10- to 14-day course of treatment. The recommended dose for IBS-D is 550 mg three times daily for 14 days; this differs from the TD administration. Rifaximin may be administered with or without meals. Patients with recurrent symptoms can be retreated up to two times with the same regime. If the diarrhea does not improve, providers should consider evaluation for *Clostridium difficile.*

Selecting the Most Appropriate Agent

The emphasis in the care of patients with IBS should be multidimensional. IBS can present in many stages: mild, moderate, or severe. In 2014, the American Gastroenterological Association (AGA) developed pharmacologic guidelines (Weinberg et al., 2014). These recommendations take into account the level of available data and analysis of risk/benefits for particular agents. As patient care evolves toward evidence-based medicine, the AGA notes that few comparative effectiveness studies exist of the various therapeutic alternatives for treatment of IBS. This fact continues to make prescribing for IBS a challenge for clinical care. Therefore, the standard is still the selection of the most appropriate drug therapy based on the presenting symptoms. Each case needs to be evaluated, and treatment should be individualized (Figure 30.3 and Table 30.8).

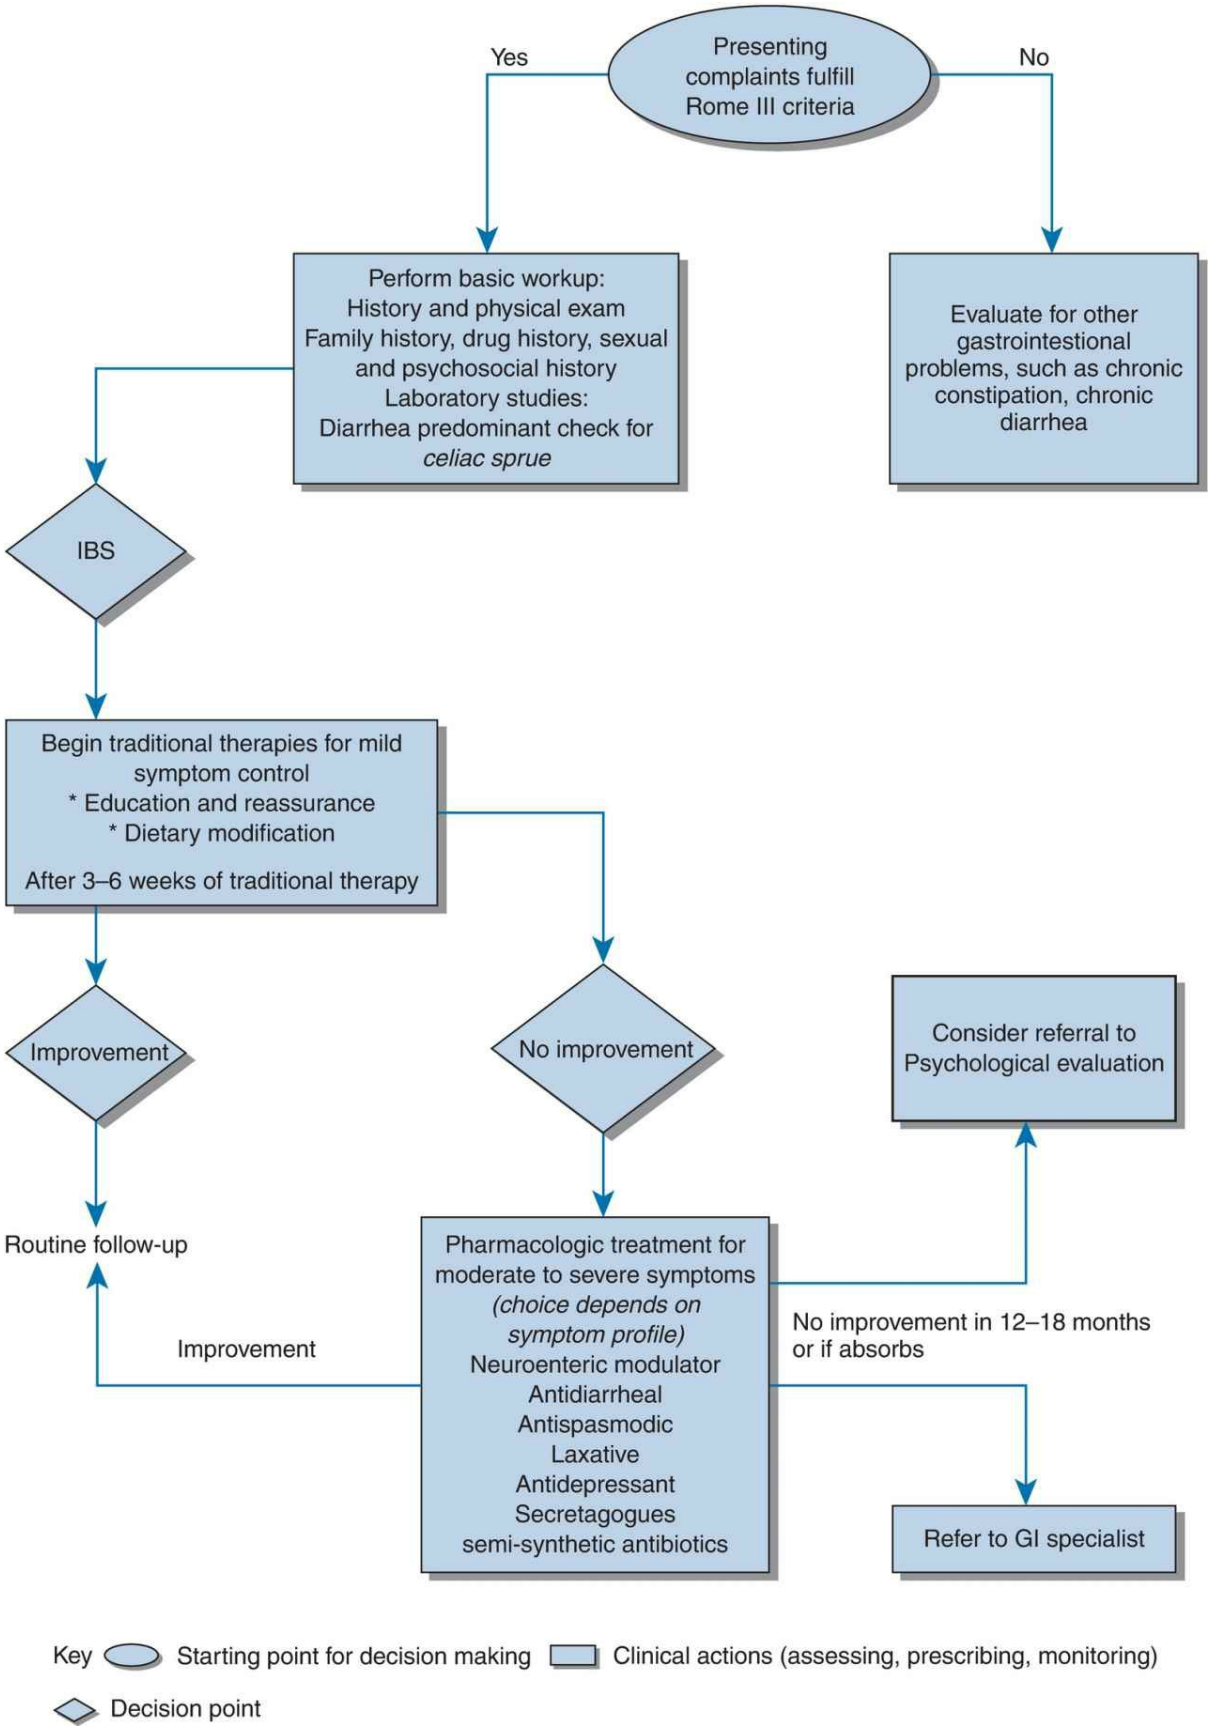

Figure 30.3 Treatment algorithm for IBS.

TABLE 30.8 Recommended Order for Treatment for Irritable Bowel Syndrome

Order	Agents	Comments
First Line		
Predominant constipation (IBS-C)	Osmotic laxative—lactulose syrup, magnesium citrate, magnesium hydroxide	Milk of magnesia is less expensive than citrate. Use magnesium products cautiously in patients with renal impairment. Use lactulose cautiously in diabetic patients.
	linaclotide or lubiprostone	Consider for first or second line for IBS-C
Predominant diarrhea (IBS-D)	Antidiarrheal—loperamide	May cause constipation
	hydrochloride (Imodium)	Caution about drowsiness; may have a dry mouth
	rifaximin	If diarrhea continues after a total of two treatments, consider *C. difficile*.
Abdominal bloating/gas	Antispasmodics—dicyclomine hydrochloride (Bentyl)	
Psychological symptoms	Antidepressants—SSRIs	Generally, as a class, these agents may be helpful with chronic syndromes. Cost may be an issue.
Second Line		Generalized CNS effects
Predominant constipation	Continue osmotic laxatives.	
	linaclotide or lubiprostone	If not used first line
Predominant diarrhea	Antidiarrheal—diphenoxylate hydrochloride (Lomotil)	Monitor for anticholinergic effects.
Abdominal bloating/gas	Antispasmodics—hyoscyamine sulfate (Levsin, Levbid, Levsin SL)	
Psychological symptoms	Antidepressants—tricyclic agents (imipramine, desipramine, amitriptyline) (Tofranil, Norpramin, Elavil)	Onset of action and steady states vary with each drug.
Third Line		
Predominant constipation	Laxatives—bisacodyl (Dulcolax), senna concentrates (Senokot), emollient laxatives, docusate sodium (Colace), docusate calcium (Surfak), alosetron (Lotronex)	Caution with cardiac patients Can aggravate abdominal cramping Use only as additive to keep stools soft. Only approved providers can prescribe alosetron.
Abdominal bloating/gas	Antispasmodics—belladonna alkaloids (Donnatal), clidinium (Librax)	More severe generalized anticholinergic effects

First-Line Therapy

First-line therapy is selected based on the presenting symptoms. Qualitatively, patients often feel the burden of this disease but believe this is not appreciated by primary care providers and specialists. Pharmacologic agents need to be considered only when an exacerbation of the disease occurs. There is strong evidence that IBS-C should be treated with linaclotide or lubiprostone as a first-line therapy. Consider an osmotic laxative on a long-term basis for those who are adverse to the incidence of diarrhea with either linaclotide or lubiprostone. Antidiarrheal agents are conditionally recommended in patients with IBS-D. Loperamide is the preferred agent because it causes the least CNS activity and has the added benefit of improving anal sphincter tone.

With the additional problems of pain, gas, and abdominal bloating, a trial of an antispasmodic may relieve symptoms. Dicyclomine is the agent of first choice because of its shorter half-life, which may minimize the anticholinergic side effects of the class. As with any chronic syndrome, use of low-level antidepressants may be helpful for symptom control. Psychological symptoms associated with IBS may be treated by antidepressants. Selection of an antidepressant should be based on the specific symptoms of depression, stress, or anxiety. The SSRIs are the most commonly selected agents because of their safety profile and efficacy.

Second-Line Therapy

Unresolved complaints of IBS-D can be treated with diphenoxylate hydrochloride, which has a longer duration of action but can be addictive because of its opioid properties and should be reserved for short-term use. Rifaximin should be tried for those whose diarrhea symptoms do not improve. For postprandial abdominal pain, gas, and abdominal bloating, longer-acting antispasmodics such as hyoscyamine sulfate can be considered. The second-line choice for psychological symptoms is the tricyclic antidepressants; these agents have more side effects than SSRIs.

Third-Line Therapy

The use of stimulant laxatives in cases of IBS-C should be reserved for more resistant cases, but these agents should be used with caution. They should not be used for long periods, and they can aggravate abdominal cramping. The older anticholinergics such as the belladonna alkaloids and clidinium should be used very sparingly for postprandial abdominal pain, gas, and abdominal bloating because they produce more intense anticholinergic side effects. In addition, both belladonna and clidinium are hard to find and can be expensive. Patients with IBS, no matter which subtype, need to have consistent evaluation and pharmacologic therapies changed as appropriate for their symptoms.

Special Considerations

Pediatric

Children with crampy abdominal pain, constipation, or diarrhea present a challenge to the practitioner. The approach to diagnosis follows the same parameters of adults; however, few if any of the pharmacologic agents are approved for pediatrics (Sandhu & Paul, 2014). Although these symptoms sound like IBS, there are no established criteria for children. As previously discussed, some experts think that these children may acquire IBS later in life. Treatment for these symptoms can include some of the same approaches of increasing fiber and use of antidiarrheal agents and the newer antispasmodics. Close follow-up is an important aspect of care.

Geriatric

Initial presentation of IBS in people older than age 50 is rare. Abdominal pain in older patients should be considered a more ominous symptom unless they have been previously diagnosed with IBS or spastic colon, a version of colitis. Older patients may report a long-standing history of bowel trouble with any of these diagnoses.

Women

In Western society, women are more likely to have IBS and to seek care. A history of verbal or sexual abuse may also contribute to IBS. Women have surgery more often when the origins of abdominal pains are unclear.

Monitoring Patient Response

Monitoring the patient's response to therapy should take place within 3 to 6 weeks of the initial evaluation. For patients with mild symptoms, the initial treatment includes working with the patient regarding dietary and lifestyle changes, education about the disease process, and reassurance about lack of organic causes. Patients with intermittent symptoms require the same initial approach, but addition of pharmacologic therapy can prove helpful, if only for the placebo effect of the drugs. Psychological counseling may also be helpful with these patients. Severe IBS requires all of these interventions and the addition of intensive psychotherapy. Patients with mild to intermittent symptoms can easily be managed in the primary care office with close monitoring initially, every 3 to 6 weeks, and then more routine care.

IBS is a disease of exacerbations and remissions, but up to 70% of patients respond to treatment within 12 to 18 months. Those with a shorter duration of symptoms and fewer psychological symptoms have a better prognosis. Referral to a specialist should occur when there is no relief with any therapies or when the patient has atypical symptomatology. Some patients do not respond. Continued symptoms rarely need a reappraisal of the diagnosis, but appropriate testing should be performed.

Patient Education

Patient education needs to cover dietary modifications, psychological stresses, and lifestyle changes. Begin by acknowledging the patient's fears and concerns, and show that you take them seriously. According to current evidence-based research, patients can be reassured of the absence of organic disease based on the history and physical examination. The patient should be informed that this is a chronic disease and that IBS does not lead to cancer, colitis, or an altered life expectancy. Making the necessary dietary changes can be crucial for symptom relief, especially with mild symptoms. A multidisciplinary approach is often the best method of care, using the services of a dietitian and psychological counselor.

Drug Information

A variety of drugs are available to help control symptoms, and most have minimal side effects. However, the drugs need to be used in conjunction with stress relief techniques, identification of influencing factors, and education about the disease to help provide an improved quality of life.

Patient-Oriented Information Sources

Many resources exist for patients with IBS. One of the most comprehensive resources is the ACG, which covers many topics on GI health. The International Foundation of Functional Bowel Disorders also has a comprehensive Web site with resources for both patients and health care providers (Box 30.11).

BOX 30.11 Patient Resources for Irritable Bowel Syndrome

http://www.gastro.org/generalPublic.html
http://www.aboutibs.org/
http://www.iffgd.org/index.html
http://digestive.niddk.nih.gov/ddiseases/pubs/ibs/

Nutrition/Lifestyle Changes

A major focus of caring for patients with IBS is helping them assess their diet, making adjustments as necessary. A trial of removing foods that trigger symptoms such as those containing lactose and gluten from the diet poses no risks to the patient and may have a benefit if it relieves symptoms.

Case Study*

C.J. is a 71-year-old woman who presents for follow-up. She complains of hard, dry stools over the past week. She remembers reading an educational brochure she picked up in her pharmacy that suggested increasing her fiber and fluid intake, but this has not alleviated her problem. C.J.'s past medical conditions include hypertension and chronic renal insufficiency. She had a stroke 1 year ago with little or no residual. Her medications include verapamil SR 240 mg daily, lisinopril 10 mg orally once daily, calcium carbonate 1,250 mg twice daily orally, and aspirin 325 mg orally once daily.

Diagnosis: Constipation

1. List specific goals of treatment for this patient.
2. What drug therapy would you prescribe? Why?
3. What are the parameters for monitoring the success of the therapy?
4. Discuss specific patient education based on the prescribed therapy.
5. List one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What would be the choice for second-line therapy?
7. What OTC or alternative medications would be appropriate for this patient?
8. What dietary and lifestyle changes should be recommended for this patient?
9. Describe one or two drug–drug or drug–food interactions for this patient.

31 Inflammatory Bowel Disease

David Dinh

Inflammatory bowel disease (IBD) is a generic term used to describe two main chronic inflammatory conditions of the gastrointestinal (GI) tract: Crohn disease (CD) and ulcerative colitis (UC). Although these conditions are similar in clinical presentation, CD is a chronic inflammatory disease characterized by transmural lesions located at any point on the GI tract, whereas UC is a chronic disease consisting of mucosal inflammation limited to the rectum and colon. IBD affects approximately 1 million Americans. In 1998, the prevalence of CD was estimated to be approximately 359,000, and for UC, it is estimated to be 619,000 (National Institute of Diabetes and Digestive and Kidney Diseases, 2013). The incidence of UC has been relatively stable over the past five decades, whereas the incidence of CD is rising (Kornbluth & Sachar, 2010; Lichtenstein, Diamond, et al., 2009; Lichtenstein, Hanauer, et al., 2009). Both conditions are more common in Whites than in any other race, and those of Jewish descent have a three- to sixfold greater incidence than does the non-Jewish population. IBD shows no gender predilection and is usually first diagnosed in men or women between ages 15 and 25 (Kappelman et al., 2007). Although the mortality rate is low for the disease, it significantly affects the patient's overall mental status, physical health, and quality of life. The most common emotional issues surrounding uncontrolled IBD appear to be anger, frustration, depression, and low self-esteem. These issues usually stem from the patient's inability to participate in routine activities, leading to a decreased quality of life. The disease has a negative impact on social interactions and daily functional status, leading to decreased productivity and attendance at work or school, decreased social engagements, and loss of independence. Health-related issues mirror those related to poor GI absorption, including nutritional deficiencies, electrolyte abnormalities, dehydration, cachexia, and iron deficiency anemia. Fatigue and lack of sleep are also common in patients with IBD. In addition, patients with long-standing CD may also be at risk for adenocarcinoma of the GI tract (Pederson et al., 2010). All of these may result in frequent hospitalizations, altered lifestyle, and poor general health. Overall, in 2004, IBD had an estimated financial burden of $328 million in indirect health care costs and over $1.8 billion dollars in direct costs (Everhart, 2008).

Causes

The etiology of CD and UC is related to the dysregulation of immunologic mechanisms. The inflammatory nature of the condition has led researchers to believe that an autoimmune mechanism may predispose patients to IBD. The development of IBD may be attributed to a defect in the GI mucosal barrier that results in enhanced permeability and increased uptake of proinflammatory molecules and infectious agents. Tissue biopsies of the GI mucosal lining from patients with IBD reveal a high proportion of immunologic cytokines, including tumor necrosis factor (TNF), leukotrienes, and interleukin-1 (IL-1). A few bacterial and viral organisms have been associated with disease progression, including *Mycobacterium paratuberculosis*, measles virus, and *Listeria monocytogenes*; however, none has been definitively correlated with IBD.

Much of the recent evidence suggests that IBD is a complex genetic disorder. The high incidence of IBD in the Jewish population supports a genetic component of the etiology of CD and UC. A study comparing relatives of patients with IBD with the general population found a 10-fold increase in risk of development of IBD in those with familial occurrence. In addition, studies in twins support the notion that the disease course and occurrence of CD is genetically influenced (Halfverson et al., 2007). Recently, the NOD2/CARD 15 gene has been associated with CD. Those who carry two copies of the risk alleles have been noted to be at higher risk for developing CD than others. The relationship between IBD and other genetic mutations and polymorphisms is currently being investigated. Until there are sufficient data to link a specific genetic mutation to IBD, the identification of genetic polymorphisms remains a research tool and not a clinical diagnostic tool.

Other factors, including psychological well-being and environmental triggers, may contribute to the exacerbation of IBD, although these factors do not have a predictable effect over a large population. Various studies have associated isolated mental instability or stressful events with IBD exacerbations, but a positive correlation between psychiatric illness and IBD is unsupported.

Environmental factors, including geographic location, dietary habits, drug-induced factors, and smoking status, are theorized to affect CD and UC exacerbations. IBD is more prevalent in the northern parts of the United States as well as in England and Scandinavian countries rather than the Mediterranean countries, suggesting that temperature or weather patterns may have an impact on CD or UC. Various dietary habits such as high sucrose consumption have been identified as exacerbating CD or UC, but no one particular food or group of foods seems to have a reliable effect in a large population. Oral contraceptive use and cigarette smoking have variable effects on CD versus UC; oral contraceptives and nicotine have been found to exacerbate CD, but not UC (Khalili et al., 2013). In addition, recently, the use of the antiacne product isotretinoin (Accutane) has been associated with the development of IBD, especially UC. The exact mechanism by which isotretinoin may cause IBD is unknown. However, isotretinoin does affect many immunologic mechanisms

that may trigger IBD (Crockett et al., 2010; Reddy et al., 2006).

Pathophysiology

Differentiating CD from UC is difficult because of their similar clinical presentations. Hallmark symptoms of IBD are bloody diarrhea, weight loss, and fever. Generally, CD can be distinguished from UC based only on endoscopic findings. The GI mucosal lining in CD is usually characterized by discontinuous, narrowed, thick, edematous, leathery patches with the presence of lesions, ulcerations, fissures, strictures, granulomas, and fibrosis. Fistulas and abscess formation occur most commonly in patients with deep transmural lesions. Granulomas and fistulas usually occur exclusively in patients with CD. UC usually affects the rectum and areas proximal, possibly extending throughout the entire large intestine with continuous, superficial uniform inflammation and ulceration. Other pathologic findings are rare in UC but may occur in patients with chronic, long-standing inflammation (Table 31.1).

TABLE 31.1 Common Signs and Symptoms of Crohn Disease versus Ulcerative Colitis

	Ulcerative Colitis	Crohn Disease
Signs		
Abdominal mass	0	++
Fistulas	+/–	++
Strictures	+	++
Small bowel involvement	+/–	++
Rectal involvement	++	+/++
Extraintestinal disease		
Arthritis/arthralgia	++	++
Erythema nodosum	+/–	+/–
Abnormal liver function test values	++	++
Iritis/uveitis	+/–	+/–
Ankylosing spondylitis	+	+
Growth retardation	+	+
Toxic megacolon	+	+/–
Recurrence after colectomy	0	+
Malignancy	+	+/–
Symptoms		
Fever	+	++
Diarrhea	++	++
Weight loss	++	++
Rectal bleeding	++	+
Abdominal pain	+	++

Key: +, common; ++, very common; +/–, possible; 0, rare.

Extraintestinal complications, including skin malformations, liver disease, joint deformities, and ocular manifestations, may also occur, although they are more common in CD than UC because of the more aggressive nature of CD, resulting in a higher probability of malabsorption of nutrients (see Table 31.1). Because the complications affect a variety of organ systems and result in nonspecific complaints, it is difficult to associate the complaints with CD or UC; however, it is important to be aware of the complications because their

presence indicates poorly controlled disease.

Diagnostic Criteria

Because the clinical presentation of patients with CD or UC is nonspecific, definitive diagnosis relies on endoscopic or radiologic studies. Initial diagnosis of IBD must rule out other causes of bloody diarrhea such as infectious causes and other colitis conditions. Visualization techniques must be used to differentiate CD from UC because of their similar clinical presentations. Usually, endoscopic techniques are preferred over radiographs and radioactive isotopes because endoscopy permits direct visualization of the mucosal lining with increased specificity as to the extent of lesions, ulcerations, and inflammation as well as provides the opportunity to obtain mucosal specimens for biopsy and further evaluation. The risk of mucosal perforation, however, may limit the use of endoscopic technology in patients with severely active disease.

Sigmoidoscopy or colonoscopy is preferred as a first-line diagnostic procedure; however, for CD, an endogastroduodenoscopy may also be required to visualize the upper GI tract. Radiologic studies with contrast, including either an upper GI series or barium enema, may be preferred in patients with severely active symptoms to decrease the risk of mucosal perforation.

Antibody tests are sometimes helpful in determining the diagnosis of CD or UC. The perinuclear antineutrophil cytoplasmic antibody (pANCA) and/or the anti-*Saccharomyces cerevisiae* antibody (ASCA) tests may be positive in patients with IBD, but there is a significant rate of false-negative results, since only 60% to 70% of patients with CD or UC are actually antibody positive (Kornbluth & Sachar, 2010). The combination of a positive pANCA and a negative ASCA may indicate the presence of UC, whereas the opposite may indicate CD. However, the combined result still has a significant percentage of false negatives. Therefore, these tests are not used routinely to differentiate UC from CD.

Initiating Drug Therapy

CD and UC share many clinical characteristics with pseudomembranous colitis, irritable bowel disease, peptic ulcer disease (PUD), traveler's diarrhea, colon cancer, and hemorrhoids. Evaluation of patients with suspected IBD must include a complete history focusing on recent use of antibiotics, recent international travel, diet history, use of laxatives or antidiarrheals, frequency and quality of daily bowel movements, history of PUD, and family history of IBD to rule out similar presenting conditions.

Physical examination should include assessment of vital signs and weight loss, a thorough abdominal examination, and special attention to extraintestinal complications. Guaiac testing and stool cultures may be helpful in ruling out PUD or infectious causes. Although there are no reliable surrogate laboratory markers that may indicate the presence of CD or UC, baseline laboratory studies, including electrolytes, liver panel, complete blood count (CBC), and hematology panel, are important in assessing the severity of the condition and patient well-being.

Initiation of proper drug therapy is based on the severity and extent of disease. CD may present as luminal or fistulizing disease. CD confined to the GI lumen can initially present as mild, moderate, or severe disease and is not predictable in its course. Fistulizing disease also has a varied clinical course, whereby certain patients may never experience a fistula and others may develop one early in the course of the disease. Treatment of fistulizing disease is typically more aggressive than that of luminal disease and may vary depending on the location of the fistula (bowel to bladder, bowel to skin, etc.). UC may be confined to the distal colon and rectum or may extend throughout the colon. Due to the location of the disease, treatment options for distal UC are greater than for extensive disease. The Working Definitions of Crohn's Disease Activity or the Criteria for Severity of Ulcerative Colitis may be used as a guide to determine severity (Tables 31.2 and 31.3). Both scales are frequently used in clinical trials; however, they are modified for use in clinical practice. There are many validated scales used to assess the severity of UC; however, there is not one gold standard. Each scale highlights specific subjective and objective parameters that should be evaluated when assessing the progression of disease. Both scales highlight certain key features when predicting the severity of the condition, such as the frequency of stools per day and the presence of abdominal pain, fever, and anemia.

TABLE 31.2 Working Definitions of Crohn's Disease Activity

Mild to Moderate

- Ambulatory patients
- Able to tolerate oral alimentation
- No evidence of:
  - Dehydration
  - High fevers
  - Rigors
  - Prostration
  - Abdominal tenderness
  - Painful mass
  - Abdominal obstruction
- 10% weight loss

Moderate to Severe

- Failed treatment for mild to moderate disease OR
- Have
  - High fever
  - >10% weight loss
  - Abdominal pain/tenderness
  - Intermittent nausea or vomiting (without obstructive findings)
  - Significant anemia

Severe to Fulminant

- Persistent symptoms despite outpatient steroid therapy OR
- Have
  - High fever
  - Persistent vomiting
  - Intestinal obstruction
  - Rebound tenderness
  - Cachexia
  - Abscess

Remission

- Asymptomatic without inflammatory sequelae
- Not dependent on steroids

TABLE 31.3 Criteria for Severity of Ulcerative Colitis

Mild UC

- <4 stools daily (with or without blood)
- No presence of anemia, fever, or tachycardia
- Normal erythrocyte sedimentation rate (ESR)

Moderate UC

- >4 stools daily
- Minimal anemia, fever, or tachycardia

Severe UC

- >6 bloody stools daily
- Positive fever, tachycardia, anemia, or elevated ESR

Fulminant UC

- >10 stools daily
- Continuous bleeding
- Abdominal tenderness and distention
- Anemia requiring blood transfusion
- Colonic dilation

Treatment for IBD consists of aminosalicylates, corticosteroids, immunosuppressive agents, antibiotics, and biological agents. The decision to use one or a combination of these agents is based on the presence of CD versus UC, the severity of the disease, and whether treatment is targeted at active disease or maintenance of remission. In general, aminosalicylates are used for treating mild to moderate exacerbations of UC and CD as well as for maintaining remission in IBD. Corticosteroids are used to treat acute exacerbations and should not be used chronically to maintain remission. Immunosuppressive agents are used for the purposes of maintaining remission in IBD, whereas intravenous (IV) cyclosporine is used in a limited population to treat severely active, steroid-refractory UC. Antibiotics are reserved for treating and maintaining remission in patients with mild CD. Biologic agents are typically reserved for inducing and maintaining remission in patients with steroid-refractory CD; however, the current recommendation is to use biologics in combination with thiopurines to induce remission in moderately severe CD (Table 31.4).

TABLE 31.4 Overview of Agents Used to Treat Inflammatory Bowel Disease

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Aminosalicylates			
sulfasalazine (Azulfidine, Azulfidine EN) Start: 500 mg twice daily Range: 1–8 g/d	Stevens-Johnson syndrome, rash, photosensitivity, nausea, vomiting, skin discoloration, agranulocytosis, crystalluria, hepatitis	Sulfa allergy, aspirin allergy, G6PD deficiency	Most efficacious at high doses Drug released in the proximal colon Available in enteric-coated tablets Dosage increases may occur as frequently as every other day.
oral mesalamine (Apriso, Asacol HD, Delzicol, Lialda, Pentasa) Start: depends on product Range: 1–4.8 g/d	Nausea, headache, malaise, abdominal pain, diarrhea	Aspirin allergy, G6PD deficiency	Products released differently in the GI tract May increase dose as frequently as every other day
rectal mesalamine (Rowasa Enema, Canasa suppository) Suppository Start: 1 g at bedtime Range: 1 g/d Enema Start: 4 g at bedtime Range: 1–4 g/d	Malaise, abdominal pain	Aspirin allergy, G6PD deficiency	Only for distal ulcerative colitis, proctitis Suppository is most effective in sigmoid colon, and enema may treat distal and sigmoid colon.

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
olsalazine (Dipentum) Start: 500 mg twice daily Range: 1–2 g	Nausea, headache, malaise, abdominal pain, diarrhea	Aspirin allergy, G6PD deficiency	Drug released in proximal colon May increase dose as frequently as every other day Higher incidence of diarrhea
balsalazide (Colazide) Start: 1.5 g twice daily Range: 1.5–6.75 g	Headache, abdominal pain, diarrhea	Aspirin allergy, G6PD deficiency	Only approved for treatment of mild to moderate ulcerative colitis
Selected Corticosteroids			
prednisone (Orasone, Deltasone) Start: 40–60 mg daily Range: 10–100 mg	Hyperglycemia, increased appetite, insomnia, anxiety, tremors, hypertension, fluid retention, electrolyte imbalances	Active GI bleeding	Taper patient off steroids within 1–2 mo of initiation to decrease risk of long-term side effects.
oral methylprednisolone (Medrol) Start: 20–50 mg daily Range: 10–100 mg	Same as above	Same as above	Same as above
IV methylprednisolone (Solu-Medrol) Start: 5–10 mg q6h Range: 10–50 mg	Same as above	Same as above	IV treatment used for severe exacerbations Treatment duration should be a maximum of 7–14 d, then switch to oral therapy.
rectal hydrocortisone suppositories (Anusol-HC) Start: 25 mg twice daily Range: 25–100 mg	Same as above	Used only for distal ulcerative colitis treatment	
hydrocortisone enema (Cortenema) Start: 100 mg bedtime Range: 100 mg/d	Enema is more effective than suppositories for distal colitis.		
IV hydrocortisone (Solu-Cortef) Start: 50–100 twice daily Range: 25–150 twice daily	Same as above	Active GI bleeding	IV treatment used for severe exacerbations Treatment duration should be a maximum of 7–14 d, then switch to oral therapy.
dexamethasone (Decadron) Start: 5–15 mg daily Range: 2–20 mg/d	Same as above	Same as above	Has longer onset of action than other agents
oral budesonide (Entocort EC) Start: 9 mg/day Maintenance: 6 mg/d for 3 mo	Minimal nausea	Same as above	Minimal systemic absorption Taper after 8 wk of therapy. Effective for mild to moderately active luminal CD and maintenance
Selected Immunosuppressives			
azathioprine (Imuran) Start: 50 mg/d Range: 2–2.5 mg/kg	Pancreatitis, fever, arthralgias, nausea, rash, agranulocytosis, diarrhea, malaise, hepatotoxicity	Pregnancy, active liver disease, bone marrow suppression	Decrease dose for patients with severe renal dysfunction
6-mercaptopurine (Purinethol) Start: 50 mg/d Range: 1–2.5 mg/kg	Same as above	Same as above	Same as above

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
oral methotrexate (Rheumatrex) Start: 5 mg three times a week Range: 5–7.5 mg three times a week	Hepatic cirrhosis and fibrosis, neutropenia, pneumonitis, skin rash, nausea, diarrhea	Same as above	Same as above
IV cyclosporine Start: 4–8 mg/kg/d	Hypertension, nephrotoxicity, superinfection, hypomagnesemia	Renal failure, hepatic failure	Only used for severely acute UC refractory to steroids; total duration of therapy 7–10 d; has many drug interactions
Selected Antibiotics			
metronidazole (Flagyl) Start: 20 mg/kg/d Range: 10–20 mg/kg/d	Nausea, diarrhea, disulfiram reaction, metallic taste, peripheral paresthesias, dizziness	Liver failure, renal failure, first trimester of pregnancy, uncontrolled seizure disorder	Should not be used with alcohol Most efficacious if used chronically >3 mo
ciprofloxacin (Cipro) Start: 500 mg twice daily Range: 500–2,000 mg/d	Dizziness, nausea, diarrhea, photosensitivity	Children <12 y, pregnancy, uncontrolled seizure disorder	May cause arthropathies in patients <12 y Must be administered 2 h before or after divalent and trivalent cations
Tumor Necrosis Factor Inhibitors			
IV infliximab (Remicade) Start: 5 mg/kg Range: 5–10 mg/kg	Infusion reactions (urticaria, dyspnea, hypotension), TB, invasive fungal infections, lymphoma, lupus-like syndrome	Class III/IV heart failure, active TB, hepatitis B or other infections	For severe, refractory UC and luminal and fistulizing CD; administered over 2 h as a single infusion Induction regimen dosed at weeks 0, 2, and 6; maintenance regimen dosed every 8 wk
adalilimumab (Humira) Start: 160 mg SQ Maintenance: 40 mg every week or every other week	Opportunistic infections (TB, fungal, bacterial, viral), lymphoma and other cancers, injection site reactions (erythema, pain, swelling)	Active TB, hepatitis B, or other infections	For luminal CD; induction regimen 160 mg initially and 80 mg at week 2
certolizumab pegol (Cimzia) Start: 400 mg at baseline, week 2, and week 4 Maintenance: 400 mg every 4 wk	Opportunistic infections (TB, fungal, bacterial, viral), lymphoma and other cancers, injection site reactions (erythema, pain, swelling)	Active TB, hepatitis B, or other infections	For luminal CD
Selective Adhesion Molecule Inhibitors			
IV natalizumab (Tysabri) 300 mg IV every 4 wk	Infusion reactions (urticaria, dyspnea, hypotension), opportunistic infections (TB, fungal, bacterial, viral) progressive multifocal leukoencephalopathy (PML), hepatotoxicity	Active TB, hepatitis B, or other infections, current or history of PML	Taper corticosteroid therapy according to clinical response; discontinue natalizumab if therapeutic benefit is not seen within first 12 wk of therapy.
IV vedolizumab (Entyvio) Start: 300 mg IV at baseline, week 2, and week 6 Maintenance: 300 mg IV every 8 wk	Infusion reactions (urticaria, dyspnea, hypotension), TB, invasive fungal infections, lymphoma, lupus-like syndrome	Active TB, hepatitis B, or other infections	Taper corticosteroid therapy off starting at week 6 of vedolizumab therapy.

G6PD, glucose-6-phosphate dehydrogenase.

Goals of Drug Therapy

Because no pharmacologic cure is available for CD or UC, the goals of treatment focus on symptom management and quality-of-life issues. With proper treatment, the patient should be able to:

- resume normal daily activities
- restore general physical and mental well-being
- attain appropriate nutritional status
- maintain remission of disease
- decrease the number and frequency of exacerbations
- decrease side effects related to medications
- increase life expectancy

Ideally, patients should expect to recover from an acute exacerbation within 2 to 4 weeks, have minimal exacerbations throughout the year, and participate in any desired activity.

Aminosalicylates

Aminosalicylates remain the gold standard for the treatment of mild to moderate CD and UC. Although the exact mechanism of action is unknown, these drugs decrease inflammation in the GI tract by inhibiting prostaglandin synthesis, which results in a decrease in various immune mediators, including IL-1, cyclooxygenase, and thromboxane synthase. Therapy with these agents may improve symptoms within 1 week of initiating therapy or dosage adjustment. However, patients may need to take these agents long term to prevent exacerbations. Although they are safe for use in most patients, aminosalicylates are contraindicated in patients with aspirin allergy or glucose-6-phosphate dehydrogenase deficiency. Sulfasalazine is also contraindicated in patients who are hypersensitive to sulfa products (see Table 31.4). All of these agents must be used at maximum doses for maximum therapeutic benefit, although the incidence of side effects also increases with increased doses.

Sulfasalazine

Sulfasalazine (Azulfidine, Azulfidine EN) is efficacious and cost-effective for CD and UC therapy but has a limited role because of its unfavorable side effect profile. Sulfasalazine is a combination product that is cleaved in the proximal colon by bacterial azo-reductases to release sulfapyridine and mesalamine. The mesalamine compound is responsible for virtually all of the therapeutic effect, whereas sulfapyridine is responsible for many of the side effects associated with sulfasalazine. Sulfasalazine may be administered up to four times a day; the most effective and maximum daily dosage is 8 g daily.

Mesalamine

Mesalamine (Asacol, Rowasa, Pentasa, Lialda, Apriso, Canasa) is available in various formulations, including oral tablets, oral capsules, enemas, and rectal suppositories. Each formulation is released in various areas of the GI tract, allowing for targeted drug therapy; however, in clinical trials, the capsules and tablets had similar efficacy at equivalent doses. Asacol, which is one of the oral tablet products, is formulated with an acrylic resin coating that disintegrates at a pH of 7, allowing the active ingredient to be released in the distal ileum and colon. Similarly, Lialda, another oral tablet formulation, has a coating that disintegrates at a pH of 6 to 7, and the core of the tablet forms a matrix that is released across a pH of 6.8 to 7.2. Pentasa, which is a sustained-release capsule, has ethylcellulose-coated granules that allow for the slow release of the drug beginning in the proximal small intestine and continuing throughout the colon. This formulation has slightly different pharmacokinetics than Apriso, which is also a delayed-release capsule. Apriso capsules are enteric coated; they disintegrate at a pH above 6 and also contain granules that are formulated in a polymer matrix for extended release. Because each of the oral products has different pharmacokinetics, the dosing interval for the products ranges from once to four times a day (see Table 31.4). The rectal suppositories are used primarily for UC-associated

proctitis, whereas the enema delivers mesalamine to the distal and sigmoid colon. The enema is typically given at bedtime to allow for direct contact of the drug with the mucosa for at least 8 hours. In patients with distal UC, a combination of oral and rectal mesalamine may be an appropriate therapeutic option. Studies have shown that combination mesalamine therapy is more effective than either single mesalamine formulation.

Olsalazine

Olsalazine (Dipentum), the third aminosalicylate preparation, consists of two mesalamine molecules joined by an azo-bond. As with sulfasalazine, the azo-bond is cleaved by bacterial azo-reductases in the GI tract, allowing the drug to be released in the proximal colon. It is administered twice daily, with patients taking up to 8 capsules per day for a total dosage of 2 g/d. Although each tablet of olsalazine has twice as much active ingredient as do the mesalamine capsules, the efficacy is minimally enhanced.

Balsalazide

Balsalazide (Colazal) is a combination product consisting of 5-aminosalicylic acid (mesalamine), the therapeutically active portion of the molecule, and 4-aminobenzoyl-alanine, an inert moiety. The product is cleaved by bacterial azo-reductases in the colon to release the active compound. Each capsule contains granules of balsalazide that are insoluble in acid and designed to be delivered to the colon intact. It is administered three times a day, up to 9 capsules per day, for a total dosage of 6.75 g/d, equaling 2.4 g/d of pure mesalamine. Currently, it has been studied only for use in mild to moderate UC in both adults and children. Side effects and contraindications are similar to those of mesalamine.

Adverse Events

Mesalamine, olsalazine, and balsalazide are poorly absorbed from the GI tract and thus are considered primarily topical agents, with limited systemic side effects and drug interactions. The major side effects of mesalamine include headache, malaise, abdominal pain, and diarrhea. Olsalazine has a similar side effect profile but has a higher incidence of diarrhea than mesalamine. Initially, diarrhea may not be easily distinguished from an IBD exacerbation, and therefore, close monitoring of improvement of symptoms is essential. If the balsalazide capsules are opened and sprinkled in food, teeth staining may occur. In rare instances, mesalamine, olsalazine, and balsalazide have been associated with renal function impairment; therefore, renal function should be monitored during therapy. Sulfapyridine is absorbed systemically, accounting for many of the side effects and drug interactions incurred by sulfasalazine. Common adverse effects include nausea, vomiting, photosensitivity, oligospermia, and skin discoloration, which may be tolerable for most patients. Severe adverse reactions associated with sulfasalazine include Stevens-Johnson syndrome, agranulocytosis, crystalluria, pancreatitis, and hepatitis, which may necessitate discontinuation of therapy. Sulfasalazine is known to decrease folate levels; therefore,

patients taking sulfasalazine should be supplemented with folic acid. Although drug interactions with sulfasalazine are limited, it may significantly decrease the effect of warfarin (Coumadin), and therefore, close monitoring of the international normalized ratio is essential.

Corticosteroids

Corticosteroids are used intermittently to treat acute IBD exacerbations only. Corticosteroids allow for immunosuppression and prostaglandin inhibition when the disease fails to respond to aminosalicylate therapy. Corticosteroids may be used in conjunction with aminosalicylates, immunosuppressants, or biologic agents or as monotherapy to treat acute exacerbations. Corticosteroids with relatively quick onset of action and high glucocorticoid activity, such as prednisone (Orasone, Deltasone) and methylprednisolone (Medrol), are desirable in the treatment of CD or UC. Controlled-release oral budesonide (Entocort EC) is a unique corticosteroid due to its long-acting formulation and limited potential for absorption from the GI tract, thus theoretically leading to a localized effect in the GI lumen with minimal systemic side effects. Oral budesonide has been used as the treatment of choice in patients with mild to moderate exacerbations of CD in combination with aminosalicylates or as monotherapy.

Dosage

Doses equivalent to oral prednisone 40 to 60 mg/d are initiated in patients with mild or moderate exacerbations of CD or UC. A beneficial effect is usually seen with 7 to 10 days of therapy. Patients with mild to moderate exacerbations of distal UC can be treated with oral or rectal corticosteroids for approximately 4 to 8 weeks, after which drug dosages are tapered. Hydrocortisone is the only rectal corticosteroid enema formulation available for use in distal UC exacerbations. There are many tapering regimens that have been studied. The most common is a 5- to 10-mg weekly taper until a daily dose of 20 mg is reached, at which time the dose is tapered by 2.5 mg/week. In severe exacerbations, patients should receive 3 to 10 days of IV corticosteroid therapy and then switch to oral corticosteroid therapy for the remainder of the treatment period (see Table 31.4).

Adverse Events

Short-term corticosteroid use (less than 3 months) is associated with increased glucose levels, increased appetite, insomnia, anxiety, tremors, and increased fluid retention, leading to increases in blood pressure and electrolyte imbalances. Although discontinuation of therapy as a result of these side effects is not recommended with short-term corticosteroid treatment, routine monitoring is necessary.

Long-term corticosteroid use is associated with decreased bone density, leading to osteoporosis; fat redistribution, leading to the characteristic “buffalo hump”; decreased prostaglandin synthesis, resulting in gastric and duodenal ulcers; hypertriglyceridemia; hypokalemia; cataracts; and hirsutism. Therefore, long-term treatment with corticosteroids is not recommended. However, if patients are taking recurrent steroid therapy for recurrent exacerbations, monitoring for these side effects is imperative.

Interactions

Many corticosteroids are substrates of the cytochrome P-450 isoenzyme 3A4, including prednisone, prednisolone, methylprednisolone, and budesonide. Therefore, agents that inhibit or induce this enzyme system, such as ketoconazole, clarithromycin, phenytoin, and pioglitazone, may alter the efficacy of the corticosteroid. Budesonide requires an acidic environment (pH less than 5.5) to be released, so agents that inhibit acid production or neutralize acid in the GI tract (i.e., histamine-2 antagonists, proton pump inhibitors, antacids) may limit the effectiveness of budesonide. Corticosteroids may also decrease the effectiveness of antidiabetic and antihypertensive agents due to their ability to increase blood glucose levels and blood pressure.

Immunosuppressive Agents

Immunosuppressive agents are used in IBD as adjunctive treatment with aminosalicylates to induce and maintain remission if exacerbations occur while the patient is being tapered off corticosteroid therapy or if frequent exacerbations occur with maximum dosages of aminosalicylates. IV cyclosporine is an exception: it is solely used to treat severe, acute exacerbations of UC when the patient is refractory to corticosteroids.

Azathioprine and 6-Mercaptopurine

Azathioprine (Imuran) and 6-mercaptopurine (Purinethol) are antimetabolites that act as purine antagonists to inhibit the synthesis of protein, ribonucleic acid (RNA), and deoxyribonucleic acid (DNA). By doing so, azathioprine and 6-mercaptopurine decrease the production of various inflammatory mediators. Because 6-mercaptopurine is the active metabolite of azathioprine, these agents are similar in efficacy, side effect profile, and dosing frequency (see Table 31.4). Although these agents have a short plasma half-life of approximately 1 to 2 hours, both have active metabolites with long half-lives of 3 to 13 days, resulting in optimal therapeutic effects within 10 to 15 weeks of initiation of therapy. 6-Mercaptopurine is metabolized by the enzyme thiopurine methyltransferase (TPMT). The activity of this particular enzyme varies in patients based on a genetic polymorphism. Therefore, patients may be at a higher risk for certain side effects if they have low enzyme activity. TPMT testing is available to identify patients who may have low enzyme activity and, in turn, may experience more side effects.

These agents should be initiated during an acute exacerbation once the patient can tolerate oral medications to induce and maintain remission. Because of their slow onset of action, however, these agents are not effective for treating an acute exacerbation. The initial dosage of these agents is 50 mg/d in one dose; the dosage is increased every 2 weeks to a target dosage of 1 to 2 mg/kg/d for 6-mercaptopurine and 2 to 2.5 mg/kg/d for azathioprine. Because these agents are cleared by the renal system, dosages must be decreased in patients with creatinine clearance values under 50 mL/min. The dose for azathioprine and 6-mercaptopurine is usually decreased by 50% if the patient's creatinine clearance value falls below 50 mL/min to decrease the risk of accumulation and unwanted effects. Although these agents have the potential to cause significant adverse events, they are in general well tolerated. These agents should not be used in pregnancy or in patients with active liver disease.

Methotrexate

Methotrexate (Rheumatrex) has a therapeutic effect similar to that of azathioprine and 6-mercaptopurine; however, it inhibits intracellular dihydrofolate reductase, which results in inhibition of purine synthesis and suppression of IL-1 production. Both the intramuscular and oral preparations of methotrexate are efficacious in the induction and maintenance of

CD remission, but similar efficacy has not been shown for UC. Doses of 25 mg/week injected intramuscularly or 5 mg orally three times a week have been effective in inducing remission in patients with steroid-dependent CD after 12 to 16 weeks of therapy. At low doses, methotrexate is nearly completely absorbed when administered orally; therefore, there is no foreseen benefit in using the intramuscular preparation over the oral formulation during normal GI function.

Methotrexate dosages must be adjusted based on renal function. Patients with creatinine clearance values less than 50 mL/min should receive 50% of the normal dose. Methotrexate should not be prescribed to patients with active liver disease or pregnant women.

Cyclosporine

Cyclosporine (Sandimmune, Neoral) is reserved for the acute treatment of severe, steroid-refractory exacerbations of UC in hospitalized patients. Cyclosporine is a lipophilic, fungus-derived polypeptide that suppresses cell-mediated immunity by predominantly inhibiting IL-2 synthesis and release. Therapeutic effect is correlated with appropriate dosing. IV infusion of cyclosporine has been found effective at dosages of 4 to 8 mg/kg/d for UC. The use of cyclosporine in acute CD exacerbations is reported to have variable results. Because of poor systemic absorption, oral cyclosporine should not be used. Improvement of symptoms with IV therapy usually occurs within 2 to 3 days, and the duration of therapy is usually 7 to 10 days.

Adverse Events

Although azathioprine and 6-mercaptopurine are usually well tolerated, significant side effects may occur. These agents are associated with both allergic- and nonallergic-type side effects. Allergic-type side effects include pancreatitis, fever, rash, arthralgias, malaise, nausea, and diarrhea, which may occur regardless of dose. The main nonallergic-type side effects include bone marrow suppression and hepatotoxicity, which appear to be dose dependent. Pancreatitis may occur at any point in therapy and warrants discontinuation of therapy. The development of pancreatitis precludes the use of either 6-mercaptopurine or azathioprine in the future. Leukopenia and hepatotoxicity usually occurs during the initiation phase of therapy and may be managed by decreasing the dose. If a patient experiences side effects with either of these agents, it is not beneficial to switch the patient to the other agent.

Side effects of methotrexate include hepatic cirrhosis and fibrosis, bone marrow suppression, pneumonitis, folic acid deficiency, and rash. Nausea and diarrhea are also reported, but they occur more frequently with the oral formulation. Bone marrow suppression and liver dysfunction are dose dependent, and doses should be decreased in patients with these disorders. Folic acid should be administered concomitantly to limit folic acid deficiency.

Cyclosporine is most associated with nephrotoxicity, hypomagnesemia, and hypertension. Risk factors for nephrotoxicity are high-dose treatment, long-term treatment, and advanced age. Discontinuation of cyclosporine may restore renal function within 2 weeks. Other side effects of cyclosporine include nausea, vomiting, opportunistic infections, paresthesias, tremor, and seizures. Opportunistic infections occur because of the drug's immunosuppressive effects and may be managed by appropriate antibiotic therapy.

Interactions

Cyclosporine significantly interacts with various agents because of its metabolism through the cytochrome P-450 3A4 isoenzyme system. Enzyme inhibitors, such as erythromycin (Eryc) and ketoconazole (Nizoral), increase blood levels of cyclosporine by inhibiting its metabolism, whereas enzyme inducers, such as phenytoin (Dilantin), carbamazepine (Tegretol), and rifampin (Rifadin), decrease cyclosporine blood levels. Grapefruit juice increases blood levels of cyclosporine, which may increase the incidence of side effects.

Antibiotics

The association between IBD and infectious causes has led to the use of antibiotics. Because the exact organism has not been isolated, it is difficult to determine which antibiotics are most appropriate for treatment. In general, an antibiotic that acts against gram-negative and *Mycobacterium* organisms with a low side effect profile and poor systemic absorption is desirable. Many agents have been studied, including broad-spectrum antibiotics, metronidazole (Flagyl), fluoroquinolones, antituberculars, and macrolides. However, based on the scarce published, controlled trials, mild to moderately active CD appears to respond only to metronidazole and ciprofloxacin (Cipro) (see Table 31.4). Beneficial effects of antibiotic therapy have not been replicated in patients with UC.

Metronidazole showed efficacy in treating perianal CD. Since then, however, a few studies have found beneficial effects of metronidazole in the treatment of mild to moderately active luminal and fistulizing CD when used in combination with aminosalicylates or alone. The mechanism by which metronidazole alone exerts its beneficial effects in CD is unknown, although it is thought that the immune-modulating effects are more prominent than the antibacterial effects.

The normal dosage for treatment of mild to moderately active CD is 20 mg/kg/d. Once remission is attained, the dosage is titrated to 10 mg/kg/d for maintenance. The usual duration of therapy is up to 12 months, although remission is usually attained within 1 to 2 months. Although exacerbations of CD have been reported with the discontinuation of metronidazole, long-term use is associated with significant side effects.

Ciprofloxacin has also been studied for perianal and luminal CD with mixed results. Ciprofloxacin covers gram-negative organisms and *Mycobacterium* species as well as some gram-positive organisms and is usually well tolerated. Along with inhibiting DNA gyrase, which is its main antibacterial mechanism of action, ciprofloxacin also is reported to have immunosuppressive properties. A dosage of oral ciprofloxacin of 500 mg, twice daily, is as efficacious as 4 g of mesalamine daily in preliminary trials. Remission is attained after approximately 6 weeks of therapy. Ciprofloxacin is contraindicated in children and pregnant women.

Adverse Events

Short-term metronidazole therapy is associated with fairly benign side effects, including dry mouth, metallic taste, nausea, and vomiting. Abdominal distress, including cramping and diarrhea, may also occur, but these effects are difficult to distinguish from IBD symptoms. Long-term use of metronidazole is associated with neurotoxic effects such as peripheral paresthesias, dizziness, pruritus, and vertigo that may warrant discontinuation of therapy.

Ciprofloxacin is usually well tolerated. The most common side effects include nausea, diarrhea, dizziness, and rashes secondary to photosensitivity. However, long-term treatment may result in tendinitis and tendon rupture.

Interactions

Metronidazole is associated with severe nausea and vomiting (disulfiram effect) if taken concurrently with alcohol. Ciprofloxacin inhibits theophylline (Slo-Phyllin) metabolism, so theophylline serum levels may need to be monitored with chronic ciprofloxacin use. Any divalent or trivalent cation, such as calcium or iron, may interfere with the absorption of ciprofloxacin; therefore, at least a 4-hour dosing interval should be maintained between these agents.

Biological Agents

Many biological agents are being investigated for the treatment of IBD, including TNF-α inhibitors, growth factors, lymphocyte inhibitors, and transcription inhibitors. Currently, there are two approved classes for the treatment of severe refractory luminal CD: TNF-α inhibitors [infliximab (Remicade), adalimumab (Humira), and certolizumab pegol (Cimzia)] and selective adhesion molecule inhibitors [natalizumab (Tysabri), vedolizumab (Entyvio)].

TNF-α inhibitors

Infliximab (Remicade) is indicated for maintaining remission in CD as well as treating UC and fistulizing CD. The GI mucosal tissues of patients with active CD are found to overexpress numerous immunologic cytokines, including TNF. Biological TNF-α is a proinflammatory cytokine that stimulates the expression of various immunologic cytokines, such as IL-8 and interferon-γ. The TNF-α inhibitor agents produce their effect by neutralizing soluble forms of TNF-α and competitively inhibit its binding to the TNF receptor. In addition, TNF-α inhibitors may also induce apoptosis of activated monocytes.

Infliximab is a synthetically derived immunoglobulin (Ig) G monoclonal antibody consisting of 25% murine antibodies and 75% human antibodies (see Table 31.4). Infliximab is available only as an IV solution, and it is administered at a dosage of 5 mg/kg over a minimum of 2 hours. A single infusion dose at baseline, week 2, and week 6 is administered for the treatment of an acute exacerbation; infusions every 8 weeks are used to maintain remission. The infusions may be delivered in an inpatient or a monitored outpatient setting. Repeated doses of the product may increase the risk of immunogenicity and infusion-related reactions due to the murine component of the product. Infliximab crosses the placenta and is detected in serum of infants for up to 6 months after in utero exposure and should be held after 30 weeks of gestation in pregnant women. Caution should be used when prescribing to patients with heart failure.

Adalimumab (Humira) is also a TNF-α inhibitor; however, it is a fully humanized IgG monoclonal antibody that binds specifically to human TNF. It is approved for maintaining remission of CD in adults and children and for treating and maintaining remission of UC in adults. In general, fully humanized monoclonal antibodies are associated with less immunogenicity and infusion-related reactions. Adalimumab is administered as a subcutaneous injection every 2 weeks and may be increased to once weekly if necessary (see Table 31.4). In addition to patients with CD who are naïve to TNF-α inhibitors, adalimumab is effective in patients with CD who may not have responded to infliximab.

Certolizumab pegol (Cimzia) is also a TNF-α inhibitor; however, it is not a full monoclonal antibody. Certolizumab pegol consists of only the fragment antigen-binding (FAB) fragment of human-derived IgG, which is attached to polyethylene glycol. Since certolizumab pegol does not contain certain regions of a full antibody, it cannot cause

antibody-dependent cell cytotoxicity or induce apoptosis as with infliximab or adalimumab. The polyethylene glycol portion of the product allows for a longer duration of action and thus a longer duration between injections. Certolizumab pegol is administered in two subcutaneous injections initially and weeks 2 and 4. For those who elicit a clinical response, certolizumab pegol may be used every 4 weeks to maintain remission (see Table 31.4). Certolizumab pegol should not be used for the treatment of fistulizing CD, as it is no more effective than placebo. It has not been studied in the treatment of UC or in children.

Selective Adhesion Molecule Inhibitors

Selective adhesion molecule inhibitors should be reserved for patients who had an inadequate response or unable to tolerate conventional CD therapies and TNF-α inhibitors. Natalizumab is a humanized monoclonal antibody active against α_4 integrin subunit, which inhibits leukocyte adhesion and migration into inflamed tissue. Natalizumab (Tysabri) is indicated for the treatment of CD in adults and is administered intravenously as a 300-mg dose every 4 weeks and should be discontinued if there is no therapeutic benefit achieved within 12 weeks. When initiating natalizumab, patients should be tapered off of concomitant corticosteroid use according to clinical response. Antibody formation may occur with natalizumab and may result in infusion reactions, hypersensitivity reactions, and loss of efficacy. Natalizumab is not well studied in pregnant patients and should be enrolled into a pregnancy exposure registry if initiated.

Vedolizumab (Entyvio) is a humanized monoclonal antibody that targets $\alpha_4\beta_7$ integrin, preventing the migration of inflammatory lymphocytes into the gut mucosa. It is indicated for initiating and maintaining remission in adults for both CD and UC. Vedolizumab is administered intravenously as a dose of 300 mg at 0, 2, and 6 weeks, then every 8 weeks thereafter. In clinical trials, the glucocorticoid doses were left unaltered until week 6 and then tapered according to patient response. Therapy should be discontinued in patients who do not achieve a response within 14 weeks.

Other Agents

Ustekinumab (Stelara) is a human monoclonal antibody active against interleukin-12 and interleukin-23. It is approved for use in plaque psoriasis, but has been studied for inducing and maintaining remission in refractory CD in adults who were resistant to anti–TNF-α therapy. Patients had a significantly increased rate of inducing and maintaining clinical remission compared to placebo; however, the optimal dose remains unclear. Further studies are needed to determine the utility and role of ustekinumab for the treatment of CD.

Adverse Events

The primary side effects associated with TNF-α inhibitors are injection site–related reactions, which include erythema, itching, and swelling. Less common but significant side effects include the development of heart failure, tuberculosis (TB), hepatitis B reactivation,

opportunistic infections, lymphoma and other malignancies, hepatotoxicity, vasculitis, and pancytopenia. Patients should be tested for latent TB and treated accordingly prior to treatment with TNF-α inhibitors. TNF-α inhibitors are contraindicated in patients with active TB and should be used cautiously in patients with heart failure.

Infliximab is also associated with infusion-related reactions, including transient hypersensitivity reactions, flushing, headache, dyspnea, rash, and fever, possibly secondary to the murine component of the product. These side effects may be managed by pretreating patients with antihistamines, acetaminophen, and/or corticosteroids. In addition, mild to moderate infusion reactions may be managed by decreasing the infusion rate.

The primary side effects associated with selective adhesion molecule inhibitors are hypersensitivity and infusion reactions. Patients on natalizumab also have the potential to develop severe hepatotoxicity, and the drug carries a black box warning for increasing the risk of developing progressive multifocal leukoencephalopathy, particularly in patients with a history of John Cunningham (JC) virus.

Drug Interactions

Extensive drug interaction studies have not been performed to date, but due to their ability to alter the immunologic response, biologics should not be administered along with live vaccines. Commonly, TNF-α inhibitors are administered to patients who are also taking immunosuppressive agents. The administration of other immunosuppressant agents (e.g., azathioprine, methotrexate) with these agents has been shown to be beneficial by decreasing the risk of immunogenicity (development of autoantibodies) and decreasing infusion-related reactions (Lichtenstein, Diamond, et al., 2009; Lichtenstein, Hanauer, et al., 2009). No significant drug interactions have been reported when TNF-α inhibitors are given with conventional IBD therapy.

Selecting the Most Appropriate Agent

For many diseases and disorders, there are drug treatment protocols that make clear distinctions between first-line, second-line, and third-line therapies. However, in IBD, the decision to use one therapeutic modality over another is based on the location of the inflammation, the severity and extent of disease, the patient's tolerance of the therapy, patient compliance, and cost (Table 31.5). The American College of Gastroenterology has developed guidelines for managing CD and UC (Kornbluth & Sachar, 2010; Lichtenstein, Diamond, et al., 2009; Lichtenstein, Hanauer, et al., 2009).

TABLE 31.5 Recommended Treatment Options for Crohn Disease and Ulcerative Colitis

Severity of Disease	Distal UC	Extensive UC	Luminal CD	Perianal/Fistulizing CD
Mild	Oral/rectal aminosalicylate OR Rectal corticosteroid	Oral aminosalicylate	Oral aminosalicylate WITH/WITHOUT Antibiotic therapy	Surgical drainage AND antibiotic therapy WITH/WITHOUT IV infliximab or SC adalimumab
Moderate	Oral aminosalicylate AND Rectal aminosalicylate Oral/rectal steroid	Oral aminosalicylate AND Oral steroid	Oral aminosalicylate AND Oral steroid (preferably budesonide)	
Severe	IV corticosteroid AND/OR IV cyclosporine	IV corticosteroid AND/OR IV cyclosporine	IV corticosteroid AND/OR biologics	
Fulminant	IV corticosteroids AND/OR IV cyclosporine, IV infliximab or SC adalimumab*	IV corticosteroid AND/OR IV cyclosporine, IV infliximab or SC adalimumab*	IV corticosteroid AND/OR biologics	
Remission	Oral/rectal aminosalicylate WITH/WITHOUT Oral immunosuppressive, IV infliximab or SC adalimumab*	Oral aminosalicylate WITH/WITHOUT Oral immunosuppressive, IV infliximab or SC adalimumab*	Oral aminosalicylate WITH/WITHOUT Oral immunosuppressive/biologics	

*Consider selective adhesion-molecule inhibitors for inadequate response/failure with TNF-α inhibitors.

Crohn Disease

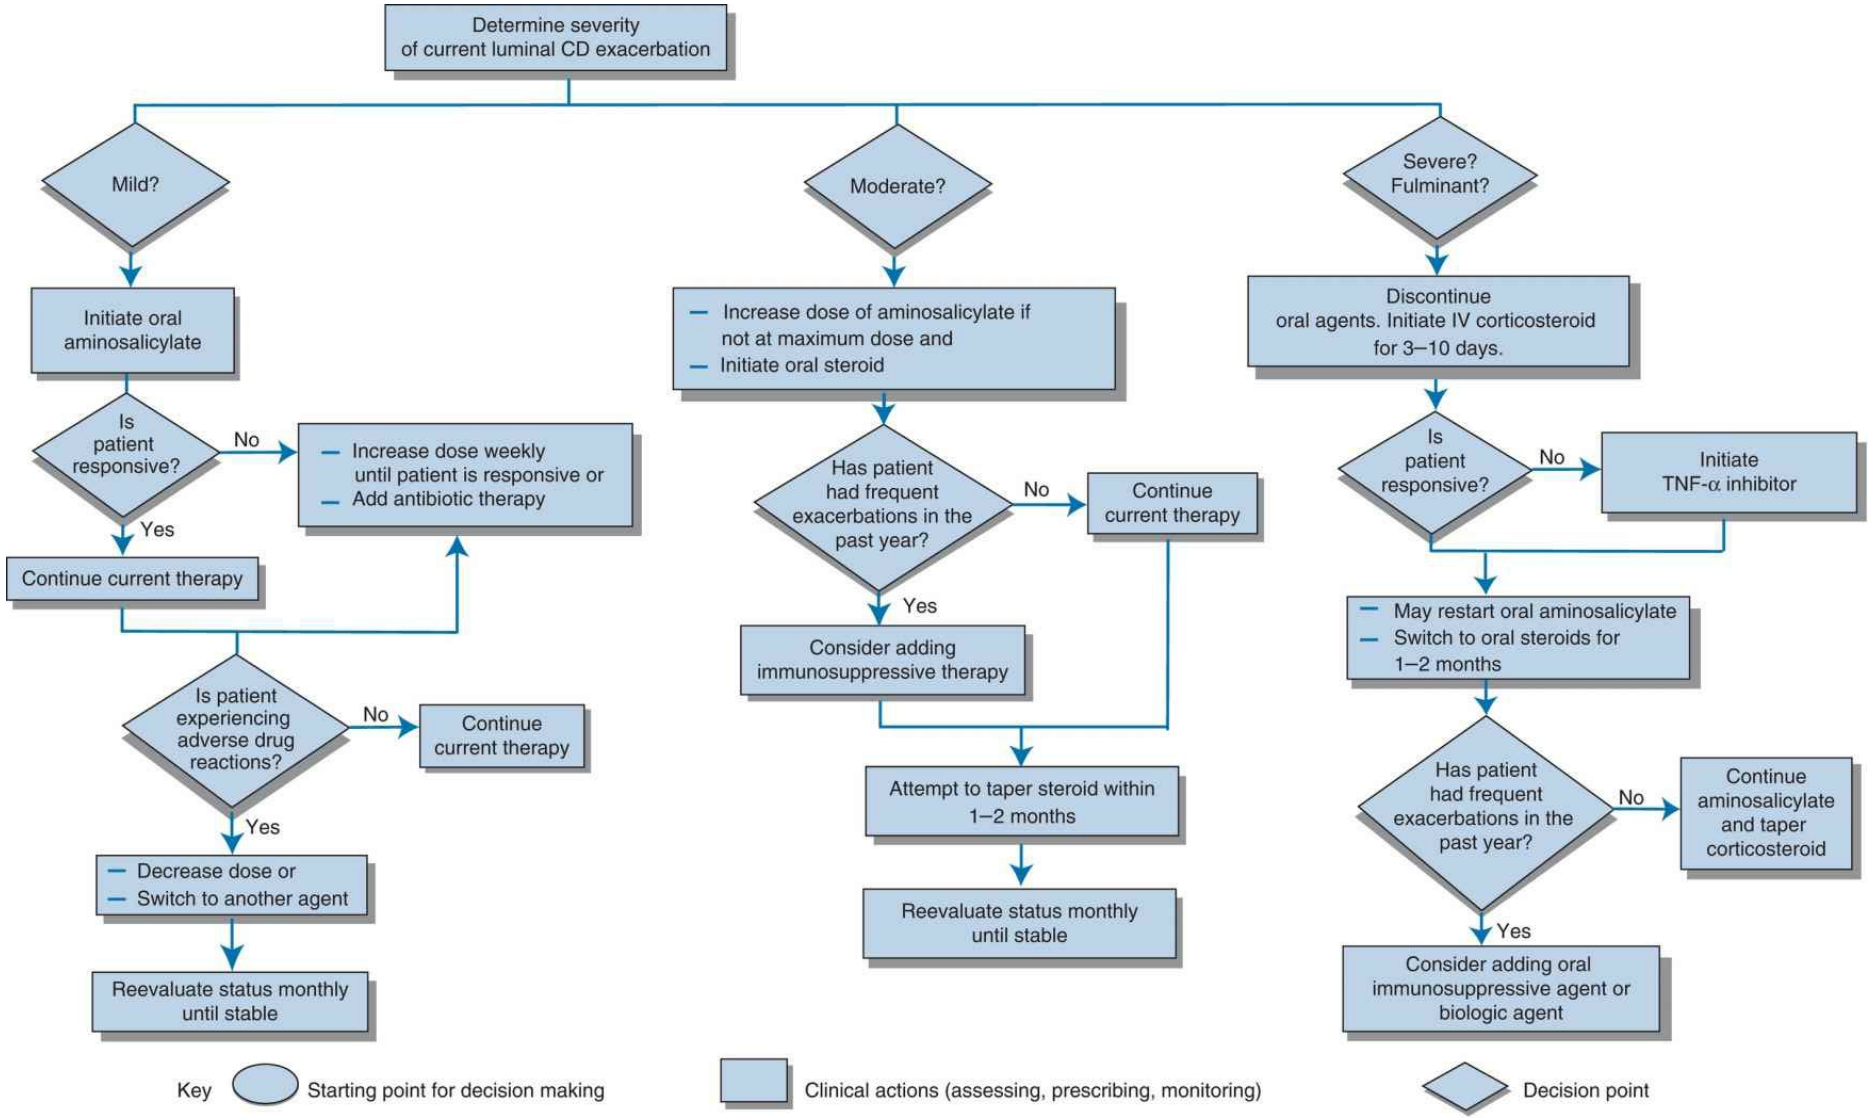
Mild to moderately active luminal CD is typically treated with oral aminosalicylates alone or in combination with antibiotic therapy. However, monotherapy with budesonide has also been used with good results, especially in patients with ileal or right colonic disease. Oral agents are chosen over rectal agents because of the random presence of CD along the entire GI tract. Patients may be maintained on aminosalicylates or antibiotic therapy for months to years, but the goal is to taper the patient off the medication as soon as possible once remission is attained. Budesonide is indicated for 3 months to maintain remission in CD.

Treatment of moderate to severe CD usually consists of combination therapy with aminosalicylates and corticosteroids. Corticosteroid therapy is used acutely on a short-term basis for patients with moderate to severe disease to attain remission. Because of their high

side effect profile, steroids are not used chronically to maintain remission. Oral agents may be used for patients with moderate to severe disease. The typical duration of therapy is 4 to 12 weeks at the full dose, and then doses are tapered by 5 to 10 mg weekly until discontinued. If patients have had multiple exacerbations and are steroid refractory or have fistulizing disease, TNF inhibitors may be indicated. The 2013 American Gastroenterology Association guideline recommends using TNF-α inhibitors in combination with thiopurines over thiopurine monotherapy to induce remission in patients who have moderately severe CD.

Severe to fulminant disease requires definitive drug therapy in addition to substantial supportive care measures due to poor oral absorption and rapid GI transit time. Oral therapy, including aminosalicylates, should not be administered until the patient can tolerate oral alimentation. IV corticosteroids are indicated to decrease inflammation and induce immunosuppression. For patients with moderate to severe or severe to fulminant disease whose disease is refractory to corticosteroids (either oral or IV), biological agents are an option. Supportive care measures, such as IV fluids, bowel rest, and parenteral nutrition, should also be considered.

Therapy to maintain remission should be considered in patients who have frequent exacerbations or who are "steroid dependent." Immunosuppressive agents, including azathioprine, 6-mercaptopurine, methotrexate, and biologics, may be used with aminosalicylates to maintain remission in patients whose disease is refractory to aminosalicylate monotherapy. The immunosuppressant agents may take effect after 10 to 12 weeks. Therapeutic effect should be seen within 8 weeks of administration of biologics. Patients may be maintained on these agents for months to years, but the goal is to taper the patient off the medication as soon as possible due to the significant side effects. Antibiotics, specifically metronidazole and ciprofloxacin, have proved beneficial in maintaining remission of perianal and fistulizing CD with long-term use (Figure 31.1).



Determine severity of current luminal CD exacerbation
Mild?
Initiate oral aminosalicylate
Is patient responsive?
No
Increase dose weekly until patient is responsive or
Add antibiotic therapy
Yes
Continue current therapy
Is patient experiencing adverse drug reactions?
No
Continue current therapy
Yes
Decrease dose or
Switch to another agent
Reevaluate status monthly until stable
Moderate?
Increase dose of aminosalicylate if not at maximum dose and
Initiate oral steroid
Has patient had frequent exacerbations in the past year?
No
Continue current therapy
Yes
Consider adding immunosuppressive therapy
Attempt to taper steroid within 1–2 months
Reevaluate status monthly until stable
Severe? Fulminant?
Discontinue oral agents. Initiate IV corticosteroid for 3–10 days.
Is patient responsive?
No
Initiate TNF-α inhibitor
May restart oral aminosalicylate
Switch to oral steroids for 1–2 months
Has patient had frequent exacerbations in the past year?
No
Continue aminosalicylate and taper corticosteroid
Yes
Consider adding oral immunosuppressive agent or biologic agent
Key
Starting point for decision making
Clinical actions (assessing, prescribing, monitoring)

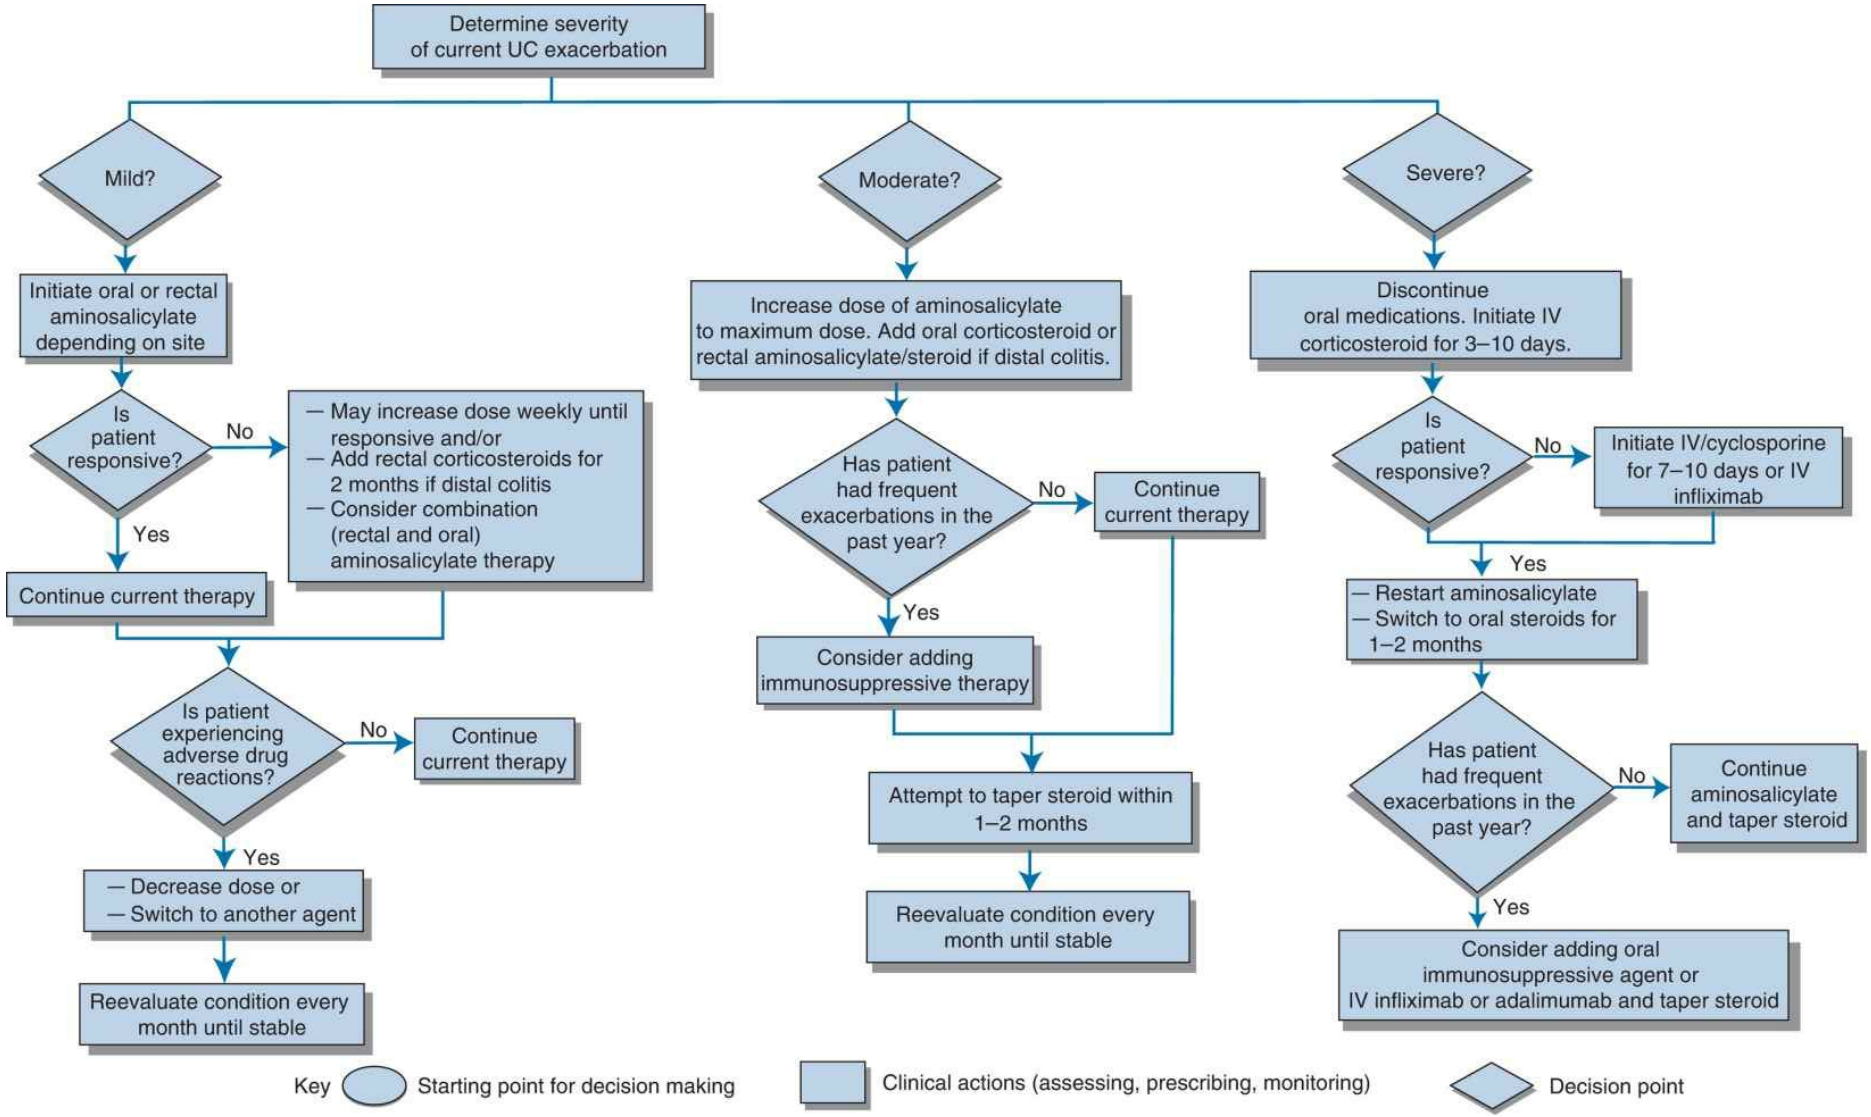
FIGURE 31.1 Treatment algorithm for active luminal Crohn disease.

Ulcerative Colitis

For UC, guidelines specify various treatment approaches depending on the severity and location of disease. Distal colitis, identified as lesions below the splenic flexure, may be treated with oral, rectal, or IV agents depending on the severity of disease. Rectal agents should not be used in patients with extensive colitis due to the location of disease. The decision to use systemic or local preparations for distal colitis largely depends on patient preference; however, topical products allow for less systemic absorption, less frequent dosing, and a quicker onset of effect (Figure 31.2). Treatment of mild UC is best achieved with the use of aminosalicylates. The combination of oral and rectal aminosalicylates is more effective than either therapy alone. Corticosteroids may be used concurrently with aminosalicylates for moderate UC exacerbations. Depending on the severity of the exacerbation and the location of the lesions, either rectal or oral preparations may be appropriate. Severe exacerbations may require hospitalization. Discontinuation of oral and topical therapy due to rapid GI transit time and the initiation of IV corticosteroid therapy are standard. If improvement in the condition is not seen in 7 to 10 days with IV corticosteroids, IV cyclosporine, IV infliximab, SC adalimumab, or IV vedolizumab may be considered. The use of IV cyclosporine is reserved for hospitalized patients who have not responded to IV steroids. Infliximab may be initiated in an outpatient or inpatient setting in patients with severe exacerbations after an adequate trial of steroids.



Determine severity of current UC exacerbation
Mild?
Initiate oral or rectal aminosalicylate depending on site
Is patient responsive?
No
— May increase dose weekly until responsive and/or
— Add rectal corticosteroids for 2 months if distal colitis
— Consider combination (rectal and oral) aminosalicylate therapy
Yes
Continue current therapy
Is patient experiencing adverse drug reactions?
No
Continue current therapy
Yes
— Decrease dose or
— Switch to another agent
Reevaluate condition every month until stable
Moderate?
Increase dose of aminosalicylate to maximum dose. Add oral corticosteroid or rectal aminosalicylate/steroid if distal colitis.
Has patient had frequent exacerbations in the past year?
No
Continue current therapy
Yes
Consider adding immunosuppressive therapy
Attempt to taper steroid within 1–2 months
Reevaluate condition every month until stable
Severe?
Discontinue oral medications. Initiate IV corticosteroid for 3–10 days.
Is patient responsive?
No
Initiate IV/cyclosporine for 7–10 days or IV infliximab
Yes
— Restart aminosalicylate
— Switch to oral steroids for 1–2 months
Has patient had frequent exacerbations in the past year?
No
Continue aminosalicylate and taper steroid
Yes
Consider adding oral immunosuppressive agent or IV infliximab or adalimumab and taper steroid
Key
Starting point for decision making
Clinical actions (assessing, prescribing, monitoring)

FIGURE 31.2 Treatment algorithm for active ulcerative colitis.

Surgery may be considered in patients whose disease fails to respond to drug therapy. The management of fulminant exacerbations is very similar to that of severe exacerbations, but the decision to perform a colectomy is considered at a much earlier stage for fulminant exacerbations. Along with definitive therapy, supportive measures including bowel rest, IV fluids, and adequate nutrition should be considered for those with severe and fulminant exacerbations. For those with frequent exacerbations or steroid dependence, immunosuppressive agents such as 6-mercaptopurine and azathioprine should be considered to induce and maintain remission. Typically, immunosuppressive agents are initiated after the patient can tolerate oral medications and are initiated along with aminosalicylate and corticosteroid therapy. The goal is to taper the corticosteroid and continue the aminosalicylate along with the immunosuppressive therapy for maintenance of remission.

Methotrexate has not been adequately studied in patients with UC and therefore is not recommended. Antibiotic therapy has not been shown to improve UC symptoms.

Drug Selection

Sulfasalazine was considered the first-line aminosalicylate because of its remarkable efficacy, low cost, and availability in oral liquid and tablet preparations; however, it must be taken four times a day and causes significant adverse drug reactions. For maximum therapeutic benefit, 4 to 8 g/d is necessary, so patients must take up to 16 tablets or 32 teaspoonfuls daily. In addition, immediate-release sulfasalazine has activity limited to the colon, making it less effective in conditions affecting the upper GI tract.

Mesalamine has emerged as the aminosalicylate of choice because of its availability in many formulations, dosing frequency, and its low side effect profile, but it is more expensive than sulfasalazine. Depending on the oral formulation and the severity of the disease, patients may need to take 6 to 16 pills daily to attain maximum therapeutic benefit. Normal dosages of oral mesalamine are 2 to 4.8 g/d. Olsalazine and balsalazide are not used as often because of their added cost without any significant clinical benefit.

The ideal corticosteroid for treating IBD would have high glucocorticoid activity, a low side effect profile, and targeted delivery to the diseased site and would be poorly absorbed from the GI tract, allowing for localized activity. Oral budesonide (Entocort) is approved specifically for the acute treatment of IBD due to its ideal characteristics, but due to its increased cost, other corticosteroids are used frequently to treat an acute exacerbation. The choice of steroid depends on the route of administration, onset of action, and glucocorticoid versus mineralocorticoid potency. In general, agents with more glucocorticoid activity are preferred over mineralocorticoid steroids because they have better anti-inflammatory action. Oral agents are used primarily in patients with localized or generalized disease with mild to moderate exacerbations, rectal formulations are reserved for patients with mild to moderate exacerbations of distal UC disease, and IV treatment may be initiated in patients with severe exacerbations of CD or UC.

The use of immunosuppressive agents varies based on the type of IBD and the severity of disease. Cyclosporine is reserved for the acute treatment of severe UC exacerbations because of the high cost of therapy and high incidence of severe side effects. Because of a lack of comparative trials of methotrexate and azathioprine or 6-mercaptopurine, it is difficult to determine which agent would be considered first line; however, there are more data to support the use of azathioprine or 6-mercaptopurine than methotrexate for CD and UC. Azathioprine and 6-mercaptopurine are equally efficacious, with similar pharmacokinetic, adverse drug reaction, and cost profiles, so no great distinction can be made between the two.

The main distinction between methotrexate and the other two agents is its availability as an intramuscular injection and its dosing schedule. The infrequent dosing schedule of oral and intramuscular methotrexate may promote either compliance or noncompliance with the medication, depending on the patient. Combining these agents for the induction and maintenance of remission is not recommended because of overlapping side effect

profiles and lack of improved efficacy data.

If antibiotic therapy is warranted, metronidazole or ciprofloxacin is an acceptable agent, depending on patient-specific factors.

There are a few differences among the biologics that may make one agent more favorable in certain patients than others. Infliximab and adalimumab are the only products approved for the treatment of patients with severe, refractory UC or fistulizing CD. Therefore, it remains the best option in these patients at this time. For patients with luminal CD who are able to self-inject themselves, either adalimumab or certolizumab pegol may be an option. Adalimumab and certolizumab pegol are available as a prefilled syringe for convenience; however, adalimumab is administered subcutaneously as one injection every 2 weeks, whereas certolizumab pegol is administered subcutaneously as two injections every 4 weeks. Infliximab may also be used for luminal CD; however, since it is an IV infusion, it must be administered by a health care practitioner in a monitored setting. Also, since adalimumab and certolizumab pegol are fully humanized monoclonal antibodies, the risk of infusion reactions, hypersensitivity, and development of autoantibodies are less likely than with infliximab. Adalimumab has also been found effective in patients who have previously not responded to infliximab (Armuzzi et al., 2013; Sandborn et al., 2007). Natalizumab, vedolizumab, and ustekinumab should be considered for patients that failed TNF-α therapy and are only available as IV infusions.

Special Population Considerations

Pediatrics

IBD is typically diagnosed early in life, usually during the second or third decade, leading to significant implications of IBD in the pediatric population. Treatment must be aggressive to limit the potential for nutritional deficiencies leading to stunted growth, malnutrition, and anemia. However, many of the medications lead to untoward effects or are not well studied in pediatrics. The use of long-term corticosteroids may lead to growth abnormalities, whereas ciprofloxacin use is contraindicated in children because it can cause arthropathy, resulting in poor bone formation. Infliximab is indicated for inducing or maintaining remission of CD and UC in children older than age 6. Certolizumab pegol has not been studied in children. Adalimumab is indicated for inducing and maintaining remission of CD in children over the age of 6. Adalimumab has been studied in children for UC, but is not indicated in children at this time. Supplemental therapy including proper nutrition, iron therapy, and adequate hydration should also be considered to maintain growth and general health. Treating IBD in children involves aggressively managing the condition as well as the side effects with the limited options.

Pregnancy

The fertility rate in women with IBD is similar to the general population, but spontaneous abortions, stillbirths, and developmental defects are more common in pregnant women with active disease. Therefore, IBD should be treated aggressively in pregnant women to limit dehydration, anemia, and nutritional deficiencies that could adversely affect fetal outcomes. However, treatment options are limited for pregnant women due to the risk of teratogenicity or unwanted effects on the fetus. Methotrexate is absolutely contraindicated in pregnancy and lactation due to its potential for spontaneous abortions and teratogenicity. Data are controversial regarding the use of mercaptopurine and azathioprine during pregnancy. If either of these agents is necessary during pregnancy, an azathioprine dosage of 2 mg/kg/d or less is recommended to limit pancytopenia in the fetus. Azathioprine and mercaptopurine are contraindicated during nursing due to the potential of fetal immunosuppression. The use of cyclosporine should be reserved for severe refractory cases because it can cause growth retardation. The TNF-α inhibitors for IBD are all pregnancy category B. Studies have shown serum levels of TNF-α inhibitors are detectable in the serum of infants for up to 6 months post in utero exposure. It is recommended to hold therapy after 30 weeks of gestational age, and all pregnant patients exposed to TNF-α inhibitors should be enrolled into their respective registries (Gisbert, 2010; Zelinkova et al., 2011). Selective adhesion molecule inhibitors have not been studied in pregnancy. Ciprofloxacin and metronidazole should also be avoided in pregnancy and lactation because they can cause fetal malformations. Corticosteroids may be used at the lowest doses possible to induce remission for the shortest period of time to limit adrenal

suppression of the fetus. Women taking sulfasalazine should be given higher dosages of folate (2 mg/d) because sulfasalazine interferes with folate absorption. Preconception counseling is imperative to discuss the condition, lifestyle changes, nutritional issues, and treatment options with the patient. Special attention should be given to maintaining body weight before conception and preventing exacerbations during pregnancy.

Monitoring Patient Response

Various parameters must be monitored to detect efficacy and toxicity associated with therapy. Efficacy parameters include signs and symptoms of CD and UC, which are well defined in the Working Definition of Crohn's Disease Activity and Criteria for Severity of Ulcerative Colitis. Nutritional parameters such as weight, albumin, vitamin B_{12} levels, iron levels, and transferrin saturation should also be followed. Mental status and quality-of-life issues such as frequency of social interactions, attendance at work, and completion of activities of daily living all may indicate effectiveness of therapy. Although there are no definitive guidelines for the frequency of monitoring, it is important to monitor these endpoints when adjustments are made in drug therapy or when exacerbations occur.

Specific monitoring of drug toxicities is imperative for all pharmacologic agents. CBC and liver function tests should be performed periodically to detect asymptomatic undesired reactions in patients taking sulfasalazine. In addition, renal function (i.e., blood urea nitrogen, serum creatinine) should be monitored routinely with aminosalicylates to identify nephrotoxicity.

Corticosteroid treatment is associated with significant drug toxicities, but most occur with long-term use. In general, short-term corticosteroid treatment does not require intense monitoring. However, patients who have uncontrolled hypertension or who are glucose intolerant must have their blood pressure or fasting blood glucose level monitored periodically while taking corticosteroids. For patients taking corticosteroids on a long-term basis, baseline tests including a lipid panel, electrolytes, and fasting blood glucose studies should be performed every 6 to 12 months. A baseline bone density scan may be judicious and may be repeated yearly.

Azathioprine and 6-mercaptopurine are both associated with significant side effects, so it is important to acquire a baseline CBC with differential and serum creatinine, amylase, and liver function tests. The CBC should be monitored more frequently during the initiation of therapy (every 1 to 2 weeks for the first 3 months) and then less frequently (every 3 to 6 months) for the duration of therapy. Liver function tests should be monitored every 3 months for the first year or until a stable dosage has been achieved, then every 4 to 6 months for the duration of treatment. Creatinine clearance is an important parameter in guiding the dosing regimen of azathioprine or 6-mercaptopurine, so serum creatinine and creatinine clearance should be monitored annually if renal function is stable and more often if fluctuations in dosages or renal function occur. Amylase is not routinely ordered, but it may be checked upon patient complaints due to the risk of pancreatitis.

During the initial phase of methotrexate therapy, CBC and liver function tests should be performed every 2 to 4 weeks. If methotrexate therapy is continued beyond 16 weeks, CBC and liver function tests should be monitored every 4 to 8 weeks for the duration of therapy. Dosage adjustments must be made based on creatinine clearance, so serum

creatinine must be monitored at baseline and at every dosage change. If renal function is stable, serum creatinine should be monitored annually at a minimum. Liver biopsies may be obtained once yearly if the patient is taking methotrexate, although formal recommendations have not been made.

IV cyclosporine therapy requires daily monitoring of cyclosporine blood levels (200 to 400 ng/mL), blood urea nitrogen, serum creatinine, and blood pressure. Although cyclosporine is extensively metabolized by the liver, it is eliminated by the kidneys and is highly associated with permanent renal dysfunction; therefore, renal function must be monitored closely. Dosages should be adjusted daily based on renal function and cyclosporine blood levels. Opportunistic infections may occur with high-dose cyclosporine use, so CBC, signs of infection, and temperature should also be monitored daily.

Biologics are associated with many side effects; however, most do not occur commonly. Due to the rare incidence of serious side effects, routine laboratory monitoring is not indicated; however, a heightened awareness of the clinical symptoms of adverse events is warranted. Patients and health care professionals should routinely monitor for symptoms of heart failure, vasculitis, TB, infection, hepatotoxicity, and lupus-like syndrome. Autoantibodies to the TNF-α inhibitors are known to develop and can be monitored via serum levels. Patients who develop autoantibodies may be more likely to develop lupus-like syndrome or have reduced efficacy with the agents (West et al., 2008). Routine administration of biologics and concomitant administration of immunosuppressants limit the development of autoantibodies.

Metronidazole and ciprofloxacin do not require significant drug monitoring, but long-term antibiotic treatment may lead to superinfection, so signs and symptoms of infection should be noted and treated. Patients receiving metronidazole therapy should also be monitored for peripheral paresthesias.

Patient Education

Drug Information

Patients and caregivers need to understand that uncontrolled IBD may affect quality of life, psychological well-being, and general physical health, so adherence to medication therapy is imperative. In addition, due to the increased GI transit time during an exacerbation, patients may not fully absorb oral medications for any of their conditions, which may lead to poor control of their other conditions during an IBD exacerbation.

Patients should swallow the enteric-coated sulfasalazine or mesalamine tablets and capsules whole so that the dosage form can penetrate the affected area. Sulfasalazine can discolor body fluids (e.g., urine and tears), which may stain clothing and contact lenses. When taking metronidazole, patients must abstain from alcohol to avoid severe nausea and vomiting.

Often, patients request chronic corticosteroid therapy because of its beneficial results, but these patients need to be informed of the long-term complications of corticosteroids and should be advised regarding other medications that may be more appropriate for chronic therapy. Patients also need to be aware that immunosuppressants (azathioprine, 6-mercaptopurine, methotrexate) take 10 to 15 weeks to take effect; therefore, adherence to the medication regimen is imperative even though resolution of symptoms will not be apparent until weeks later.

Although the biologics are quite efficacious for IBD, patients must be made aware of the significant risks associated with them. In addition, if patients are prescribed either adalimumab or certolizumab pegol, they must be instructed on the proper self-administration of a subcutaneous injection as well as sterile technique and safe needle disposal.

Patient-Oriented Information Sources

Along with their health care professionals, there are many other resources available for patients who are seeking information on IBD. A local support group may be a good resource for patients having trouble dealing with the illness. Many local hospitals as well as the Crohn's and Colitis Foundation of America organize support groups for patients with IBD. For general medical information regarding IBD, the following Web sites offer helpful patient-specific information:

- AGA: www.gastro.org
- American College of Gastroenterology: www.acg.gi.org
- Crohn's and Colitis Foundation of America: www.ccfa.org
- MedlinePlus: www.nlm.nih.gov/medlineplus/
- National Institute of Diabetes, Digestive, and Kidney Diseases: www.niddk.nih.gov

Preventive Care

Nutritional Status

Nutritional status is a significant issue for patients with active IBD and those with surgical resections. Patients with IBD are at risk for stunted growth, malnutrition, dehydration, weight loss, iron deficiency anemia, macrocytic anemia, osteopenia, and other conditions. Nutrient deficiencies of iron, vitamin B_{12}, zinc, folate, calcium, and vitamin D may result from decreased oral intake, malabsorption, excessive losses, hypermetabolism due to infection, or drug-induced side effects. Concurrent administration of folate with methotrexate and sulfasalazine and administration of calcium and vitamin D with corticosteroids are recommended to limit the potential for nutritional deficiencies. Also, due to folate deficiencies, patients with IBD are at risk of hyperhomocysteinemia, resulting in an elevated potential for thrombosis. Vitamin B_6 and vitamin B_{12} supplementation is recommended to decrease homocysteine levels. Folate supplementation is especially important in women of child-bearing age.

Many special dietary agents have been studied in patients with IBD with varying results. Diets high in short-chain fatty acids are associated with a small decrease in disease severity, potentially due to an anti-inflammatory effect. Fish oils have been associated with a decreased frequency of exacerbations potentially due to their anti-inflammatory properties. An area of new research interest is the role of probiotics such as *Lactobacillus* and *Saccharomyces* in the treatment of IBD. By altering the GI flora, it is theorized that probiotic agents assist with controlling IBD exacerbations.

Enteral and parenteral routes of nutrition have been routinely used to improve the nutritional status of IBD patients. In general, enteral nutrition is preferred due to the complications of infection, thrombosis, and pancreatitis associated with parenteral nutrition. Along with correcting nutritional deficiencies, enteral nutrition has also been studied as a primary treatment measure in combination with aminosalicylates. Parenteral nutrition, however, is advocated in severe exacerbations when bowel rest is in order for proper healing of the IBD. In general, nutritional supplementation plays a large role in the management of IBD. Depending on the severity of weight loss and general health status of the patient, a combination of vitamin and mineral supplementation along with either enteral or parenteral nutrition should be advocated.

Vaccination

Vaccination status in patients with IBD is critical. Since IBD is an autoimmune disease and treatment is focused on immunosuppressant therapy, patients are at higher risk for developing infections. Vaccination records should be reviewed routinely and updated as necessary. Patients on biologic therapy are at risk for hepatitis B reactivation; therefore, screening patients prior to therapy may be prudent. Patients taking an immunosuppressant

cannot receive live vaccines; however, they are eligible for inactivated vaccines such as influenza, pneumococcal, meningococcal, tetanus, and hepatitis B (Kornbluth & Sachar, 2010). Prior to the initiation of any biologics, consider bringing all immunizations up to date.

Cancer Screening

Patients with IBD are at a higher risk for colorectal cancer (Eaden et al., 2001). The extent of the risk depends on the extent, course, and duration of the disease in a particular individual (Jesse et al., 2012). Due to the increased risk, patients with IBD for a minimum of 8 years should be screened for colorectal cancer with a colonoscopy and biopsy. Although the data are conflicting as to how often patients should be screened, the American College of Gastroenterology recommends either annually or biannually (Kornbluth & Sachar, 2010).

Complementary and Alternative Therapies

Alternative therapies are used by many patients with IBD: according to one study, 47% of patients with IBD had used alternative therapies for their condition. The most common alternative therapies used were Acidophilus and flaxseed, along with massage therapy, even though data are limited regarding the efficacy of these agents in IBD. Omega-3 fatty acids have also been studied for use in IBD. The National Institutes of Health reported variable results with the use of omega-3 fatty acids for IBD, so widespread use cannot be endorsed at this time (Cabre et al., 2012).

Surgical options are considered in patients who are at risk for a further decline in physical health and quality of life resulting from frequent exacerbations that are unresponsive to conventional therapy. Surgical options include proctocolectomy for UC and a variety of ostomy procedures for patients with CD, depending on the location of disease (Table 31.6). Proctocolectomy, the removal of the entire colon and rectum, is a curative intervention for UC. However, surgical procedures for CD are not curative because exacerbations may recur in existing areas of the GI tract, and surgery is used only to maintain remission.

TABLE 31.6 Surgical Interventions

Procedure	Area of Resection
Sigmoid colostomy	Distal end of large intestine
Descending colostomy	Descending colon and rectum
Transverse colostomy	Small portion of transverse colon
Proctocolectomy/ileostomy	Entire rectum and large intestine

For patients who have undergone surgery, the practitioner must pay close attention to general drug therapy issues. Because of the resection of the GI tract, these patients have issues similar to those of patients with short bowel syndrome. Rectally administered agents such as suppositories and enemas are ineffective in patients with any type of lower GI resection. Depending on the site of resection, sustained-release agents and medications targeted to specific areas of the GI tract also are ineffective in general.

Case Study*

B.F., age 28, presents with diarrhea and abdominal pain. He says he feels weak and feverish. His symptoms have persisted for 5 days. He tells you he has 8 to 10 bowel

movements each day, although the volume of stool is only about "half a cupful." Each stool is watery and contains bright red blood. Before this episode, he had noticed a gradual increase in the frequency of his bowel movements, which he attributed to a new vitamin regimen. He has not traveled anywhere in the past 4 months and has taken no antibiotics recently. His medical history is significant for UC; his most recent exacerbation was 2 years ago. He is taking no medications except vitamins.

Examination findings include a tender, slightly distended abdomen. His BP is 122/84 sitting, 110/78 standing; HR 96 bpm; and temperature 100°F. Otherwise, physical findings are unremarkable. Laboratory study results reveal hemoglobin, 12 g/dL; hematocrit, 38%; white blood cell count, 12,000/mm^3; platelet count, 242 k; sodium, 132; and potassium, 3.6. All other study results are within normal limits. The most recent colonoscopy findings (4 years ago) revealed granular, edematous, friable mucosa with continuous ulcerations extending throughout the descending colon.

Diagnosis: Exacerbation of Ulcerative Colitis

1. List specific goals of treatment for B.F.
2. What drug therapy would you prescribe? Why?
3. What are the parameters for monitoring success of the therapy?
4. Discuss specific patient education based on the prescribed therapy.
5. List one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What would be the choice for the second-line therapy?
7. What over-the-counter and/or alternative therapies might be appropriate for B.F.?
8. What lifestyle changes would you recommend to B.F.?
9. Describe one or two drug–drug or drug–food interactions for the selected agent.

* Answers can be found online.

UNIT 7
Pharmacotherapy for Genitourinary Tract Disorders

32 Urinary Tract Infection

Virginia P. Arcangelo

Urinary tract infection (UTI) is a broad term used to describe inflammation of the urethra, bladder, and kidney. Bacteria, yeast, or chemical irritants can cause inflammation in the urinary tract. UTIs are a common problem encountered in health care. It is estimated that each year, there are at least 150 million cases of symptomatic UTIs worldwide (Foxman, 2014). UTIs occur across the life span. As many as 10% of women experience at least one episode of acute uncomplicated urinary infection in a year, and 60% have at least one episode during their lifetime. The peak incidence of infection occurs in young, sexually active women ages 18 to 24. Recurrent episodes are experienced by as many as 5% of women at some time during their life.

The clinical spectrum of UTIs ranges from asymptomatic bacteriuria, to symptomatic and recurrent UTIs, to sepsis associated with UTI requiring hospitalization. Recent evidence helps differentiate asymptomatic bacteriuria from symptomatic UTI. Asymptomatic bacteriuria is transient in older women, often resolves without any treatment, and is not associated with morbidity or mortality. The diagnosis of symptomatic UTI is made when a patient has both clinical features and laboratory evidence of a urinary infection. Absent other causes, patients presenting with any two of the following meet the clinical diagnostic criteria for symptomatic UTI: fever, worsened urinary urgency or frequency, acute dysuria, suprapubic tenderness, or costovertebral angle pain or tenderness. A positive urine culture (≥105 CFU/mL) with no more than two uropathogens and pyuria confirms the diagnosis of UTI. Risk factors for recurrent symptomatic UTI include diabetes, functional disability, recent sexual intercourse, prior history of urogynecologic surgery, urinary retention, and urinary incontinence. Testing for UTI is easily performed in the clinic using dipstick tests.

Causes

Women contract UTIs in a 30:1 ratio to men because of their short urethra and its proximity to the rectum. Sexual intercourse is a contributing factor. With intercourse, periurethral and urethral bacteria may ascend into the bladder. After age 65, the ratio of UTIs in women to men becomes closer to 1. Risk factors for UTIs in men include homosexuality, intercourse with an infected partner, and an uncircumcised penis.

Normal urine is sterile. Infection occurs when microorganisms, usually bacteria from the digestive tract, cling to the opening of the urethra and multiply. *Escherichia coli* is the causative pathogen in 85% to 90% of community-acquired UTIs. *Staphylococcus saprophyticus* accounts for approximately 5% to 15% of UTIs in young women. The microbial spectrum of complicated UTIs is broader and also includes *Pseudomonas*, *Enterococcus*, *Staphylococcus*, *Serratia*, *Providencia*, and fungi.

Bacterial growth is decreased by dilute urine and a low urine pH. Glucose in urine is an enhanced medium for the growth of *E. coli*. The urine from pregnant women has a more suitable pH for growth of *E. coli*. Diaphragm and spermicide use (nonoxynol 9), estrogen deficiency, and constipation also are risk factors for UTIs. Inefficient bladder emptying causes UTIs because of stagnating urine. Underlying conditions that predispose to UTI are listed in Box 32.1.

BOX 32.1 Underlying Conditions That Predispose Individuals to Urinary Tract Infections

- Female sex
- Pregnancy
- Diabetes
- Chronic degenerative neurologic conditions
- Paralysis
- Recurrent UTI
- Ineffective bladder emptying
- Estrogen deficiency
- Constipation
- Delayed postcoital micturition
- History of recurrent childhood UTI
- Sickle cell disease
- Polycystic kidney disease
- Structural defects of the urinary system
- Renal transplant

In the normal male urethra, the distance between the end of the urethra and the bladder is too long to allow ascending transport of bacteria to the bladder. Therefore, bacteriuria in men should always be considered an abnormal finding, and men cannot have uncomplicated infections.

Pathophysiology

The development of a UTI depends on the virulence of the organism, the inoculum size, and the adequacy of the host's defense mechanisms. In general, the urinary tract is resistant to invading bacteria and rapidly eliminates organisms that reach the bladder. When bacteria enter the bladder, there is increased micturition and diuresis to empty the bladder.

Most pathogens enter the urinary tract and ascend the urethra to the bladder. Most of the microorganisms are from fecal flora, but the vagina is an important source of infecting organisms. Bacteria that cause UTIs originate in the fecal flora, colonize the vagina and periurethral introitus, and ascend to the urethra and bladder. In the bladder, the bacteria multiply and travel up the urethra to the renal pelvis and parenchyma, especially if there is vesicoureteral reflux. With cystitis, there is silent involvement of the kidneys in approximately 50% of cases.

The longer urethra in men increases the distance between the rectum and the urethral meatus, and the drier environment around the urethra and the antibacterial activity of prostatic fluid also decrease the risk of UTIs in men.

Diagnostic Criteria

In women of childbearing age, the most frequent presentation of cystitis is the classic triad of urinary urgency, frequency, and dysuria, with symptoms of abrupt onset. There may also be pressure or fullness in the suprapubic area and back pain. Pyelonephritis presents with flank pain, nausea and vomiting, and temperature greater than 100.4°F (38°C) with or without symptoms of cystitis.

Differentiation must be made between complicated and uncomplicated UTI before progressing with diagnostic evaluation. An uncomplicated UTI is defined as occurring in a premenopausal, sexually active, nonpregnant woman who has not recently had a UTI. A complicated UTI is one that occurs in a man, a postmenopausal or pregnant woman, or a patient with urinary structural defects, neurologic lesions, or a catheter. A UTI also is considered complicated if symptoms have persisted for more than 7 days. In sexually active men with symptoms of cystitis, urethritis must be ruled out. Pyelonephritis presents with recurrent fevers, chills, flank pain, and a positive urine culture.

The diagnosis of UTI is made after a careful history, physical examination, and limited laboratory studies. Because UTI is the most common infection for which adults receive antibiotics, its evaluation and management must be cost-effective. Cultures do not need to be performed if the criteria for an uncomplicated UTI are met, because antimicrobial susceptibility profiles are predictable and culture results do not return until after the symptoms have resolved.

The leukocyte dipstick test is 75% to 95% sensitive in detecting pyuria. Examination of spun or unspun urine that does not show leukocytes should suggest a diagnosis other than UTI. Hematuria occurs in approximately half of all acute UTIs. Pretreatment and posttreatment cultures should be performed for male patients. Pretreatment cultures are ordered in suspected pyelonephritis; posttreatment cultures are performed only if symptoms recur within 2 weeks or if the symptoms do not resolve with treatment initially.

Initiating Drug Therapy

Without treatment, 25% to 42% of uncomplicated acute cystitis cases in women resolve spontaneously. However, the standard therapy for all UTIs is antibiotic treatment.

A urine culture with 10^5/mL organisms or greater is a diagnostic indicator of UTI with or without symptoms. A patient who has symptoms and a culture with 10^2/mL organisms or greater is treated. All symptomatic UTIs should be treated. The purpose of early treatment of cystitis is to reduce the risk of progression to pyelonephritis, although the incidence is small. Treatment does not affect the duration of symptoms, which is 3 to 4 days. In patients with pyelonephritis, early treatment is important to reduce the duration of symptoms, eliminate microorganisms from the renal parenchyma, and reduce the risk of dissemination to the blood.

For some patients with cystitis, a urinary analgesic may be useful to relieve discomfort caused by severe dysuria. A 2-day course is usually sufficient to allow time for symptomatic response to antimicrobial therapy and minimize inflammation. Dysuria is usually diminished within a few hours after the start of antimicrobial therapy.

Although most UTIs resolve spontaneously if not treated, they are treated for symptom relief. The treatment for UTI is antibiotics. The choice of antibiotic and the length of treatment depend on whether the infection is uncomplicated or complicated and on the sex and age of the patient.

A short course of treatment increases compliance and decreases the cost and side effects. For women infected with susceptible *E. coli*, cure rates of 90% to 95% are achieved with 1 to 3 days of therapy. There is no benefit to treatment exceeding 3 days in uncomplicated UTIs in women unless nitrofurantoin is used; the length of treatment for this drug is 5 to 7 days.

Current resistance to ampicillin is near 50% in most regions of the United States. Therefore, it is not recommended for first-line therapy unless the organism is shown to be sensitive to it. Resistance to trimethoprim–sulfamethoxazole (TMP–SMZ) is up to 20% in some areas of the United States, but resistance to nitrofurantoin remains low.

Goals of Therapy

The goals of therapy for UTIs are to destroy the offending organism, relieve symptoms, and prevent complications.

Antibiotics are discussed in detail in Chapter 8. Those used to treat UTIs are listed in Table 32.1.

TABLE 32.1 Overview of Selected Agents for Urinary Tract Infection

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Antibiotics			
trimethoprim–sulfamethoxazole (Bactrim) Children: 5 mg/kg/d in divided doses for 10 d Adults: 1 DS ql2h for 10d	Nausea/vomiting, anorexia, megaloblastic anemia, hallucinations, depression, seizures	Megaloblastic anemia Pregnancy (category C) Breast-feeding mother Not recommended for children <2 mo G6PD deficiency	May consider newer macrolide antibiotics, such as clarithromycin and azithromycin
trimethoprim (Trimpex) 100 mg q12h for 3 d	Same as above	Megaloblastic anemia Pregnancy (category C) Breast-feeding mother Sulfa allergy	G6PD-deficient patients can have hemolysis. May cause falsely elevated creatinine Increase fluid intake.
nitrofurantoin (Macrobid, Macrodantin) Macrobid—100 mg q12h for 7 d Macrodantin—100 mg qid for 7 d	Nausea, pulmonary allergic reaction, dizziness, hemolytic anemia Diarrhea, vaginitis, rhinitis, headache	Anuria Oliguria Pregnancy at term Nursing mother Caution if hepatic impairment	Take with food to increase absorption. Avoid use with live vaccines
ciprofloxacin (Cipro) 100–250 mg q12h for 3 d for uncomplicated cystitis and 7 d for complicated cystitis and 500 mg for 10–14 d for uncomplicated pyelonephritis	Nausea, diarrhea, altered taste, dizziness, drowsiness, headache, insomnia, agitation, confusion Serious: pseudomembranous colitis, Stevens-Johnson syndrome	Allergy to fluoroquinolones Avoid in patients <18 y Pregnancy Use with caution in renal disease, central nervous system disease, breast-feeding (safety not established)	Raises serum level of theophylline Avoid taking with aluminum- or magnesium-containing antacids. Food slows absorption. Drug interacts with antacids, theophylline, warfarin, probenecid, digoxin, foscarnet, glucocorticoids.
ofloxacin (Floxin) 200 mg q12h for 3 d for uncomplicated cystitis and 7 d for complicated cystitis and 200–300 mg for 10–14 d for uncomplicated pyelonephritis	Nausea, diarrhea, headache, insomnia, photosensitivity	Pregnancy (category C) Breast-feeding Not recommended in children	Take at least 30 min before or 2 h after meal. Avoid taking with aluminum- or magnesium-containing antacids or sucralfate, iron, and multivitamins with zinc because these can decrease absorption. Increase fluid intake significantly.

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
levofloxacin (Levaquin) 250 mg qd for 3 d for uncomplicated cystitis and 7 d for complicated cystitis and 10–14 d for uncomplicated pyelonephritis	Nausea, diarrhea, photosensitivity	Same as above	Increase fluid intake significantly. Avoid taking with aluminum- or magnesium-containing antacids or sucralfate, iron, and multivitamins with zinc because these can decrease absorption.
norfloxacin (Noroxin) 400 mg q12h for 3 d for uncomplicated cystitis and 7 d for complicated cystitis and 10–14 d for uncomplicated pyelonephritis	Seizures, dizziness, nausea, headache, tendinitis/tendon rupture	Same as above	Same as above
cefixime (Suprax) 400 mg qd for 3 d for uncomplicated cystitis and 7 d for complicated cystitis and 10–14 d for uncomplicated pyelonephritis	Diarrhea GI upset, rash, drug fever, pruritus, headache, dizziness, vaginitis	Known allergy to cephalosporins Use with caution in penicillin-allergic patients. Use with caution in patients with renal impairment, continuous ambulatory peritoneal dialysis, dialysis, GI disease.	Pregnancy category B
Urinary Analgesics			
methenamine (Urised) 2 tabs qid	Rash, anticholinergic effects, xerostomia, flushing, difficulty in urinating, acute urinary retention with benign prostatic hyperplasia, tachycardia, dizziness, blurry vision, urine or fecal discoloration	Glaucoma Not recommended in patients <6 y Pregnancy (category C) Breast-feeding Bowel obstruction Urinary obstruction Cardiospasm	May cause blue-green discoloration of urine or feces Is not antibacterial
phenazopyridine (Pyridium) 200 mg tid	Headache, rash, GI upset, hemolytic anemia	Renal insufficiency	Discolors urine and clothes (red-orange) Is not antibacterial Take after meals.
flavoxate (Urispas) 100–200 mg tid–qid	Nausea and vomiting, anticholinergic side effects, vertigo, headache, drowsiness, urticaria, confusion, tachycardia	GI obstruction Obstructive uropathies Glaucoma	Reduce dose on improvement.

G6PD, glucose-6-phosphate dehydrogenase.

Urinary Analgesics

This class of drugs is used for the symptomatic relief of pain, urgency, burning, frequency, and discomfort associated with trauma to the lower urinary tract mucosa. They are used in infection, trauma, surgery, endoscopic procedures, and catheterization. They should not be used for more than 2 days and are not used for treatment of a UTI per se, but for symptom relief.

The azo dye in this class is excreted in the urine and exerts a rapid topical analgesic effect on the mucosa of the urinary tract. The urinary analgesics are used with caution in pregnancy and lactation and are contraindicated in renal insufficiency. For additional information, see Table 32.1.

Selecting the Most Appropriate Agent

Antibiotics are selected by identifying the uropathogen, knowing local resistance rates, and considering adverse effect profiles. A 3-day course of TMP–SMZ or trimethoprim alone continues to be recognized as first-line treatment. There are concerns, however, about rare but serious skin reactions to the sulfa component and about growing resistance (about 10% in Canada). This drug should be avoided in patients treated within 6 months because they are more likely to have resistant organisms.

Nitrofurantoin has a long history of good efficacy and continues as a first-line choice, even though a 7-day course is required. Despite heavy use, very little resistance to nitrofurantoin has developed.

Another choice for first-line therapy is fosfomycin. This is a powder dissolved in water. The advantage of this drug is the one-time dosing.

Fluoroquinolones have more recently been introduced to treat UTIs, and they are very effective in a 3-day course. Their cost and the potential for developing resistance, however, suggest that they should remain a second-line choice for treatment. Cephalosporins, ampicillin, and amoxicillin should not be used unless the cultured organism is sensitive to these agents.

Cystitis and pyelonephritis are treated with the same antibiotic, but the treatment course for pyelonephritis is longer. The most desirable antibiotic is one that is low in cost with an infrequent dosing schedule, lack of resistance in local pathogens, long duration in the urinary tract, and the potential to decrease the number of *E. coli* in the vaginal and fecal reservoirs. The antibiotic selected should spare the protective, natural bacterial flora of the vagina and gastrointestinal tract, and there should be a low side effect profile. Nonpregnant women with uncomplicated cystitis may be treated with a 3-day course of antibiotics (except with nitrofurantoin, which is 5 to 7 days). Postmenopausal women should be treated for 7 days (Figure 32.1; Tables 32.2 and 32.3). Men also require a 7-day treatment because of the increased chance of a complicated infection and prostatic infection.

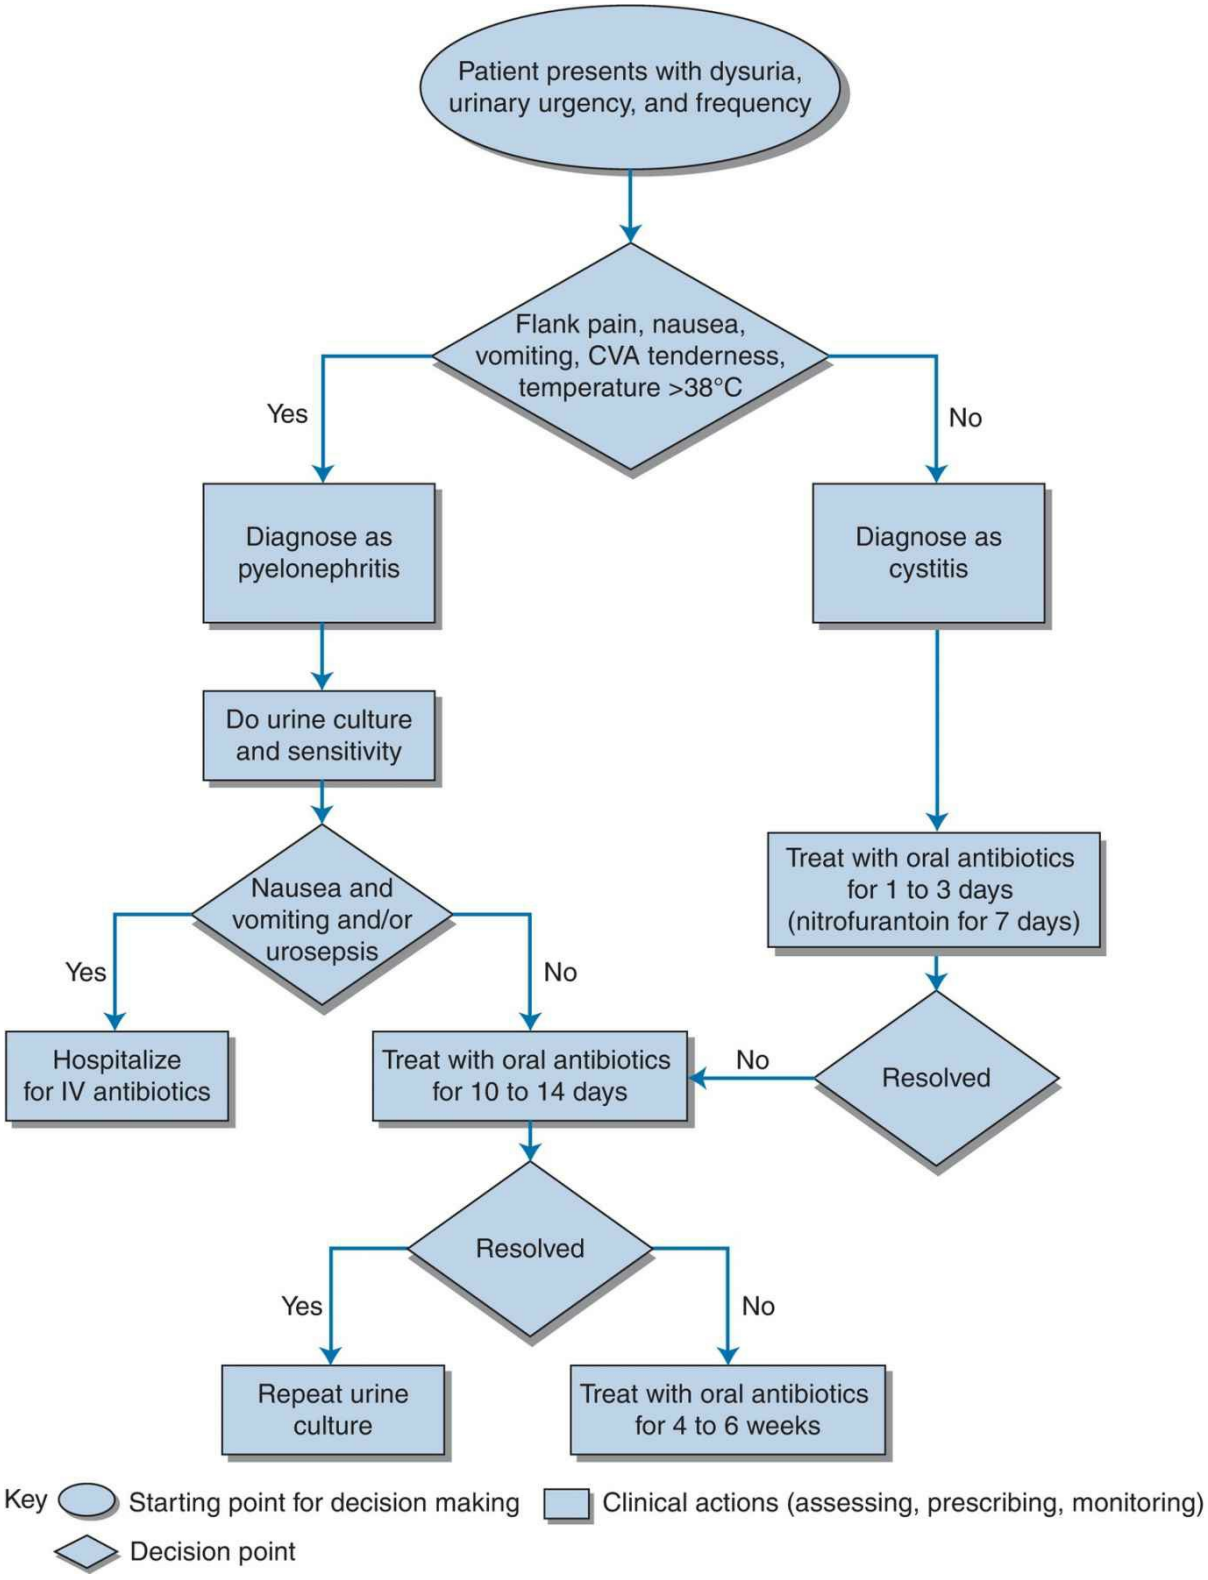

FIGURE 32.1 Treatment algorithm for UTI.

TABLE 32.2 Recommended Order of Treatment for Uncomplicated Cystitis

Order	Agent	Comments
First line	3-day oral therapy of • TMP–SMZ Or 7-day therapy of nitrofurantoin	Drink at least 8 glasses of fluids. Initiate 7-day therapy in postmenopausal women and in men. May use urinary analgesics in combination with antibiotics Higher incidence of treatment failure with nitrofurantoin for 3 d, so 7-day use is recommended
Second line	7-day oral therapy of • TMP–SMZ May also use 7-day oral therapy of: • ciprofloxacin • levofloxacin • ofloxacin • norfloxacin	
Third line	Culture and sensitivity/testing, then treat based on results	

TABLE 32.3 Recommended Order of Treatment for Uncomplicated Pyelonephritis

Order	Agents	Comments
First line	Oral for 10–14 d: • ciprofloxacin • levofloxacin • enoxacin • norfloxacin • ofloxacin • sparfloxacin • TMP–SMZ • cefixime • cefpodoxime proxetil	Urine culture and sensitivity testing should be performed before treatment.
Second line	Oral therapy for 2–6 wk	
Third line	Hospitalization for IV therapy	For severe illness or possible urosepsis

First-Line Therapy

The first-line choice for cystitis is TMP–SMZ (Bactrim). This drug combination has little impact on normal vaginal flora but decreases the number of *E. coli* in vaginal and fecal reservoirs, decreasing the chance of reinfection. Trimethoprim appears to be similar in efficacy but with fewer side effects; it can also be used in patients with sulfa allergies. The sulfa ingredient may be more important for complicated cystitis and pyelonephritis.

Nitrofurantoin has a long history of good efficacy and continues as a first-line choice, even though a 7-day course is required. Despite heavy use, very little resistance to nitrofurantoin has developed.

Fosfomycin (Monaural) is also used in first-line therapy. It is dissolved in water. This is a one-time drug. The disadvantage is that the price is high. There is no generic substitute.

Patients with cystitis can also be given urinary tract analgesics. This group includes methenamine (Urised), phenazopyridine (Pyridium, Uristat), or flavoxate (Urispas).

Uncomplicated pyelonephritis is usually treated in the outpatient setting because of the available oral antibiotics. The patient with pyelonephritis is admitted to the hospital only if he or she cannot take oral fluids or oral antibiotics, has a high fever or marked debility, or has a social situation incompatible with outpatient treatment. First-line therapy for pyelonephritis is an antibiotic, as mentioned previously, for 10 to 14 days. Fluoroquinolones are usually given first if culture results are not available because of their broad spectrum of activity. No follow-up is required if the symptoms resolve.

Second-Line Therapy

Fluoroquinolones are options for empiric therapy of recurrent cystitis. If symptoms of cystitis do not resolve after 3 days of therapy, a 7-day course of antibiotics is recommended. Fluoroquinolones are not recommended as first-line agents for uncomplicated cystitis because of the increased cost and concerns over development of quinolone resistance. They should be reserved for treatment of UTIs in men and postmenopausal women and for patients with complicated UTIs and pyelonephritis.

In pyelonephritis, a culture is obtained after treatment. If the urine is not free of bacteria after initial therapy, 4 to 6 more weeks of therapy is prescribed.

Third-Line Therapy

The recurrence rate for UTIs is approximately 20%. At this point, a urine culture is done and treatment is based on the culture results. If the patient has fewer than two UTIs a year, treatment can be based on the previous culture results. Women who have three or more recurrences annually may be offered the option of self-treatment of recurrences. Postcoital use of antibiotic prophylaxis is effective for women who have recurrences related to intercourse. Continuous antibiotic prophylaxis in a single bedtime dose is also accepted practice for women who have frequent recurrences. Antibiotics that have been shown to reduce the number of recurrences to 0.3 or fewer per year are TMP–SMZ 40 mg/200 mg, TMP 100 mg, norfloxacin 200 mg, and nitrofurantoin macrocrystals 50 to 100 mg.

Special Population Considerations

Geriatric

In elderly patients, UTIs are commonly asymptomatic, but should be strongly considered as a diagnostic possibility for individuals who have changes in mentation. Postmenopausal women are more prone to UTIs because there is uropathogen-dominant vaginal flora with the loss of estrogen. Lactobacilli diminish and pH increases. Elderly patients are at increased risk for UTIs. Vaginal estrogen therapy effectively reduces symptomatic UTI episodes in the elderly population.

Approximately 10% to 20% of the population older than age 65 has bacteriuria related to factors such as fecal incontinence, incomplete bladder emptying, malnutrition, and increased urine pH. Any UTI in a man is considered complicated. *E. coli* and *Enterobacter* species are the usual organisms. In elderly men, *Proteus*, *Klebsiella*, *Serratia*, *Pseudomonas*, and *Enterococcus* species are also responsible for UTIs. UTIs in men are most often seen in conjunction with prostatic hyperplasia with partial obstruction or persistent prostatitis.

Nitrofurantoin is not recommended in the elderly because it requires a creatinine clearance of 40 mL/min. Treatment is for 7 to 10 days in women and 10 to 14 days in men with uncomplicated UTIs.

Pregnancy

Asymptomatic bacteriuria occurs in approximately 7% of pregnant women. Of these, pyelonephritis develops in 30% if the bacteriuria is not treated. Untreated UTIs can contribute to prematurity or stillbirth. Amoxicillin is effective in approximately two thirds of UTIs in pregnant women and is safe for the fetus. Also safe are cephalexin and nitrofurantoin (only during the first and second trimesters). Sulfonamides are safe except in the last trimester. In pregnancy, the urine is cultured 1 week after treatment and every 4 to 6 weeks during the pregnancy.

Physiologic changes in pregnancy increase the risk for pyelonephritis. The ureters become obstructed because of blockage from the enlarged uterus. In addition, increased progesterone relaxes the smooth muscles of the ureter and bladder. Bacteriuria in pregnancy has been associated with a 20% to 30% incidence of pyelonephritis and premature delivery, intrauterine growth retardation, increased risk for death in the perinatal period, and congenital anomalies.

In 5% to 10% of women with UTI, there are no symptoms. Pregnant women should be screened for UTIs, and they must be treated regardless of whether they are symptomatic.

Children

UTIs in children may indicate a genitourinary anomaly. Accurate diagnosis usually requires

invasive collection of urine, especially in very young children. It is important to start treatment quickly, especially in young children, because there is an increased risk of renal scarring in children under age 5 from UTIs. UTIs recur in 32% to 40% of children.

UTI should be suspected in febrile infants without an obvious source. Urine specimens collected with a bag are considered insufficient to make a diagnosis. Transurethral and suprapubic catheterization are accepted methods of urine collection in children. All children younger than 3 years diagnosed with a first UTI should have a renal ultrasound scan and a voiding cystourethrogram (VCUG). Boys older than 3 years can either have ultrasonography with VCUG or a renal cortical scan with follow-up VCUG as indicated based on the results. Girls between the ages of 3 and 7 years should have either ultrasonography with VCUG or a renal scan if febrile or observation without imaging if afebrile. Girls older than 7 years can be observed without imaging.

First-line antimicrobial agents include the β-lactams amoxicillin–clavulanate (25–45 mg/kg/d divided every 12 hours), cephalexin (25–50 mg/kg/d, divided every 6–12 hours), and cefpodoxime (10 mg/kg/d divided every 12 hours) as well as TMP–SMX (8–10 mg/kg/d divided every 12 hours). Two-day to 4-day courses have been shown to be as effective as 7 to 14 days.

Monitoring Patient Response

Prescribers need to evaluate for cystitis that does not resolve or that recurs within a week after treatment requires culture and sensitivity testing and treatment with a fluoroquinolone for 7 days. UTIs recur within a year in approximately half of all women, although there is a very low incidence of pyelonephritis that develops as a result.

If pyelonephritis recurs within 2 weeks after treatment, a urine culture and sensitivity test and renal ultrasound or computed tomography scan should be performed to determine whether there is a urologic abnormality. If the organism is the same as the first, a 4- to 6-week course of antibiotics is recommended.

Patients who have three or more UTIs a year should be given prophylaxis, either continuous or postcoital. Continuous prophylaxis usually consists of TMP–SMZ 40 to 200 mg daily or three times a week. Postcoital therapy is indicated in women who identify intercourse as the cause of infection; the selected therapy is taken after intercourse. The use of estrogen replacement therapy in postmenopausal women decreases the number of recurrent UTIs. In cases of true relapse, the culture is repeated and therapy is prescribed for 2 to 4 weeks.

In pyelonephritis, a culture is repeated 1 to 2 weeks after completion of therapy. If there is a recurrence, therapy is recommended for 6 to 12 months.

Patient Education

Drug Information

Patients can get information about UTIs at http://www.nlm.nih.gov/medlineplus/urinarytractinfections.html, http://kidney.niddk.nih.gov/KUDiseases/topics/uti.aspx, and http://www.healthline.com/health/urinary-tract-infection-adults.

Lifestyle Changes

The most important advice is for sexually active women to urinate shortly after sexual intercourse. In doing so, they wash out the increased number of bacteria in the distal urethra. Another useful suggestion is for patients with recurrent UTIs to practice double or triple voiding and changing position while urinating helps rid the bladder of residual urine.

Other behavioral factors to consider are the direction of toilet paper use after bowel movements, type of menstrual protection used, and method of contraception. The use of spermicides changes the vaginal flora, increasing the colonization of *E. coli* and the frequency of UTIs. Women with recurrent UTIs should use a method of birth control that does not involve spermicides.

Other preventive measures include avoiding bubble baths and "feminine hygiene" products. Urinating every 2 hours, taking the time to empty the bladder completely, also helps prevent UTIs. Foods that irritate the bladder should be avoided, including tea, coffee, alcohol, cola, chocolate, and spicy foods.

Patients with frequently recurring cystitis can benefit from early self-treatment if they are well informed and compliant. If treatment is started very shortly after the onset of symptoms, a 3-day course or even a single dose of antimicrobial provides rapid relief of symptoms.

Complementary and Alternative Medicine

Cranberry juice concentrate or cranberry concentrate capsules have been recognized as alternatives to antibiotics or for the prevention of UTIs. Cranberry is believed to have antiadherence properties in the urinary tract and acidifies urine. Small studies have reported that a daily intake of 150 to 750 mL of cranberry juice is effective in preventing recurrent UTIs (Kontiokari et al., 2001). An alternative to juice is one 300- to 400-mg capsule taken two times a day with a glass of water. Additionally, 8 to 16 ounces of preparations with at least 30% cranberry juice can be taken. Vitamin C, 500 mg every 4 hours for the duration of the UTI, has been suggested, with 1,000 to 1,500 mg/d for prevention of UTIs.

Probiotics may decrease UTIs by restoring normal vaginal flora. Lactobacillus is thought to prevent colonization with *E. coli*.

Case Study*

J.S., a 65-year-old woman with diabetes, seeks treatment for dysuria, frequent urination, flank pain, and costovertebral angle tenderness. She has a temperature of 102°F, and under the microscope, her spun urine contains a large number of leukocytes.

Diagnosis: Cystitis With Possible Pyelonephritis

1. List specific goals for treatment for J.S.
2. What drug therapy would you prescribe? Why?
3. What are the parameters for monitoring success of the therapy?
4. Discuss specific patient education based on the prescribed therapy.
5. List one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What would be the choice for second-line therapy?
7. What over-the-counter and/or alternative medications would be appropriate for J.S.?
8. What lifestyle changes would you recommend to J.S.?
9. Describe one or two drug–drug or drug–food interactions for the selected agent.* Answers can be found online.

33 Prostatic Disorders and Erectile Dysfunction

Virginia P. Arcangelo

Disorders of the prostate appear as part of the normal aging process and also as abnormalities distinct from normal aging. Often, it is not until age 40 that a man begins to show some form of noncancerous prostatic disorder, whereas prostate cancer usually is found after age 50. At 70, approximately 40% of men report lower urinary tract symptoms (LUTS), increasing to 50% at the age of 75, most often from benign prostatic hypertrophy (BPH).

Prostate cancer is the second most common type of cancer affecting men, with a lifetime prevalence of 15%. Black men have the highest incidence of prostate cancer. Asian and Hispanic men are at lower risk than White men. In addition to race, other risk factors for prostate cancer are age and family history. The disease rarely occurs before age 45, but the incidence rises exponentially thereafter; nearly 70% of cases are diagnosed in men age 65 and older. There are 147.8/100,000 cases of newly diagnosed prostate cancer per year.

Prostate disorders are diagnosed through clinical manifestations and screening procedures used to detect or rule out prostate cancer. Lack of knowledge about prostate cancer and lack of available screening procedures are the major deterrents to accurate and timely diagnosis of prostate cancer.

Treatment of prostatic disorders itself may result in some untoward side effects, which must then also be managed. Often, the man postpones seeking medical intervention and blames aging for many of the manifestations, thus delaying treatment. Some difficulties in seeking treatment can relate to the man's culture; sexuality—specifically, masculinity—can be perceived as synonymous with virility. For this reason, a man may choose not to discuss (even with a health care worker) clinical manifestations.

Prostatic disorders and LUTS occur because of inflammation or infection (prostatitis), BPH, and prostate cancer; prostatitis can involve the bladder neck, thus becoming prostatocystitis. A bacterial infection is often the cause of prostatitis, although some nonbacterial forms of prostatitis do exist. Inflammation can be chronic or acute.

Adenocarcinoma is the most common type of prostate cancer. Metastasis can follow slowly or quickly, and often, the symptoms of metastasis are what lead the man to seek medical intervention.

Presenting manifestations of prostatic disorders are usually specific to the urinary tract and include difficulty in onset of urine flow with or without a low flow of urine, frequency

or urgency in voiding, incontinence, distention of the bladder, and hematuria. Management of prostatic disorders is specific to the particular disorder (cancerous vs. noncancerous), with some overlap in treatment.

Prostatitis

Causes

Prostatitis is one of the most common urological infections afflicting adult men and has recently been divided into four different categories based on the National Institutes of Health (NIH) consensus classification (Weidner & Anderson, 2008). This category system includes category I (acute bacterial prostatitis); category II (chronic bacterial prostatitis); category III chronic nonbacterial prostatitis and pelvic pain syndrome, including inflammatory and noninflammatory types (CP/CPPS); and category IV (asymptomatic inflammatory prostatitis). Acute and chronic bacterial prostatitis affects less than 5% of men with prostatitis. Most patients with prostatitis are found to have either nonbacterial prostatitis or prostatodynia. This disorder can be acute or chronic. With acute bacterial prostatitis, the chief organisms involved are *Escherichia coli* and *Pseudomonas* species, although strains of staphylococci or streptococci also are seen. Chronic bacterial prostatitis is associated with *Pseudomonas*, *E. coli*, *Proteus mirabilis*, *Klebsiella pneumoniae*, and *Enterococcus* species, particularly *Enterococcus faecalis*. Nonbacterial prostatitis is essentially an inflammatory disorder.

Pathophysiology

Often chronic, nonbacterial prostatitis is nonetheless problematic for the patient. Primary etiologies of this condition include two predominant patterns of inflammation. The first is that of an allergic condition and is associated with eosinophil infiltration. The second is a nonspecific form in which granulomatous inflammation by peculiar, large, pale macrophages is found.

In acute bacterial prostatitis, as with any type of bacterial invasion, the prostate becomes overwhelmed by the bacteria, leading to inflammatory response activation. Usually, acute bacterial prostatitis is seen as an infection ascending up the urinary tract, and younger men, ages 30 to 50, can be affected with this illness.

Diagnostic Criteria

Symptom manifestation revolves around urinary tract signs. There is pain in the lower abdomen, difficulty in bladder emptying with or without a small stream during urination, nocturia, and fever to 104°F (40°C). Along with the febrile state, as with other infections, general arthralgia and malaise can occur.

On examination and interview, the man often admits to painful ejaculation and pain in the rectal or perineal areas. All the symptoms are due to the edema associated with acute inflammation of the prostate. Because of the risk of generalized septicemia, pharmacotherapeutics are urgently warranted.

Culture isolation of prostatic urine is the most accurate method of diagnosis. Prostatic urine is defined as the third and fourth (urine) secretion specimens of four serial urine sample because prostatic fluid is at a significantly higher concentration in these last two of four serial voids. The four urine samples are obtained sequentially, beginning with the initial void, followed by a midstream urine specimen, prostatic massage secretion, and finally the urine voided after the prostatic massage. Standard laboratory culture techniques are applied to establish the causative organism.

Nonbacterial prostatitis is confirmed by negative prostatic urine cultures with a positive elevated white blood cell count and the presence of inflammatory cells in prostatic secretions. This condition and another nonbacterial type of prostatitis known as *prostatodynia* have the same symptoms as does bacterial prostatitis. Treatment of the nonbacterial forms usually consists of symptom management without the use of antibiotics.

Initiating Drug Therapy

Antibiotics are the required pharmacotherapy. (See Chapter 8.) Given that causative organisms are usually gram negative and, less commonly, gram positive, appropriate antibiotics are needed. The overall course of antibiotic therapy is of longer duration than that used to treat other systemic infections. Usually, antibiotics are given for 4 to 6 weeks, but up to 12 weeks of therapy may be necessary due to poor penetration of prostate tissue. Because chronic bacterial prostatitis is a bacterial infection, an appropriate antibiotic with good tissue penetration in the prostate should be selected. Fluoroquinolones have demonstrated the best tissue concentration and are recommended as first-line agents. Although trimethoprim–sulfamethoxazole (TMP-SMZ) may be considered, the tissue penetration may not be as effective, and in many areas of the United States, there is evidence of increasing uropathogenic resistance.

Second-line drugs include doxycycline, azithromycin, and clarithromycin. A 4- to 6-week course of therapy is usually recommended; however, a 6- to 12-week course is often needed to eradicate the causative organism and to prevent recurrence, especially if symptoms persist after completion of the initial therapy. No guidelines exist for treating gram-positive organisms, but ciprofloxacin and levofloxacin have adequate gram-positive coverage as well as excellent gram-negative coverage, and both medications penetrate the prostate tissue well.

Adjunctive therapies that may be beneficial include the use of sitz baths, analgesics, stool softeners, and antipyretics, along with rest. Prostatic massage, voiding in a warm bath (to relax pelvic muscles), and discontinuation of alcohol and caffeinated beverages can also help to relieve symptoms. If possible, withdrawal from antidepressants, anticholinergics, or sedatives may also help bladder function.

Goals of Drug Therapy

The goal of pharmacotherapy for prostatitis is to eradicate the causative organism and restore the prostate to health. Prostatitis often becomes chronic, and therefore, repeated trials with antibiotics or prolonged dosage schedules may be warranted.

Anti-Infectives

Table 33.1 depicts dosage information, adverse events, contraindications, and special considerations for the anti-infective management of bacterial prostatitis.

TABLE 33.1 Overview of Selected Antibiotics Used to Treat Acute Bacterial Prostatitis

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
trimethoprim–sulfamethoxazole (TMP-SMZ, Septra, Bactrim) 160 mg of TMP with 800 mg SMZ PO q12h	GI distress, rash	Allergy to sulfa and sulfa products	May prolong the INR for patients on oral anticoagulants
fluoroquinolones ciprofloxacin (Cipro) 500 mg bid norfloxacin (Noroxin) 400 mg bid levofloxacin (Levaquin) 250 mg daily	Headache, diarrhea, nausea, drowsiness, altered taste, insomnia, agitation, confusion Serious: pseudomembranous colitis, Stevens-Johnson syndrome	Allergy to macrolides Pregnancy and lactation Use with caution in patients with severe hepatic or renal disease.	May interfere with theophylline metabolism
doxycycline (Vibramycin) 200 mg PO as first dose, thereafter 100–200 mg PO q12h	GI distress, potential acute hepatotoxicity, potential for nephrotoxicity	Hypersensitivity to any of the tetracyclines Pregnancy and lactation	Decreased effectiveness with food and dairy products, so do not take with food unless side effects are significant Can lead to diabetes insipidus because of antagonistic effect with antidiuretic hormone

Trimethoprim–Sulfamethoxazole

This drug is a bacteriostatic combination product and is considered to be more powerful than its two components given separately. Also, when given as the combined form, resistance on the part of the causative organism arises less frequently. This agent ultimately adversely affects the production of proteins and nucleic acids of bacteria at the target (prostate) site. TMP-SMZ further inhibits growth of bacteria because of its antimetabolite property toward PABA (*para*-aminobenzoic acid). Drug–drug interactions can present when the patient is also taking phenytoin (Dilantin), oral hypoglycemics, or warfarin (Coumadin). Close monitoring of the seizure threshold, serum glucose level, or partial thromboplastin time is important in the patient on TMP-SMZ who is also taking these other agents.

Fluoroquinolones

Fluoroquinolones are also effective for bacterial prostatitis. Effective against gram-negative anaerobes and some gram-positive bacteria, these agents decrease the growth and replication of bacteria by inhibiting bacterial deoxyribonucleic acid (DNA) during synthesis. These agents may be the first choice for someone sensitive or allergic to TMP-SMZ.

The absorption of fluoroquinolones is reduced by milk, antacids (aluminum or magnesium based), iron or zinc salts, and sucralfate. For the patient who is also taking any of these medications, the dose should be taken either 2 hours after or 4 hours before the other medication.

Fluoroquinolones also affect the use of theophylline and warfarin. Elevated levels can occur, and thus, a lower dosage of theophylline or warfarin may be necessary.

Doxycycline

A long-acting tetracycline, doxycycline (Vibramycin) acts by inhibiting protein synthesis: binding of peptidyl transfer ribonucleic acid (tRNA) is blocked at ribosomal mRNA.

Many of the metal ions—aluminum, calcium, iron, magnesium, and zinc—can interfere by creating chelates with doxycycline. Thus, if these metals are given (and they often are as components of antacids), at least 2 hours should separate their use from the ingestion of doxycycline.

Azithromycin and Clarithromycin

These are macrolide antibiotics. Macrolides inhibits RNA-dependent protein synthesis by reversibly binding to the 50S ribosomal subunits of susceptible microorganisms. They induce dissociation of tRNA from the ribosome during the elongation phase. Thus, RNA-dependent protein synthesis is suppressed, and bacterial growth is inhibited. Macrolides are mainly bacteriostatic but can be bacteriocidal depending on bacterial sensitivity and antibiotic concentration.

Selecting the Most Appropriate Agent

Oral antibiotics are the treatment agents of choice.

First-Line Therapy

The primary choice for first-line antibiotic therapy is a fluoroquinolone (Table 33.2). Therapy lasts for 4 to 6 weeks. See Figure 33.1 for more information. TMP-SMZ may also be considered if treatment is in an area where there is not a high incidence of resistance.

TABLE 33.2 Recommended Order of Treatment for Prostatitis

Order	Agents	Comments
First line	Fluoroquinolones or TMP-SMZ	Ineffective against enterococci Treat for 4–6 wk.
Second line	Doxycycline or azithromycin or clarithromycin	

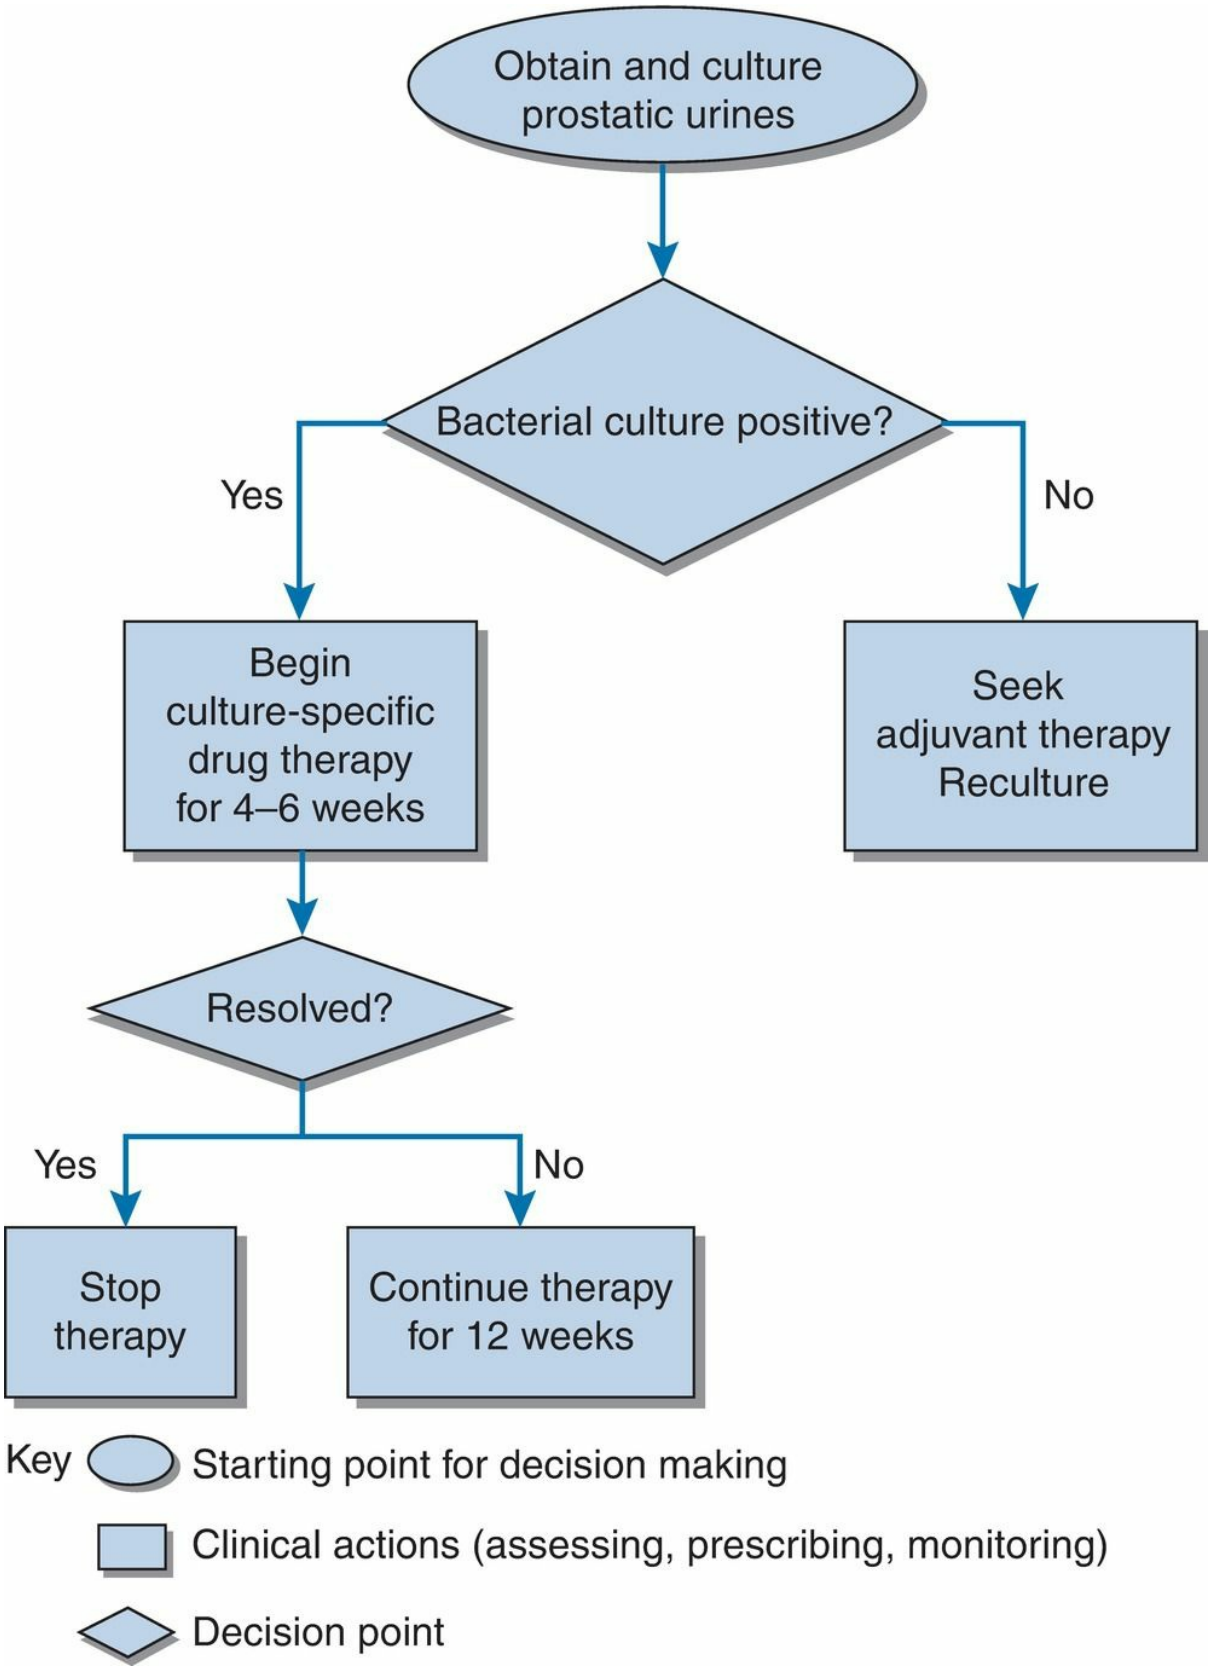

FIGURE 33.1 Treatment algorithm for prostatitis.

Second-Line Therapy

Doxycycline, azithromycin, and clarithromycin are second-line agents. If the infection is not resolved with 4 to 6 weeks of drug treatment, therapy can be continued for up to 12 weeks.

Special Population Considerations

In older men who are taking fluoroquinolones, creatinine clearance must be monitored.

Monitoring Patient Response

As a group, anti-infective agents should begin to elicit results after the first week of therapy. Subjective response from the patient indicating alleviation of symptoms is helpful in monitoring the effectiveness of these medications. Some patients may not notice symptom resolution until after 2 weeks; they should be told this and encouraged to continue taking the medication. Ultimately, 12 weeks of therapy may be required. Follow-up cultures may be obtained at the practitioner's discretion. Further diagnostic criteria may also be recommended for ongoing symptom manifestation.

Patient Education

The patient should understand potential side effects, interactions, and appropriate use of the medications. Literature can provide patients with a guide for such potential concerns as well as dosing information. With a prepared and knowledgeable patient, these medications are effective against prostatitis. Cost also can be a factor of concern to the patient. The practitioner should be aware of any financial constraints the patient may have, because compliance with medication is important for effective treatment of bacterial prostatitis.

Benign Prostatic Hyperplasia

Benign prostatic hyperplasia (BPH) is the most common prostate problem in men older than age 50; the disease rarely causes symptoms before age 40. As life expectancy rises, so does the occurrence of BPH—an estimated 6.3 million men have BPH. In the United States alone, the disease accounts for 6.4 million doctor visits and more than 400,000 hospitalizations annually. Approximately 90% of men age 80 and older have histologic evidence of BPH, and more than 80% have BPH-related symptoms. Approximately 25% of men older than age 55 and 50% of men older than age 75 experience decreased urinary flow.

Causes

The cause of BPH is not well understood. It has been observed that BPH does not develop in men whose testes were removed before puberty. For this reason, some researchers believe that factors related to aging and the testes may spur the development of BPH. Men produce both testosterone and small amounts of estrogen. As men age, the amount of active testosterone in the blood decreases, leaving a higher proportion of estrogen. Studies performed on animals have suggested that BPH may occur because the higher amount of estrogen within the gland increases the activity of substances that promote cell growth. Another theory focuses on dihydrotestosterone (DHT), a substance derived from testosterone in the prostate, which may help control its growth. Some research has indicated that even with a drop in the blood's testosterone level, older men continue to produce and accumulate high levels of DHT in the prostate. This accumulation of DHT may encourage the growth of cells. Researchers have also noted that men who do not produce DHT do not develop BPH.

Pathophysiology

The dynamic component of BPH and LUTS is based on autonomic input to the smooth muscles in the lower urinary tract, including the bladder, prostate, and urethra. These areas have a large concentration of α_1-adrenergic receptors that, when stimulated by various stressors, cause increasing smooth muscle tone. This increased smooth muscle tone leads to increased urethral resistance and contributes to the bladder outlet obstructive symptoms of BPH. This physiology leads to the basis for a main class of drugs to treat BPH, the use of α_1-adrenergic blockers.

An underlying pathophysiologic process of BPH is the formation of large, nonmalignant lesions at the periurethral region of the prostate gland. Prostatic hyperplasia is an overgrowth of normal cells in the stromal and epithelial tissues of the prostate gland. The hyperplasia originates in the transition zone of the prostate, which surrounds the prostatic urethra between the bladder and the anus. The etiology of the hyperplastic process is unknown, but it has been speculated that it is hormone related because it occurs only in older men. The male aging process involves a decrease in testosterone production with a concomitant increase in estrogen; estrogen may be a sensitizer for the escalating hyperplasia. Bladder control involves reflex activity of the peripheral autonomic nervous system (ANS). The reflex for normal micturition is housed in the brain stem and supported by descending and ascending pathways from the spinal cord. Both the external sphincter and the detrusor muscle are needed for bladder control. Reflex micturition is innervated at the S2 to S4 and T1 to L1 levels in the spinal cord. The cortical center of the brain appears to be important for inhibition or control of the micturition center to modulate contractile, filling, and expulsion activity.

Parasympathetic and sympathetic innervation is crucial to the role of the ANS in voiding. Parasympathetic interplay allows for the detrusor muscle to maintain tone and to contract, whereas sympathetic interplay allows for the bladder to expand and maintain a large filling capacity. The dynamic component of BPH and LUTS is based on autonomic input to the smooth muscles in the lower urinary tract, including the bladder, prostate, and urethra. These areas have a large concentration of α_1-adrenergic receptors that, when stimulated by various stressors, cause increasing smooth muscle tone. This increased smooth muscle tone leads to increased urethral resistance and contributes to the bladder outlet obstructive symptoms of BPH. This physiology leads to the basis for a main class of drugs to treat BPH, the α_1-adrenergic blockers.

BPH disease manifests as urinary tract symptoms. Obstructed urine outflow, the predominant pattern, includes diminished force of the urine stream, an urgent need for nocturnal voiding, residual urine with or without overflow incontinence, and even a feeling of pressure in the abdomen. These manifestations result from either partial or complete compression of the urethra by the hyperplastic prostate. Bladder wall hypertrophy occurs,

and herniation into the bladder can occur. Ultimately, if treatment is not initiated, a postrenal cause of acute renal failure can develop because of back pressure on the renal system (i.e., the ureters) and the onset of hydronephrosis.

Diagnostic Criteria

Diagnosis of BPH usually begins with the patient seeking medical intervention because of the annoying symptoms. Along with a complete social history and physical examination, a digital rectal examination (DRE) is performed to palpate the prostate. The degree of prostate enlargement has not been found to correlate with the severity of symptoms; rather, the location of the enlargement is what leads to symptom manifestation.

BPH severity is assessed using validated, self-administered symptom questionnaires such as the American Urological Association Symptom Index (AUASI) (http://www.urologyhealth.org/_media/_pdf/AUA%20Symptom%20Score.pdf) (Table 33.3) or International Prostate Symptom Score (http://www.urospec.com/uro/Forms/ipss.pdf). Mild or nonbothersome symptoms do not require treatment. Bothersome symptoms are managed with lifestyle modifications, medications, and surgery.

TABLE 33.3 AUA Symptom Index Scale

Questions to Be Answered	AUA Symptom Score (Circle 1 Number on Each Line)					
	Not at All	Less Than 1 Time in 5	Less Than Half the Time	About Half the Time	More Than Half the Time	Almost Always
1. Over the past month, how often have you had a sensation of not emptying your bladder completely after you finished urinating?	0	1	2	3	4	5
2. Over the past month, how often have you had to urinate again <2 h after you finished urinating?	0	1	2	3	4	5
3. Over the past month, how often have you found that you stopped and started again several times when you urinated?	0	1	2	3	4	5
4. Over the past month, how often have you found it difficult to postpone urination?	0	1	2	3	4	5
5. Over the past month, how often have you had a weak urinary stream?	0	1	2	3	4	5
6. Over the past month, how often have you had to push or strain to begin urination?	0	1	2	3	4	5
7. Over the past month, how many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning?	0 (None)	1 (1 time)	2 (2 times)	3 (3 times)	4 (4 times)	5 (5 times or more)

In the AUASI, symptoms are scored as mild (0 to 7 points), moderate (8 to 19 points), or severe (20 to 35 points). The American Urological Association (AUA) recommends that this scale be used on initial assessment and then for following the course of illness by periodic ongoing assessment of the patient. Such follow-up management enables the practitioner to initiate more acute or intensive therapy when the score increases. Patients with severe BPH symptoms should not be managed by this scale.

Postvoid catheterization is performed to ascertain the degree of urine retention; any amount of residual urine beyond 100 mL is considered significant. Uroflowmetry provides information about the force of the urine stream. Urodynamics can also be assessed using noninvasive pneumatic technology. Other diagnostic tools include x-ray films, digital ultrasound, computed tomography (CT) scans, magnetic resonance imaging (MRI), and radionuclide scans. Biopsies can be added to the diagnostic workup for further clinical assessment of any hardened prostatic areas found by DRE. Laboratory monitoring of creatinine and blood urea nitrogen should be incorporated to determine whether renal involvement exists and, if so, to what degree. Prostate-specific antigen (PSA) levels can be elevated in patients with BPH.

Many symptoms of BPH stem from obstruction of the urethra and gradual loss of bladder function, which results in incomplete emptying of the bladder. The symptoms of BPH vary, but the most common ones involve changes or problems with urination, including a hesitant, interrupted, or weak stream; urgency, dribbling, or urinary retention; more frequent urination, especially at night; painful urination; and incontinence.

It is extremely important to evaluate men at risk for these symptoms. In 8 out of 10 cases, these symptoms suggest BPH, but they also can signal more serious conditions, such

as prostate cancer.

Initiating Drug Therapy

There are three major classes of drugs used to treat BPH. One group is α-adrenergic antagonists or α-blockers (doxazosin, terazosin, tamsulosin, alfuzosin, and silodosin). Tamsulosin, silodosin, and alfuzosin are selective α_1-adrenoreceptor antagonists, selective for α_{1A}-adrenergic receptor. While causing smooth muscle relaxation in the lower urinary tract, it minimizes blood pressure–related adverse effects. These relax the smooth muscle fibers of the bladder neck and prostate, thereby reducing the dynamic components of prostatic obstruction.

Another group is 5-α-reductase inhibitors (finasteride and dutasteride). Five-α-reductase inhibitors decrease levels of intracellular DHT (the major growth-stimulatory hormone in prostate cells) without reducing testosterone levels. This leads to prostatic size reduction of 20% to 30%. Symptom relief occurs within 2 weeks of initiating α-blockers, compared with several months with finasteride.

The third category is PDE type 5 inhibitor. The only drug in this class approved for this use is tadalafil (Cialis). PDE5 inhibitors have been found to regulate smooth muscle tone in human prostate. These are useful in patients who do not respond to α-blockers, especially in men with concomitant erectile dysfunction (ED).

Management of BPH can include medical, surgical, and a combination of medical and surgical intervention. Choosing the right treatment should be guided by patients' symptoms, comorbidities, and potential side effects of available drugs. Silodosin is a valid option for elderly and for people taking antihypertensive drugs. BPH patients affected by ED can target both conditions with continuous tadalafil therapy.

Pharmacotherapy is prescribed with both medical and surgical approaches to care. The progression of BPH is unique to the individual; the man often will "watch and wait" before proceeding further into active therapy because the process of hyperplasia can be slow. This is acceptable as long as the AUA score is 19 or less.

The Medical Therapy of Prostatic Symptoms (MTOPS) trial tested whether finasteride (Proscar), doxazosin (Cardura), or a combination of the drugs could prevent progression of BPH and the need for surgery or other invasive treatments (Slawin, 2003; Marberger, 2006). Physicians at 17 MTOPS medical centers treated 3,047 men with BPH for an average of 4.5 years. Participants were randomly assigned to receive doxazosin, finasteride, combination therapy, or a placebo. Vital signs, urinary symptoms, urinary flow, adverse effects, and medication use were assessed every 3 months. DRE, serum PSA level, and urinalysis were performed yearly. Prostate size was measured by ultrasound at the beginning and end of the study. Progression of disease was defined by one of the following: a four-point rise in the AUA score, urinary retention, recurrent urinary tract infection, or urinary incontinence.

Finasteride, a 5-α-reductase inhibitor, and doxazosin, an α1-receptor blocker, together

reduced the overall risk of BPH progression by 66% compared with a placebo. The combined drugs also provided the greatest symptom relief and improvement in urinary flow rate. Doxazosin alone reduced the overall risk of progression by 39% and finasteride alone by 34% relative to a placebo. The risk of urinary retention was reduced by 81% with combination therapy and 68% with finasteride alone. Doxazosin alone did not reduce the risk of urinary retention. The risk of incontinence was reduced by 65% with combination therapy. Only five men developed urinary tract or blood infections. No patients developed impaired kidney function related to BPH.

Twenty-seven percent of men taking doxazosin, 24% of men taking finasteride, and 18% of men taking combination therapy stopped treatment early, primarily because of adverse effects. The most common adverse effects included sexual dysfunction in men treated with finasteride and dizziness and fatigue in men treated with doxazosin.

Goals of Therapy

The goals of therapy include reduced bladder outlet obstruction, improved quality of life, fewer symptoms, and decreased residual urine volume.

The mainstay of medical management is pharmacotherapy. Pharmacotherapy is used for both controlling hyperplasia and managing annoying side effects, either as primary therapy or as an adjunct to surgical intervention. Management of hyperplasia is based on the premise that there are hormonal changes related to aging and that alpha-adrenergic receptors are present in prostate tissue, specifically smooth muscle. Pharmacotherapeutic interventions consist of hormonal manipulation and blocking effects achieved by alpha-adrenergic blockers. For dosage, adverse events, contraindications, and special considerations of drugs used for BPH, see Table 33.4.

TABLE 33.4 Overview of Selected Agents Used to Treat Benign Prostatic Hyperplasia

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Alpha-Adrenergic Blockers			
terazosin (Hytrin) 1–20 mg PO qd	Orthostatic hypotension, somnolence, dizziness	Hypersensitivity to terbutaline Tachyarrhythmias, hypertension, pregnancy, lactation Use with caution in patients with cardiac insufficiency.	Take at bedtime to avoid hypotension.
doxazosin (Cardura) 4–8 mg PO qd	Dizziness, headache, fatigue, malaise	Lactation Use with caution in patients with CHF, renal failure, hepatic impairment.	May have secondary benefit to client with cardiac disease Avoid combination with alcohol, nitrates, or other antihypertensive drugs.
tamsulosin HCl (Flomax) 0.4 mg/d PO qd; increase to 0.8 mg/d PO qd	Orthostasis, headache, problems with ejaculation	Allergy to tamsulosin Prostatic cancer, pregnancy, lactation	Ejaculatory problems more common in higher dosage (0.8 mg/d)
silodosin (Rapaflo) 8 mg PO qd	Orthostatic hypotension, priapism, headache, URI symptoms	Hepatic impairment, Severe renal impairment	Interaction with cimetidine decreases clearance of tamsulosin. Contraindicated with clarithromycin
5-α-Reductase Inhibitor			
finasteride (Proscar) 5 mg daily	Impotence, decreased libido, smaller ejaculate	Not to be handled by pregnant women	Inform patient that effective outcome of therapy may take up to 6 mo.
dutasteride (Avodart) 0.5 mg daily	Orthostatic hypotension, priapism, increased risk for prostate cancer	Caution if sensitivity to sulfonamides	Avoid handling if pregnant or potentially pregnant.
dutasteride/tamsulosin (Jalyn) 1 capsule (0.5/0.4) qd			

5-Alpha-Reductase Inhibitors

Finasteride (Proscar) and dutasteride (Avodart), androgen hormone inhibitors, are used for managing the symptoms of BPH. They aid in the inhibition of androgen transformation from their steroid precursors. On average, most men achieve 20% to 40% reduction in prostate size after at least 6 months of use. In general, these agents are most effective in men with prostate glands more than 30 g (or cm^3). Both drugs lower PSA levels by about 50% after 6 months of use. This is critical to take into account when screening for prostate cancer. If the PSA level does not fall by one half and the patient has been compliant with medication, the patient should be referred to an urologist for a workup.

Mechanism of Action

5-α-reductase inhibitors act by specifically blocking 5-α-reductase, the enzyme that activates testosterone in the prostate. It impairs prostate growth by inhibiting the conversion of testosterone to DHT and causes changes in the epithelial cells of the transition zone. By preventing testosterone activation, 5-α-reductase inhibitors lessen or prevent urinary system symptoms. They also decrease prostatic volume and prevent the progression of the disease in men with a significantly enlarged prostate. There is a slow reduction of 80% to 90% in the serum DHT level. As a result, prostatic volume decreases by about 20% over 3 to 6 months of treatment. Dutasteride blocks both types 1 and 2 5-α-reductase.

Studies have been done to determine the efficacy of finasteride and placebo. The larger Proscar Safety Plus Efficacy Canadian Two-Year Study (PROSPECT) found that treatment with finasteride led to significant improvements in urinary symptoms and flow rates (Nickel et al., 1996). However, in the PROSPECT study, the improvements with finasteride were significantly less than those with any α-blocker or surgery.

5-α-reductase inhibitors decrease PSA levels by 40% to 50%. In a patient taking finasteride who has PSA screening, PSA levels should be doubled and then compared in the usual fashion to age-related norms.

Dosage

The dosage for finasteride is 5 mg/d; that for dutasteride is 0.5 mg/d. These dosages are recommended for use as long-term therapy; studies have shown benefit beyond the usual 2-year period, with beneficial effects in the third year.

Adverse Events

Adverse events include decreased libido, impotence, ejaculatory failure, and gynecomastia. Finasteride can also falsify the PSA level after 6 months of therapy.

Alpha-Adrenergic Blockers

Alpha-adrenergic blockers include terazosin (Hytrin), doxazosin (Cardura), prazosin (Minipress), tamsulosin (Flomax), and silodosin (Rapaflo). It is recommended to use α-blockers in men with smaller prostate glands (less than or equal to 30 to 35 g or cm^3), in younger men, and in patients in whom rapid effect is needed. Side effects of this class include headache, dizziness, asthenia, drowsiness, and retrograde ejaculation. Silodosin is an α_1-adrenoreceptor antagonist that is selective for α_{1A}-adrenergic receptor. While causing smooth muscle relaxation in the lower urinary tract, it minimizes blood pressure–related adverse effects.

Mechanism of Action

As a pharmacologic classification, α-adrenergic blockers are functional antihypertensives with potential effects on glomerular filtration rate, renal perfusion, and heart rate. They are strongly linked with fluid retention. These agents relax the smooth muscle of the prostate and bladder neck without interfering with bladder contractility, thereby decreasing bladder resistance to urinary outflow. In general, weeks to months may pass before benefits from these medications are noted. However, benefits may last for up to 2 years, in some cases longer.

Adverse Events

Side effects can be a major concern, especially considering the potential for hypotension, specifically orthostatic hypotension, and fluid retention. However, cardiac output can actually improve, thus preventing heart failure. Of the four agents, prazosin has more potential for causing orthostatic hypotension than the others.

Side effects such as dizziness, postural hypotension, fatigue, and asthenia affect 7% to 9% of patients treated with nonselective α-blockers. Side effects can be minimized by bedtime administration and slow titration of the dosage.

Tamsulosin (Flomax) is a highly selective α_{1A}-adrenergic antagonist that was developed to avoid the side effects of nonselective agents. Some patients who do not respond to nonselective α-blockers may respond to tamsulosin and, because of the selectivity, may have fewer side effects.

Dutasteride/tamsulosin (Jalyn) is a combination 5-α-reductase inhibitor and α_1-adrenergic antagonist for the treatment of symptomatic BPH. The complementary mechanisms affect hormonal and smooth muscle pathways, inhibiting enlargement of the prostate and producing muscular relaxation resulting in a decrease of symptoms. Although monotherapy with dutasteride or tamsulosin is beneficial for many men, the combination drug is slightly better than either component alone at decreasing symptom scores. In carefully diagnosed, selected, and monitored patients who do not respond to monotherapy,

Jalyn may produce clinical benefit.

Phosphodiesterase-5 Inhibitors (See Erectile Dysfunction)

The use of tadalafil (Cialis) at a dose of 5 mg daily has been approved for BPH.

Selecting the Most Appropriate Agent

The most appropriate agent is the one that achieves symptom control and produces the fewest adverse effects (Table 33.5 and Figure 33.2).

TABLE 33.5 Recommended Order of Treatment for Benign Prostatic Hyperplasia

Order	Agents	Comments
First line	If AUA score is 7 or less, watchful waiting	
Second line	α-adrenergic blocker or 5-α-reductase inhibitor or PDE5 inhibitor	α-adrenergic blocker can be prescribed for patients with hypertension; 5-α-reductase inhibitor is recommended if prostate enlargement exceeds 40 g.
Third line	Combination of α-blocker and 5-α-reductase inhibitor or PDE5 inhibitor

Decision point

FIGURE 33.2 Treatment algorithm for benign prostatic hyperplasia (BPH).

First-Line Therapy

If symptoms are mild (AUA score less than 7), no medical treatment is recommended. The man should limit his fluid intake after dinner, avoid decongestants, massage the prostate after intercourse, and void frequently.

Second-Line Therapy

Pharmacotherapy is initiated when the AUA score is more than 7. An α-adrenergic blocker is effective first-line pharmacotherapy. The addition of a 5-α-reductase inhibitor is effective in men with moderate to severe symptoms and a documented enlarged prostate when an α-adrenergic blocker is not effective. Choosing the right treatment should be guided by patients' symptoms and comorbidities and potential side effects of available drugs. Silodosin is a valid option for elderly and for people taking antihypertensive drugs. BPH patients affected by ED can target both conditions with continuous tadalafil therapy.

Third-Line Therapy

Combination therapy with a 5-α-reductase inhibitor and alpha blocker may show greater improvement.

Fourth-Line Therapy

Referral to urology for possible surgery is recommended if other therapy fails.

The prevailing surgical intervention is prostatic resection or prostatectomy. Transurethral resection of the prostate (TURP) is the most common surgical intervention. Regardless of the surgical technique used (i.e., retrograde, perineal, or suprapubic approach), removal of the prostate is not without potential complications. The primary side effect, which can be permanent, is impotence from nerve damage. Incontinence is rare and usually only temporary; retrograde ejaculation can occur. Prostatectomy using laser technique is also an option, as is balloon dilation or urethral stent implantation. Laser surgery requires only an overnight stay; stent insertion is recommended for the man with cardiac or pulmonary morbidities, although it does not address the underlying problem of BPH itself.

Transurethral microwave thermotherapy is performed on an outpatient basis. Although anesthesia is not required, use of a local or general antianxiety agent may be helpful because the procedure is performed by catheter insertion into the prostate, through the urethra. This procedure uses heat derived from microwave energy (approximately 45°C) to remove or destroy excess cells of the prostate while cool water is circulated to preserve surrounding tissue.

Monitoring Patient Response

As noted previously, the AUA symptom score can be used to monitor men with mild or even moderate BPH. A three- or four-point improvement in the AUASI score is clinically significant. Abatement of symptoms is used to evaluate the success of pharmacotherapy. If side effects become evident with a chosen agent, a different agent can be tried. The patient's blood pressure should be monitored frequently during the first 2 weeks of treatment to observe for an untoward hypotensive response. In addition, the practitioner should not pass off subjective complaints related to sexual health, because it could lead to medication noncompliance.

Patient Education

Drug Information

With terazosin use, an improvement in urine flow may begin within 1 to 2 weeks; thus, the patient must be informed that urine flow improvement will not occur overnight. The man should rise slowly from a sitting or standing position and quickly sit down or recline if abrupt vertigo occurs.

Lifestyle Changes

Patients with BPH can obtain symptomatic relief with regular, relaxed, and frequent voiding; decreasing fluid intake several hours before bedtime; and avoiding diuretics and alcohol. Other medications to avoid include anticholinergics, antihistamines, and antidepressants.

Alternative Therapies for BPH

Many men are using herbal and nutritional therapies to support prostate health although there is no scientific proof that these are effective. Men are encouraged to lose weight if overweight; to eat a low-fat, high-fiber diet; and to drink a minimum of two quarts of water daily. Supplements to maintain prostate health include saw palmetto, pygeum, and zinc (Table 33.6). Because these are not found in standard pharmacologic compendiums, dosages for saw palmetto and pygeum should follow the manufacturer's recommendations.

TABLE 33.6 Alternative Therapies for Benign Prostatic Hyperplasia

Agent	Dosage
Saw palmetto	Doses vary based on manufacturer.
Pygeum	50–100 mg PO bid
Zinc	150 mg PO qd for 2 mo, 50–100 mg qd thereafter

Saw palmetto, a herb derived from the dark berries of a palm tree native to the southern United States, is reported to have been in use since the 1700s. Purportedly, it is useful for the management of prostate inflammation by a threefold mechanism. First, it inhibits testosterone conversion to DHT, resulting in the prevention of prostate enlargement. Second, it stops DHT binding to receptor sites; third, it has a general inhibitory effect on both estrogen and androgen receptors. There is no evidence of deleterious effects on PSA levels with the use of saw palmetto. Saw palmetto is available in capsule, liquid, or softgel form and as a tea; the tea is not believed to be effective for BPH. Saw palmetto often is used in combination with pygeum (http://www.sawpalmetto.com).

Pygeum is the ground and powdered bark of the pygeum tree, an evergreen of Southern Africa. It is prepared as a tea for easing complaints related to the genitourinary system. Widely used in Europe for symptom relief in BPH and thus postponement of surgery or the use of stronger medications, the efficacy of pygeum is being researched at the University of Southern California. Dosage recommendations are 50 to 100 mg twice daily; gastrointestinal irritation is a rare side effect (http://www.mothernature.com).

Zinc also plays a role in BPH, improving general prostate health by preventing or even decreasing prostate enlargement. Research has supported that doses of zinc sulfate lead to the inhibition of 5-α-reductase, the enzyme for conversion of testosterone to DHT. The recommended dosage for zinc sulfate is 150 mg/d for 2 months followed by a maintenance dose of 50 to 100 mg/d.

Prostate Cancer

In the decade from 1980 to 1990, the incidence of prostate cancer increased by 50%, although this is actually perceived as a positive development, indicating enhanced screenings rather than a truly increased incidence of disease. This disease is more common in African American men than in White men and, in general, in men from North, Central, and South America, Africa, and the Near East. Ironically, in African American men, prostate cancer develops at a significantly higher rate than in their native African counterparts. Men of Asian heritage have a low incidence of prostate cancer and low death rates from the disease. Once again, Asian American men have a slightly higher incidence of prostate cancer than their native Asian counterparts.

As men age, the overall risk of developing prostate cancer also increases. Incidence reports estimate that 6 or 7 of every 100 men who are currently 60 years old have a 6.29% chance of developing prostate cancer by the age of 70 (Howlader et al., 2014; U.S. Cancer Statistics Working Group, 2015).

Causes

The disease seems to be closely aligned with the aging process; the exact cause is not well understood, although a genetic predisposition has been found. Thus, sons of men who have had prostate cancer are at higher risk for developing prostate cancer themselves. No link between prostate cancer and BPH has been uncovered. From an environmental and occupational perspective, association with cadmium in the workplace is correlated with the later onset of prostate cancer.

Essentially, 95% of prostate cancers are adenocarcinomas, with most occurring at the prostate's periphery. How aggressive the neoplasm becomes seems to be more highly correlated with the degree of anaplasia, or lack of differentiation, of the cancer cells as opposed to tumor size. Progression of the cancer begins with local extension, but metastasis to distant sites occurs through blood and lymphatic vessels. Given the anatomic location of the prostate, it is easily understood how progression to the pelvis and rectum, lumbar and thoracic spine and ribs, and femur can ensue.

Pathophysiology

In many cases, symptoms present only with advanced disease. As with BPH, bladder-associated problems occur first—slow urine stream, inadequate emptying of bladder, painful urination, frequency, and nocturia. However, with prostate cancer, unlike BPH, there is no remission from these symptoms. Difficulty in defecation, and even obstruction of the large bowel, can also occur depending on how the tumor is spreading, but again this is usually seen with advanced disease.

Diagnostic Criteria

While early detection of prostate cancer is crucial, routine screening is controversial depending on age, and according to the U.S. Preventive Services Task Force (USPSTF), AUA, and needs to be a shared decision for men between 55 and 69 years of age (Eggener et al., 2015). That being said, prostate cancer remains a significant problem specifically for African American men who tend to be diagnosed at a more advanced stage, and their rate of survival is poorer than among Whites (Carter et al., 2010; Lehto et al., 2010). Thus, public education targeting African American men is of paramount importance.

Three screening methods are commonly used. The first is the DRE; the second is the serum level of PSA. When either result is abnormal, an ultrasound study is performed transrectally. The man should be cautioned to avoid ejaculation for 48 hours before obtaining a PSA because false-positive results may be obtained. The diagnostic yield rises dramatically when ultrasound is incorporated with DRE and PSA. It is recommended that all men older than age 45 undergo an annual DRE and all men older than age 50 have a conversation about annual testing of their PSA level in addition to the DRE. Normal PSA values should be less than 2.7 in men younger than age 40 and 4.0 or less in men older than age 40.

However, for confirmation of cancer, and with suspect findings, further diagnostic investigation is warranted. This includes a biopsy to confirm the diagnosis and identify the cancer's histologic type, after which MRI and CT scans are necessary to determine the extent of metastasis.

Treatment options include surgery, chemotherapy, and radiation, either alone or in combination. Regardless of the treatment modality, loss of physiologic function can occur. This loss of function varies from temporary loss of urinary control to permanent incontinence. In addition to loss of urinary control, fecal incontinence can also result. Sexual dysfunction frequently occurs and involves the ability to attain an erection or have emission or ejaculation. Return to normal physiologic function often occurs over time, but some permanent dysfunction can result.

Initiating Drug Therapy

Pharmacologic intervention can also help the patient return to normal physiologic function after other treatments, such as partial or radical prostatectomy, which are options based on the cancer's histologic type and the extent of metastasis. Often, surgery is performed after a period of radiation or chemotherapy. A main postoperative concern is that bladder dysfunction will persist; this manifests as incomplete emptying, incontinence, decreased force of stream, and urinary scarring.

Bilateral orchiectomy has also been used for advanced disease to decrease the risk of complications and spread of prostate cancer, but it is not considered curative in the setting of metastasis or advanced disease. Bilateral orchiectomy is radical surgery used to extend the man's life; it provides relief from symptoms. There is minimal morbidity and mortality associated with the surgery, but it may have a negative impact on the man's self-esteem and sense of identity. Postsurgical pharmacologic management is crucial to promoting the man's self-esteem and correcting, as much as possible, the altered physiologic function.

Erectile Dysfunction

ED is the most common sexual problem in men. It is defined as the repeated inability to achieve or maintain an erection that is firm enough for sexual intercourse. ED can be a total inability to achieve erection, an inconsistent ability to do so, or a tendency to sustain only brief erections. Approximately 18 million men in the United States over age 20 are affected by ED. The prevalence ranges from 20% to above 50% with increasing age. The prevalence is also increased threefold in men with diabetes. An organic cause can be found in about 80% of men with ED. The other 20% have psychogenic causes.

ED treatment costs in the United States are estimated at $328 million annually. Even with insurance, a patient may spend from $119 to $30,000 for ED therapy in 1 year.

Lifestyle choices associated with ED include being sedentary, obese, smoking, and abuse of either illicit substances (e.g., cocaine) or alcohol. Lower education levels are also associated with higher prevalence of ED.

Causes

An erection requires a precise sequence of events, and ED can occur when any of the events are disrupted. The sequence includes nerve impulses in the brain, the spinal column, and the area around the penis and response in muscles, fibrous tissues, veins, and arteries in and near the corpora cavernosa. As men age, libido decreases, probably because of a decline in testosterone levels. Cardiovascular diseases encompass vascular damage associated with diabetes, hypertension, coronary heart disease, and dyslipidemia. Any history of psychological or psychiatric problems including depression, anxiety, sexual abuse, or stress predisposes to developing ED. Damage to nerves, arteries, smooth muscles, and fibrous tissues (often as a result of disease) is the most common cause of ED. Chronic diseases such as diabetes, kidney disease, chronic alcoholism, multiple sclerosis, atherosclerosis, vascular disease, and neurologic disease account for about 70% of ED cases. Between 35% and 50% of men with diabetes experience ED. Psychological issues can also lead to ED, and it is often a combination of physical and psychological issues. See Box 33.1 for a list of risk factors for ED.

BOX 33.1 Risk Factors for Erectile Dysfunction

Advancing age

Cardiovascular disease

Cigarette smoking

Diabetes mellitus

History of pelvic irradiation or surgery, including radical prostatectomy

Hormonal disorders (e.g., hypogonadism, hypothyroidism, hyperprolactinemia)

Hypercholesterolemia

Hypertension

Illicit drug use (e.g., cocaine, methamphetamine)

Medications (e.g., antihistamines, benzodiazepines, selective serotonin reuptake inhibitors)

Neurologic conditions (e.g., Alzheimer disease, multiple sclerosis, Parkinson disease, paraplegia, quadriplegia, stroke)

Obesity

Peyronie disease

Psychological conditions (e.g., anxiety, depression, guilt, history of sexual abuse, marital or relationship problems, stress)

Sedentary lifestyle

Venous leakage

Surgery (especially radical prostate surgery for cancer) can injure nerves and arteries near the penis, thus causing ED. Injury to the penis, spinal cord, prostate, bladder, and pelvis can lead to ED by harming nerves, smooth muscles, arteries, and fibrous tissues of the corpora cavernosa.

Many common drugs such as antihypertensives, antihistamines, antidepressants, tranquilizers, appetite suppressants, and cimetidine can have ED as an adverse event. Psychological factors such as stress, anxiety, guilt, depression, low self-esteem, and fear of sexual failure cause 10% to 20% of ED cases. Other possible causes of ED include smoking, which affects blood flow in veins and arteries, and hormonal abnormalities, such as low testosterone levels.

Pathophysiology

Sexual performance in men has four stages: libido (desire), erection (arousal or engorgement), ejaculation, and detumescence. Problems in any stage can result in male sexual dysfunction. The basic mechanical or primary focus of ED is in stage 2. Erection is a complex neuroendocrine psychophysiological event that can occur even during sleep, indicating that sexual stimulation is not required.

Nitric oxide (NO) is essential for erection. The release of NO in the cells of the corpus cavernosa following parasympathetic stimulation leads to the conversion of guanylate cyclase to cyclic guanosine monophosphate (cGMP). This causes smooth muscle relaxation that permits the influx of blood causing engorgement of the penis. This mechanism also slows the outflow of venous blood from the penis thus enhancing penile engorgement. Other contributors to vasodilation during erection include vasoactive intestinal peptide (VIP) and prostaglandins E1 and E2 (PGE1 and PGE2).

The penis is innervated by both autonomic and somatic nerves. Sympathetic and parasympathetic fibers in the cavernous nerves regulate blood flow into the corpus cavernosum during erection and detumescence. Erection, at the level of the penis, begins with transmission of impulses from parasympathetic nerves and nonadrenergic, noncholinergic nerves. This neural stimulus leads to the release of nitric oxide from the nonadrenergic, noncholinergic nerves and possibly the endothelial cells. Nitric oxide increases intracellular levels of cGMP in the cavernosal smooth muscle, which acts to relax cavernosal tissue, perhaps by activating protein kinase G and stimulating phosphorylation of the proteins that regulate corporal smooth muscle tone. The actions of the parasympathetic nervous system, nitric oxide, and cGMP permit rapid blood flow into the penis and the development of an erection. As pressure within the corporal body increases, small emissary veins traversing the tunica albuginea are occluded, trapping blood in the corpus cavernosum. The erection is maintained until ejaculation, which usually leads to detumescence.

Phosphodiesterases (PDEs) are hydrolytic enzymes that play a critical role in regulating physiologic processes by terminating signal transduction through their hydrolytic action on cyclic nucleotides. They play a key role in the physiology of erection.

Significant changes in penile structure occur with aging. Collagen and elastic fibers in the tunica albuginea are key structures that permit increases in the girth and length of the penis during tumescence, and ultrastructural analysis of penile biopsies has shown that the concentration of elastic fibers decreases with age. This decrease results in a reduction in elasticity, which could contribute to ED in elderly men. Additionally, there is a decrease of up to 35% in the smooth muscle content of the penis in men older than age 60. Decreases in the ratio between corpus cavernosum smooth muscle and connective tissue have been associated with increased likelihood of diffuse venous leak that may contribute to ED. It

has also been noted that the concentration of type III collagen decreases and that of type I collagen increases in the aging penis. It has been suggested that this change makes the corpus cavernosum less compliant, reduces filling of vascular spaces, and also contributes to veno-occlusive dysfunction. It has also been hypothesized that changes in the collagen content of the penis may result in chronic ischemia that leads to loss of smooth muscle cells. Any condition, disease, medication, or injury or surgery that affects the ability to initiate erections or to fill the lacunar space or store blood may cause ED.

ED involves multiple organic and psychogenic factors, which often coexist. Psychogenic factors are the most common causes of intermittent ED in younger men, but these are usually secondary to or may coexist with organic factors in older men. Other factors contributing to ED include vasculogenic, neurogenic, endocrinologic, structural (traumatic), and pharmacologic causes and lifestyle factors, such as obesity, a sedentary lifestyle, and alcohol and tobacco use. Many of the conditions that contribute to ED are chronic and systemic, involving multiple avenues of damage. These conditions include cardiovascular disease, hypertension, diabetes mellitus, and depression. Many of the diseases linked to ED involve endothelial dysfunction.

There are many drugs that can affect erectile function. These include

- alcohol
- analgesics
- anticholinergics
- anticonvulsants
- antidepressants
- antihistamines
- antihypertensives
- anti-Parkinson agents
- corticosteroids
- diuretics
- nicotine
- tranquilizers

Diagnostic Criteria

A thorough history is paramount to diagnosing ED. Every male patient should be asked about medical conditions, medications, and sexual function. Initial diagnostic workup should usually be limited to a fasting serum glucose level and lipid panel, thyroid-stimulating hormone test, and morning total testosterone level.

Initiating Drug Therapy

ED can be very traumatic to men. There are now drugs that can assist with achieving and maintaining an erection that is firm enough for sexual intercourse. Testosterone levels should be determined, and a complete cardiac history and evaluation should be done to determine whether there are contraindications to these medications. Approximately one third of men with ED do not respond to therapy with phosphodiesterase-5 (PDE5) inhibitors.

Goals of Drug Therapy

The goals of drug therapy for ED are to enable the patient to achieve sexual satisfaction and to achieve and maintain an erection.

Phosphodiesterase-5 Inhibitors

PDE5 inhibitors promote penile erection by inhibiting the breakdown of one of the messengers involved in the erectile response. PDE5 is the main cGMP-catalyzing enzyme in human trabecular smooth muscle. It is also expressed in vascular smooth muscle, lung, platelets, and a wide variety of other tissues but is not present in cardiac muscle cells. Human corpus cavernosum also contains PDE types 2, 3, and 4 enzymes. PDE5 inhibitors are contingent on the presence of cGMP in the smooth muscle cell. In the presence of sexual stimulation, PDE5 inhibitors reinforce the normal cellular signals that increase cyclic nucleotide concentrations by blocking cyclic nucleotide hydrolysis, thereby facilitating the initiation and maintenance of an erection.

Dosage

The recommended dosage of sildenafil is 50 mg 30 to 60 minutes before intercourse, but doses range from 25 to 100 mg. The maximum is one dose a day. Food can delay absorption, especially if taken close to a fatty meal.

The recommended dose of tadalafil is 10 mg, but doses range from 5 to 20 mg. Tadalafil can be taken without restriction on food or alcohol intake.

The recommended dose of vardenafil is 10 mg, but doses range from 2.5 to 20 mg. It is taken 60 minutes before intercourse. Food can delay absorption.

Avanafil (Stendra) is a new novel second-generation PDE5 inhibitor with a much shorter half-life. The recommended dose is 100 mg, but doses range from 50 to 200 mg. It is taken 15 minutes prior to intercourse. Dosing is not restricted by food intake, but alcohol intake should be limited.

Time Frame for Response

Sildenafil (Viagra) and vardenafil (Levitra) are rapidly absorbed, reaching maximum plasma concentrations within 30 to 120 minutes (median 60 minutes) of oral dosing in the fasted state; a high-fat meal has been found to reduce the rate of absorption. The elimination half-life is approximately 4 hours, and no more than one dose should be taken per 24-hour period.

Tadalafil (Cialis) has an onset of action of 30 minutes and allows intercourse for at least 30 hours. This is significant because it may eliminate the need for planning sexual activity.

Avanafil (Stendra) has an onset of action of 30 to 45 minutes. Absorption occurs quickly following oral administration elimination half-life of 5 hours. As with sildenafil and

vardenafil, no more than one dose should be taken in 24 hours.

Contraindications

PDE5 inhibitors can potentiate the vasodilatory properties of nitrates, so their administration in patients who use nitrates in any form is contraindicated. In an emergency situation, nitrates can be used 24 hours after administration of sildenafil and vardenafil and 48 hours after tadalafil.

PDE5 inhibitors are contraindicated in patients with unstable angina, hypotension with a systolic blood pressure below 90 mm Hg, uncontrolled hypertension of more than 170/110 mm Hg, history of recent stroke, life-threatening arrhythmia, myocardial infarction (MI) within 6 months, and severe cardiac failure. They are also contraindicated in patients with severe hepatic impairment or end-stage renal disease requiring dialysis.

Sildenafil has a relative contraindication with the concomitant use of α-blockers and should not be taken within 4 hours of an α-blocker and at a dose no greater than 25 mg. Tadalafil should not be taken with an α-blocker other than tamsulosin, 0.4 mg once a day. Vardenafil is contraindicated with any α-blocker. Avanafil should be administered cautiously with an α-blocker, preferably at the 50 mg dose.

Adverse Events

Most adverse events are vasodilatory, including headache, flushing, and nasal congestion. Dyspepsia has also been reported. With sildenafil, abnormal color vision has been reported.

Interactions

Potent CYP3A4 inhibitors can cause increased levels of PDE5 inhibitors. They may also be affected by amlodipine, beta blockers, cimetidine, diuretics, and erythromycin.

Selecting the Most Appropriate Agent

It is important to include the significant other in counseling about ED. A complete cardiac history must be taken. If there is any question as to the stability of the cardiac status, further testing must be done. Testosterone, serum glucose (or alternatively glycosylated hemoglobin), and serum lipid levels must be determined in all cases of ED. Depending on patient history and physical examination findings, more extensive laboratory tests may be necessary. If testosterone levels are abnormal, testosterone replacement is needed. See Table 33.7 for selected agents.

TABLE 33.7 Overview of Selected Agents Used to Treat Erectile Dysfunction

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
tadalafil (Cialis) 5–20 mg/d	Headache, flushing, GI disturbance, nasal congestion, rash, priapism	Nitrates and α-blockers except tamsulosin 0.4 mg once a day	Food and alcohol make no difference in absorption. May remain in system for 36 h.
vardenafil (Levitra, Staxyn) 5–20 mg/d	As above	Nitrates and α-blockers	High-fat meal delays absorption.
sildenafil (Viagra) 25–100 mg/d	As above and color disturbances	Nitrates and within 4 h of an a blocker and at a dose no >25 mg	As above
avanafil (Stendra) 50–200 mg/d	As above	Nitrates and α-blockers	Food makes no difference in absorption. Caution with alcohol.

The patient with the following factors is considered at low risk for a cardiac event with the use of PDE5 inhibitors: fewer than three risk factors for coronary artery disease; controlled hypertension; mild, stable angina; uncomplicated MI more than 8 weeks previously; mild valvular disease; and New York Heart Association class 1 heart failure. See Box 33.2 and Figure 33.3.

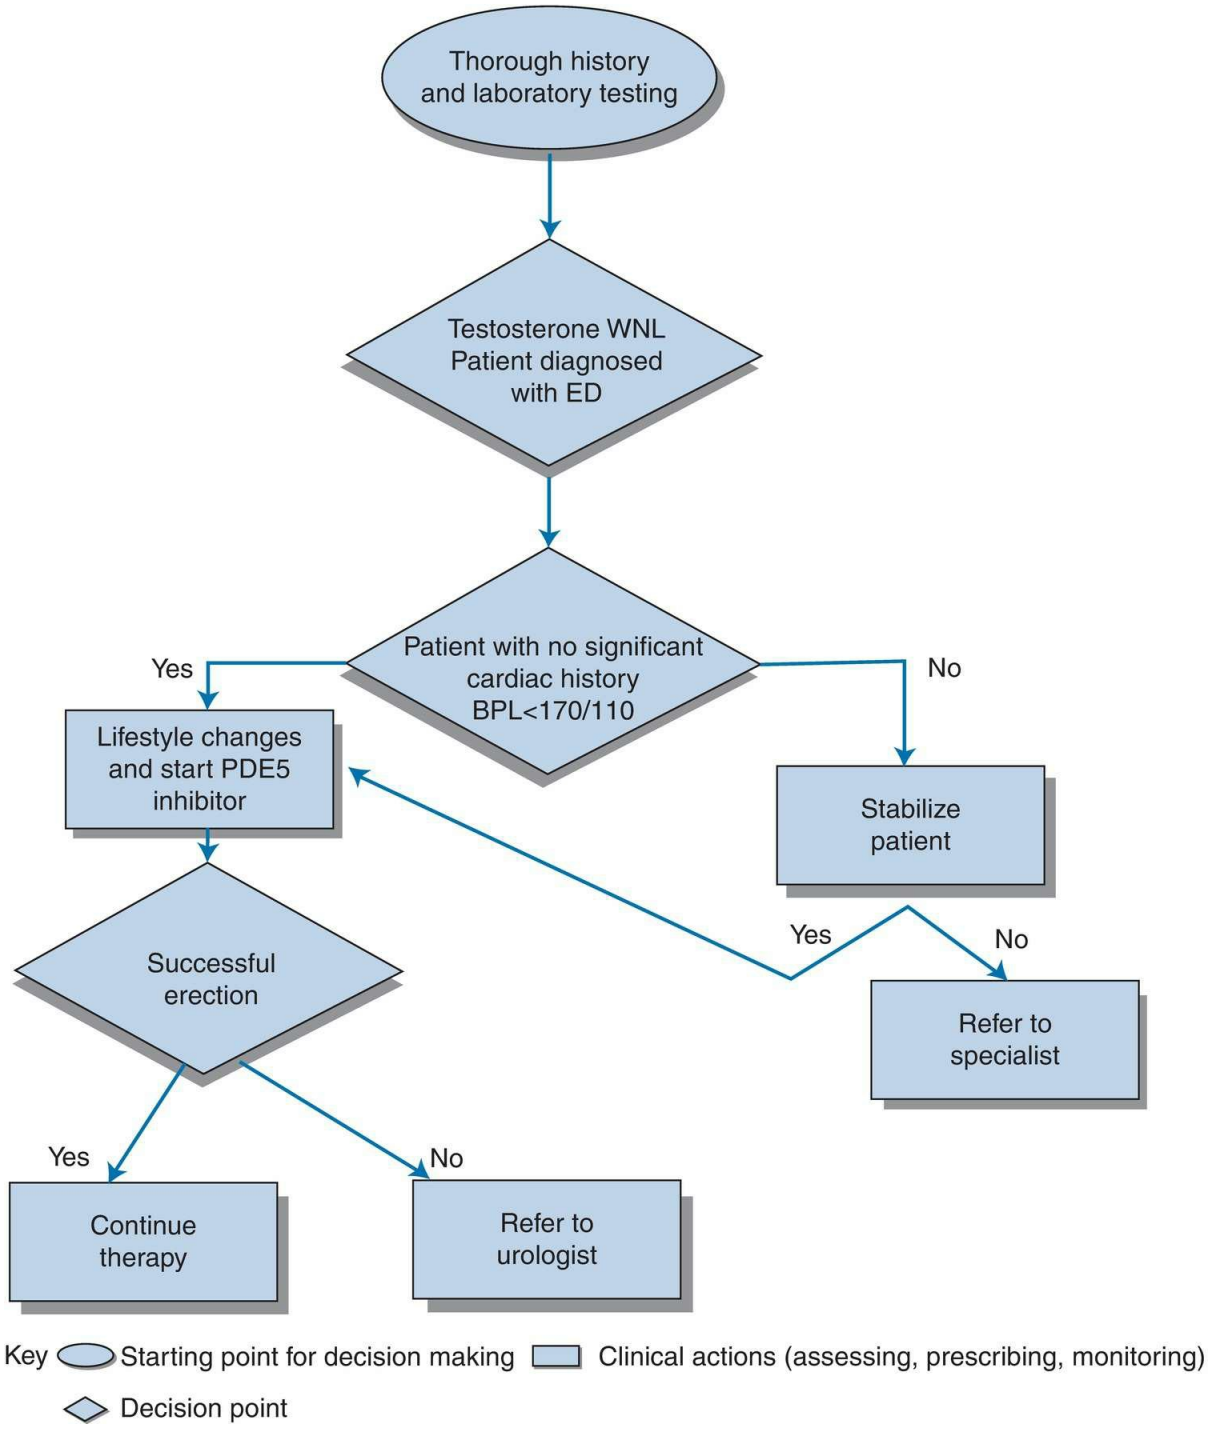

FIGURE 33.3 Treatment algorithm for erectile dysfunction (ED).

BOX 33.2 Low-Risk Factors for Cardiac Events from PDE5 Inhibitors

Fewer than three risk factors for coronary artery disease

Controlled hypertension

Stable angina

Uncomplicated MI more than 8 weeks previously

Mild valvular disease

New York Heart Association class 1 heart failure (see Chapter 22)

First-Line Therapy

First-line therapy for ED is aimed at lifestyle changes and modifying pharmacotherapy that may contribute to ED. A PDE5 inhibitor is also prescribed (Table 33.8).

TABLE 33.8 Recommended Order of Treatment for Erectile Dysfunction

Order	Agent	Comment
First line	PDE5 inhibitors	Contraindicated if on nitrates, unstable hypertension, unstable cardiac condition
Second line	Referral to urologist	Procedures available include penile intracavernosal injection therapy, medical intraurethral system for erections, vacuum erection device, penile prostheses

Second-Line Therapy

If PDE5 inhibitors are not successful in treating ED, the patient should be referred to an urologist. Alternative therapies include penile intracavernosal injection therapy, a medical intraurethral system for erections, a vacuum erection device, and penile prostheses.

Monitoring Patient Response

The patient should be followed in 6 months to determine the effectiveness of therapy and to re-evaluate his cardiac status. If the patient does not meet the criteria for low risk, the PDE5 inhibitors are discontinued.

Patient Education

Drug Information

With sildenafil and vardenafil, a high-fat meal has been found to reduce the rate of absorption. Food and alcohol have no effect on the absorption of tadalafil.

Sildenafil has a relative contraindication with the concomitant use of α-blockers and should not be taken within 4 hours of an α-blocker and at a dose no greater than 25 mg. Tadalafil should not be taken with an α-blocker other than tamsulosin 0.4 mg once a day. Vardenafil is contraindicated with any α-blocker.

Complementary and Alternative Medicine

Yohimbine, an agent derived from the bark of the African yohimbe tree, has been found to be beneficial in some cases of ED. It is reported to act by both peripheral and central mechanisms, acting peripherally as a presynaptic stimulant at parasympathetic nonnoradrenergic, noncholinergic transmitter (NANC) nerves and presynaptically as an adrenergic depressant at sympathetic alpha$_1$-adrenoceptors, both mechanisms augmenting penile blood flow. It also appears to have central nervous system activity, with blockade of the erection-suppressing α_2-adrenoceptors; several studies have reported a more favorable response with yohimbine compared with placebo in ED of psychogenic origin. Ginkgo biloba, ginseng, human chorionic gonadotropin (HCG), and l-arginine are some of the popular supplements advertised for ED. Patient should be asked about use of these therapies, and those patients who choose to continue use should be monitored for adverse effects and potential drug–drug interactions.

Case Study*

M.P., age 45, works as an accountant in a busy firm. He is of African American descent. He and his wife have been married for 25 years and have 2 children, ages 21 and 18. His father is alive and well at age 68 but was diagnosed with BPH 5 years ago. M.P. considers himself to be in good health and has no allergies; he is approximately 15% overweight. His wife insisted that he seek medical intervention because of urinary symptomatology: he has difficulty starting his stream of urine, burning on urination, nocturia, and lower back and pelvic discomfort. The result of a PSA test, his first in over 2 years, is 3.1.

Diagnosis: BPH

1. List specific goals for treatment for M.P.
2. What drug therapy would you prescribe? Why?
3. What are the parameters for monitoring the success of the therapy?
4. Discuss specific patient education based on the prescribed therapy.
5. List one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What would be the choice for second-line therapy?
7. What over-the-counter and/or alternative medications would be appropriate for this patient?
8. What dietary and lifestyle changes should be recommended for this patient?
9. Describe one or two drug–drug or drug–food interactions for the selected agent. Use caution if on another antihypertensive because α-blockers may intensify the effect.

* Answers can be found online.

34 Overactive Bladder

Jennifer A. Reinhold

Overactive bladder (OAB) is a highly prevalent yet underreported condition that transcends the boundaries of race, gender, and socioeconomic class. OAB is loosely defined by the International Continence Society (ICS) as a constellation of symptoms that include primarily urinary urgency usually accompanied by frequency (voiding eight or more times per 24 hours) and nocturia (awakening two or more times at night to void), with or without urge urinary incontinence (UUI). It is a symptom syndrome and not a discrete diagnosis. The most recent data suggest that OAB affects between 16% and 17% of adults in the United States, or about 34 million people. However, given the substantial underreporting and the inherent challenges in identifying sufferers of OAB, the actual prevalence is likely markedly higher. Women and men tend to be affected by OAB proportionately; however, women are more likely than men to present with the symptom of incontinence as part of their clinical picture. The incidence of OAB increases linearly with age and is predicated on a number of factors that are impacted by aging. However, OAB with or without incontinence is not considered a normal part of aging; OAB symptomatology and any instance of urgency are always considered pathologic.

OAB syndrome has extensive ramifications with respect to morbidity, mortality, and economic impact. A preponderance of literature supports the assertion that OAB is associated with increased rates of depression, decreased self-esteem, social isolation, general fragility, and falls and fracture. Upon development of OAB symptoms, patients tend to engage in avoidance behaviors in order to escape the social stigma and embarrassment associated with urinary incontinence (UI) or urinary urgency. Eventually, this translates into substantial lifestyle changes and the potential for social isolation. Total costs attributable to OAB are estimated to be $65.9 billion ($49.1 billion direct medical, $2.3 billion direct nonmedical, and $14.6 billion indirect) (Ganz et al., 2010). A leading cause of morbidity in the elderly population and the most commonly cited reason for assisted living and long-term care facility admission, OAB needs to be assessed in the primary care setting preemptively.

The terms OAB, detrusor overactivity (DO), and UI are frequently used interchangeably erroneously. UI is a possible symptom as part of the symptomatology construct that constitutes OAB; it does not necessarily need to be present in patients diagnosed with OAB. While urgency is the cardinal symptom of OAB and must be present in order to yield a diagnosis of OAB, only about 25% to 35% of patients experience *incontinence* as well. DO implies an involuntary and inappropriate contraction of the bladder; however, it is considered a surrogate marker of OAB that may or may not correlate

with urgency. DO is further delineated into idiopathic (absence of an identifiable cause) or neurogenic (an underlying neurological condition, deficit, or injury is the causative factor). There is considerable overlap between nonpharmacologic and pharmacologic treatments for OAB, UI, and DO; therefore, UI subtypes will be discussed. The accepted nomenclature for UI differentiates between the underlying pathophysiology and the nature of the urine loss. UUI implies a strong and sudden urge to urinate that cannot be deferred and results in involuntary loss of urine. Stress urinary incontinence (SUI) occurs when an internal or external force impacts the bladder or the musculature that supports it. Common examples of such pressures include coughing, sneezing, heavy lifting, or prolapsed pelvic organs. Mixed UI is a combination of both SUI and UUI. The historical term *overflow incontinence*, which suggested some level of obstruction or voiding difficulty, has been replaced with bladder outlet obstruction (BOO) and is no longer part of the classification schema.

Causes

The exact cause of the OAB symptom constellation is multifactorial and not completely elucidated. There are numerous underlying anatomic, physiologic, and comorbidity-related factors that precipitate or exacerbate OAB. The majority of cases are considered idiopathic, with the remainder being attributed to myogenic or neurogenic causation.

Pathophysiology

The bladder and the corresponding micturition cycle are controlled by a complex, coordinated interplay among the central nervous system (CNS), peripheral nervous system, and the anatomic components of the lower urinary tract (LUT). The LUT is composed of the bladder, urethra, bladder outlet, internal and external urethral sphincters, and the musculature of the pelvic floor (Figure 34.1). The discord between the continuous production of urine (1 to 2 L/d) and the episodic nature of voiding necessitates the storage of urine. The bladder (detrusor muscle) is a highly compliant, viscoelastic hollow organ that expands to accommodate the storage of urine while maintaining a constant pressure throughout this filling phase. As the bladder fills, it maintains a pressure that is lower than that of the urethra, therefore facilitating the development of a pressure gradient that prevents urine from being expelled. The normal urge to void is under voluntary control, and therefore, only when the bladder reaches a critical volume, or about 75% of total capacity, will an individual feel the desire to void. This urge, which is different from pathologic urgency and is under different neural control, can be deferred until an appropriate time. Upon conscious and deliberate urination, the urethral resistance decreases and phasic contractions in the bladder result in increased bladder pressure and the subsequent voiding of urine.

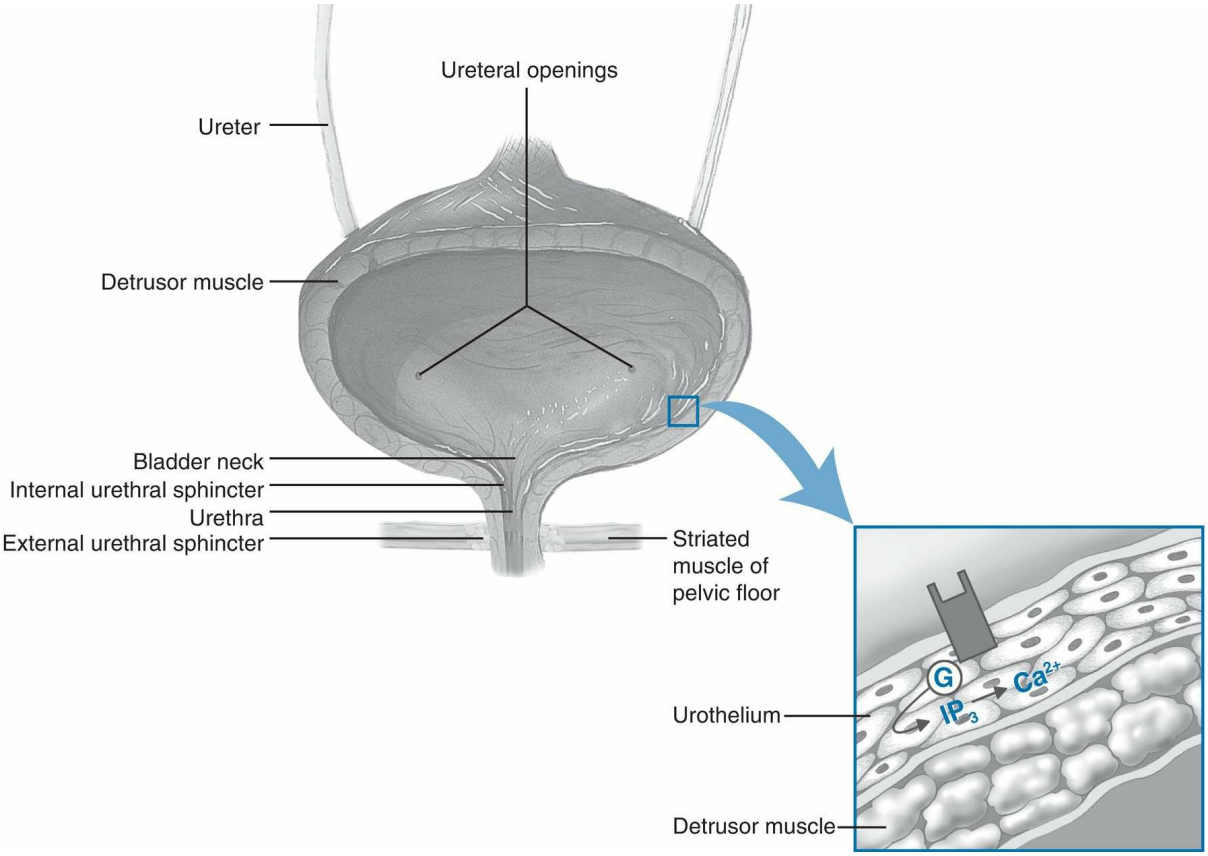

FIGURE 34.1 M_3 receptors are coupled to G proteins, which activate phospholipase, generating inositol triphosphate (IP_3). IP_3 causes the release of stored Ca^{2+}, which stimulates bladder contraction.

The LUT is innervated by efferent and afferent neuronal complexes involving sympathetic, parasympathetic, and somatic nerves. The *sympathetic* nervous system primarily stimulates urethral sphincter closure and detrusor relaxation during filling, while the *parasympathetic* system influences contraction of the detrusor and relaxation of the urethral sphincters during the emptying phase. Somatic innervation maintains the tone of the striated pelvic floor muscles and the external urethral sphincter (Table 34.1). The bladder is continuously bombarding the CNS with afferent signals during the filling phase via Aδ fibers and C fibers. These normal impulses indicate when the bladder is filling and also when it is nearing capacity. The impulses are transmitted to higher brain centers such as the cortex, pons, and brain stem, which also exert some level of control over micturition. The sensations generated by this neurotransmission will result in variable degrees of the normal urge to urinate. The Aδ fibers generally respond to the mechanical stretch of the bladder during the filling phase. However, during pathologic conditions, it is thought that the unmyelinated C sensory fibers may precipitate abnormal OAB sensations. The C sensory fibers are dappled with vanilloid receptors (which can be stimulated by capsaicin), purinergic receptors or $P2X_2$ and $P2X_3$ (which can be stimulated by adenosine triphosphate), and neurokinin receptors (which can be stimulated by neurokinin A and

substance P). (see Figure 34.2).

TABLE 34.1 Bladder and Urethral Innervation

Nerve	Anatomic Location	Nervous System	Spinal Cord Origin	Physiologic Function
Pudendal	External sphincter	Somatic	S2, S3, S4	Maintains tone in pelvic floor Excitatory innervation to external urethral sphincter
Pelvic	Urethra	Parasympathetic	S2, S3, S4	Relaxes sphincter
Hypogastric	Urethra	Sympathetic	T1–L2	Stimulates sphincter closure
Pelvic	Bladder neck	Parasympathetic	S2, S3, S4	Relaxes sphincter
Hypogastric	Bladder neck	Sympathetic	T1–L2	Stimulates sphincter closure
Pelvic	Bladder	Parasympathetic	S2, S3, S4	Contraction of detrusor during micturition
Hypogastric	Bladder	Sympathetic	T1–L2	Relaxes detrusor during filling phase

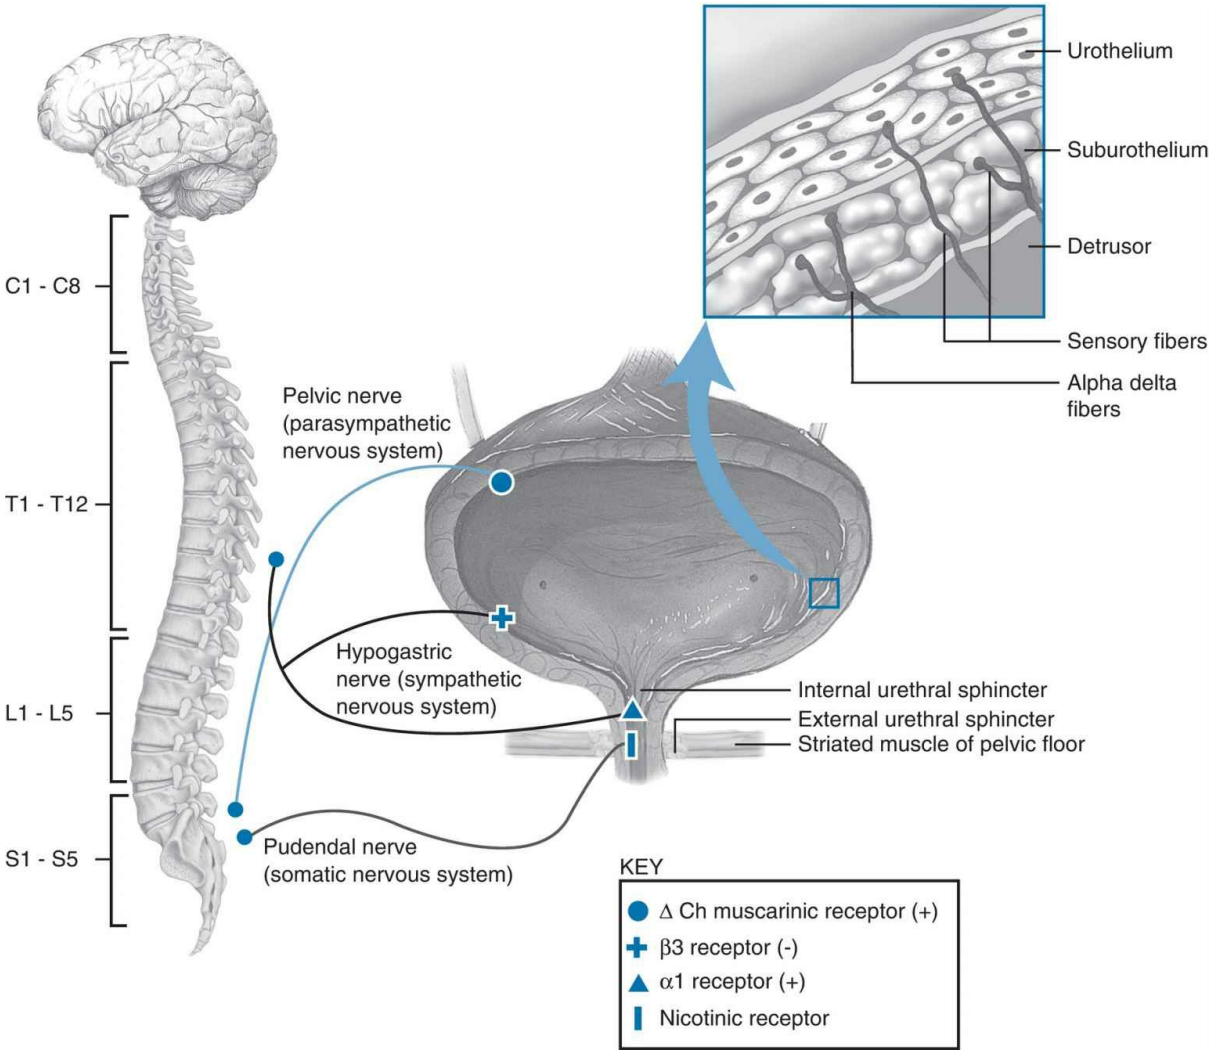

FIGURE 34.2 The bladder is innervated by the sympathetic, parasympathetic, and somatic nervous systems. The pudendal nerve maintains external sphincter and pelvic muscle tone. The pelvic nerve stimulates bladder contraction. The hypogastric nerve stimulates internal sphincter closure and detrusor relaxation.

Acetylcholine-mediated activation of muscarinic receptors is the predominant physiologic mediator of detrusor contraction. Muscarinic receptor subtypes M_1, M_2, and M_3 are found in the urinary bladder; however, it is the M_3 subtype that is primarily responsible for bladder contraction. These receptors, particularly the M_3 subtype, have become drug targets for purposes of treating OAB.

Any aberration of any individual component or combination of components involved in the micturition reflex can result in OAB or UI, as can separate comorbid conditions or physiologic states. Transient and reversible conditions or behaviors may contribute to symptoms consistent with OAB, namely, increases in fluid intake or increases in caffeine or alcohol consumption. Benign prostatic hyperplasia (BPH) or obstruction can manifest in incontinence. Sacral nerve damage can lead to urinary retention. Irrespective of the etiology

of OAB, the common themes include increased bladder pressure at low volumes during filling, altered response to stimuli, amplified myogenic activity and contraction, and changes in the smooth muscle anatomy.

Owing to the poor electrical coupling between smooth muscle bundles in the bladder, the highly innervated bladder is able to ignore some of the errant impulses that would otherwise cause unwanted contraction. Patchy denervation and morphologic changes in the electrical coupling may result in bladder hypertrophy and incomplete emptying. Abnormal micturition can be stimulated by damage to the afferent neurons in the dorsal root ganglia as well, which can then confer an abbreviated delay in the micturition reflex. Ischemic conditions such as diabetic neuropathy, peripheral vascular disease, and urethral stricture may also result in compromised blood flow and ultimately neuronal death with subsequent detrusor hyperactivity. Inevitable physiologic changes that occur during the aging process may also contribute to impaired cortical inhibition of bladder contraction. Stroke, Alzheimer disease, and multiple sclerosis have been implicated in contributing to the disease process as well. Nonneurogenic conditions may also yield OAB symptoms; polyuria may be produced by uncontrolled diabetes, and nocturia may be precipitated by sleep apnea (Box 34.1).

BOX 34.1 Factors That May Precipitate or Worsen Overactive Bladder

Neurologic Conditions
- Stroke

Spinal cord injury
Diabetic neuropathy
Alzheimer disease
- Multiple sclerosis

Systemic or Metabolic Conditions
- Sleep disorders (apnea)

Venous insufficiency/heart failure
- Diabetes mellitus

Behavioral Considerations
- Excessive fluid or caffeine consumption

Constipation
- Impaired mobility

Psychological Conditions
- Depression

Medications
- Diuretics

Narcotic pain relievers

Calcium channel blockers
Alpha-adrenergic antagonists
Anticholinergics
  Alpha-adrenergic agonists
Miscellaneous
  Prostate enlargement
  Estrogen deficiency
Urinary Tract Pathology
  Urinary tract infection
  Urinary obstruction

Once OAB symptoms have emerged, a self-propelling cycle of factors can further exacerbate the condition. Urgency, a central feature of OAB, increases the frequency of micturition and therefore reduces the volume of each micturition provided that fluid intake remains constant. This sometimes leads to incomplete bladder emptying and subsequent residual volume that promotes the urgency and increased frequency of urination. Similarly, DO can result from neurogenic or myogenic causes. The contractions tend to be weak, which results in incomplete bladder emptying, a reduced bladder capacity, and therefore increased urinary frequency.

Diagnostic Criteria and Evaluation

OAB is a markedly underreported condition, owing mostly to the embarrassment and stigma with which it is associated. It tends to elude the typical clinical assessments and patient interviews that constitute the primary care visit and is generally diagnosed only when it is reported by the patient. The only diagnostic criteria that have been firmly established are the presence of urgency with or without nocturia and frequency. These criteria are inherently subjective; however, there have been attempts to impose objective measurements and ratings in order to determine whether a symptom is pathologic.

Current recommendations suggest that pointed questioning should be integrated into the patient interview during routine primary care visits in order to capture urinary symptoms that may otherwise be overlooked. If patient complaints or interview-generated information is suggestive of OAB, the practitioner should perform a genitourinary exam and urinalysis as well as a more in-depth medical history that is germane to urinary health. One of the major goals of this interview would be the establishment of potential causative factors acutely or chronically (acute infection, changes in fluid intake, menstrual history, obstetric history, prostate pathology). The urinalysis is intended to assist in ruling out hematuria or an infection.

Since abnormalities or pathology in the LUT can precipitate OAB symptoms, it is imperative to evaluate the bladder, urethra, and pelvic floor muscles as well. In patients at risk for urinary retention (diabetics, spinal cord injury patients, patients with BPH), more invasive testing may be required. A residual urine volume of more than 100 mL suggests urinary retention, and these patients may need to be evaluated by cystoscopy to rule out malignancy. OAB is a constellation of symptoms, all of which could be reasonably attributed to other conditions. Therefore, OAB is often diagnosed after the exclusion of other pathology. Primarily, infections, cancers (bladder, prostate), structural abnormalities (urethral, prostate), and urinary retention should be ruled out during the evaluation process.

A neurologic exam, with emphasis on the sacral neuronal pathways, is recommended because OAB may be caused by neurogenic LUT dysfunction. In addition to assessments of gait, abduction/dorsiflexion of toes, and sensory innervation to the LUT, a rectal exam will provide some information relevant to voluntary sphincter control. In males specifically, a measurement of prostate-specific antigen (PSA) and administration of the American Urological Association's subjective symptoms assessment (AUA-7) should occur (Box 34.2).

BOX 34.2 Diagnostic Differential

Bladder cancer, bladder calculus, interstitial cystitis

Endometriosis
Prostate cancer
Urethral calculus
Bacterial cystitis, prostatitis, urethritis
Urinary retention, polyuria, psychogenic urinary frequency

One of the tools with the highest level of clinical evidence is the "bladder diary" or "voiding diary," a patient-generated daily log that includes fluid intake and urinary output with corresponding times. Typically, entries are made by the patient over either a 3- or 7-day period. It yields information regarding urinary habits, estimation of bladder capacity, volume voided with each micturition, diurnal and nocturnal frequency, urgency, and incontinence. A number of clinical trials have used this tool to assess outcomes and have found that bladder diaries are an accurate measure of OAB symptoms, including urgency. Another parameter that is thus far not validated is "warning time," the length of time between an initial perception of the urge to void and the time at which it can no longer be deferred.

The use of urodynamic testing (UDT), the comprehensive evaluation of bladder and urethral performance during micturition, has been met with some controversy. UDT consists of a collection of urodynamic assessments that range from simple direct observations to complex, sophisticated, invasive evaluations. In order to best assess a LUT dysfunction or OAB, the symptoms need to be reproducible in a clinical setting. Table 34.2 provides a list of the possible components of UDT. UDT is not required for a diagnosis of OAB; however, it may be indicated if there is suspicion of a BOO, neurogenic voiding dysfunction, or an uncertain diagnosis.

TABLE 34.2 Urodynamic Testing

Component	Description	Clinical Utility
Uroflowmetry	Measurement of the volume over urine voided, speed at which voiding occurs, and duration of void	Obstruction is likely if speed is <10 mL/s.
Postvoid residual (PVR)	After voiding, determination of PVR made via ultrasound or through catheterization	<25 mL is considered normal and >100 mL is abnormal.
Multichannel filling cystometry	Evaluation of bladder capacity, bladder compliance, and at what volume the urge to void occurs; accomplished by filling the bladder with normal saline and measuring detrusor pressure	Bladder pressure during filling should be <10 cm H_2O; dysfunction is diagnosed if the pressure rises at an unacceptable rate.
Leak point pressure	Evaluation of the first urine leakage and the abdominal pressure at which it occurs; the patient is instructed to perform Valsalva maneuver (e.g., coughing); patient is observed for urine leakage.	Low readings (<40 cm H_2O) are associated with sphincter weakness.
Pressure flow study	Assesses the interaction among the bladder, bladder outlet, pelvic floor, and urethra during voiding; patient is instructed to void with all catheters in place (catheters include urethral catheterization and possibly vaginal or rectal catheterization).	Useful for diagnosing bladder outlet obstructions
Electromyography	Assessment of the coordination between the perineal muscles and the bladder	Useful in diagnosing neurogenic etiology of OAB

Initiating Drug Therapy

Once a diagnosis of OAB has been established, the subsequent steps include an assessment of the degree of impairment or annoyance resulting from OAB, initiation of empiric or disease-specific therapy if required, treatment of comorbid conditions, and referral to a specialist if warranted. If it is determined that the patient is significantly bothered by OAB and/or has begun to engage in avoidance behaviors that are compromising quality of life, therapy should be initiated. The 2014 American Urological Association (AUA) recommends utilizing behavioral therapies as the first-line intervention, a series of behaviors that change patient behavior or the environment. The most common behavioral interventions are bladder training, pelvic floor muscle exercises, and weight loss. The nondrug therapies usually are ultimately combined with pharmacologic therapy (Table 34.3 and Figure 34.3).

TABLE 34.3 OAB Medication Overview

Medication	Usual Dose	Uroselectivity	Clinical Considerations	Level of Evidence
Anticholinergics/Antimuscarinics				
oxybutynin (Ditropan)	5–15 mg orally three times daily	No	Dry mouth occurs in up to 66% of patients. Indicated for neurogenic and nonneurogenic detrusor overactivity	1A
oxybutynin ER (Ditropan XL)	5–15 mg orally once daily	No	Dry mouth occurs in up to 66% of patients. Indicated for neurogenic and nonneurogenic detrusor overactivity	1A
oxybutynin (Oxytrol transdermal patch)	3.9 mg/patch twice weekly (every 3–4 d)	No	Dry mouth occurs half as frequently as compared to the oral formulation.	1A
tolterodine (Detrol)	2 mg orally twice daily	Yes	Incidence of dry mouth is 20% to 25%.	1A
tolterodine ER (Detrol LA)	4 mg orally once daily	Yes	Dry mouth occurs in <20% of patients.	1A
trospium (Sanctura)	20 mg orally twice daily	Yes	Take before meals or on an empty stomach. No CYP P-450 metabolism	1A
trospium extended release (Trospium XR)	60 mg orally once daily	Yes	Take before meals or on an empty stomach. No CYP P-450 metabolism	1A
solifenacin (VESIcare)	5–10 mg orally once daily	Yes		1A
darifenacin hydrobromide (Enablex)	7.5–15 mg once daily (may titrate up to 15 mg after 2 wk if tolerated)	Yes	Possibly less impact on cognitive function than other antimuscarinics	1A
fesoterodine (Toviaz)	4–8 mg orally daily	No	Less CYP2D6 interaction potential	1A
Beta-3-Adrenoreceptor Agonists				
mirabegron (Myrbetriq)	25–50 mg orally once daily	Yes	Less incidence of anticholinergic and cognitive adverse effects	1B
onabotulinumtoxinA 100U injections (interval undetermined but generally every 6–9 mo) OnabotulinumtoxinA (Botox)		Yes	Efficacy maintained for several months; possible risk of urinary retention and voiding dysfunction	B, C
Serotonin Norepinephrine Reuptake Inhibitors				
duloxetine (Cymbalta)	40–80 mg orally once daily	No	Avoid concomitant administration with other serotonergic drugs.	1A
Alpha-Adrenergic Antagonists				
alfuzosin (Uroxatral)	2.5 mg orally three times daily	No	4D	
doxazosin (Cardura)	1–16 mg orally once daily	No	Dizziness occurs in up to 20% of patients.	4D
prazosin (Minipress)	1–10 mg orally twice daily	No	4D	
tamsulosin (Flomax)	0.4–0.8 mg orally once daily		No	4D
terazosin (Hytrin)	1–10 mg orally at bedtime	No	4D	
silodosin (Rapaflo)	8 mg orally once daily	No	Retrograde ejaculation occurs in up to 28% of patients.	4D

Medication	Usual Dose	Uroselectivity	Clinical Considerations	Level of Evidence
Miscellaneous				
1 tablet vaginally (estradiol) daily for 2 wk and then 1 tablet twice weekly 0.5 g cream applied nightly for 2 wk and then twice weekly				
estrogen	Vaginal ring: 2 mg intravaginally; following insertion, ring should remain in place for 90 d.	No	Risk of worsening estrogen-responsive malignancies Potential for CHD risk	4D
desmopressin	20–40 mg spray intranasally at bedtime 0.1–0.4 mcg orally 2 h prior to bedtime	No	Risk of worsening estrogen-responsive malignancies Potential for CHD risk	1B

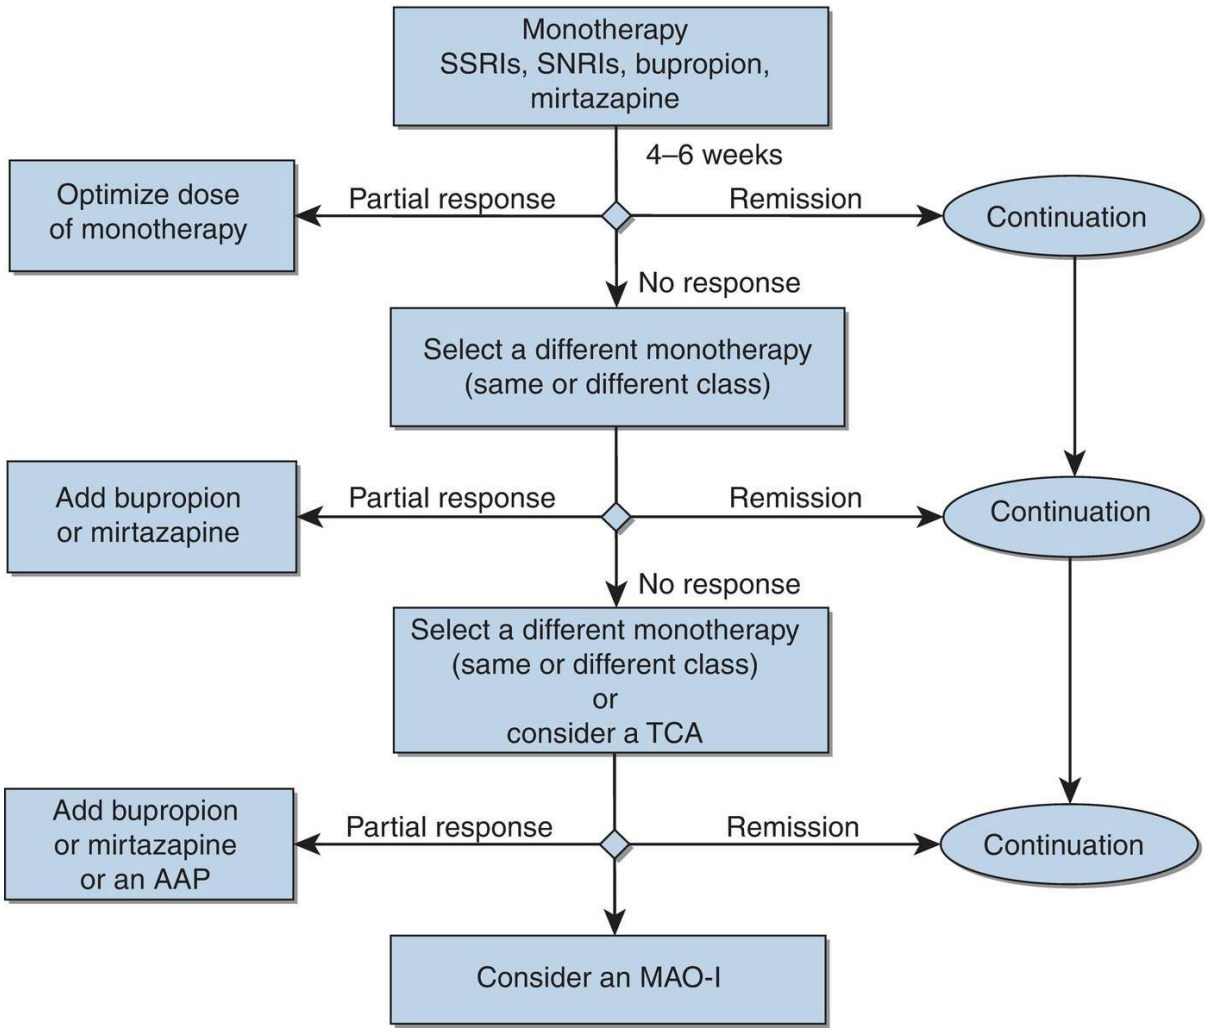

FIGURE 34.3 Treatment algorithm for overactive bladder.

The *anticholinergic* or antimuscarinic drugs (oxybutynin, tolterodine, trospium, darifenacin, solifenacin, fesoterodine) have the greatest level of evidence with respect to their safety and efficacy in treating OAB and are recommended as first-line pharmacologic therapy by the 2014 AUA guidelines. Their clinical use is sometimes limited, however, by their inherent anticholinergic adverse effects, most commonly dry mouth, blurred vision, constipation, cognitive dysfunction, and urinary retention. This is particularly challenging because the population with the highest prevalence of OAB is the elderly, an age cohort that is also more predisposed to cognitive dysfunction, urinary retention, and visual disturbances.

If tolerability issues preclude the use of anticholinergic drugs, tricyclic antidepressants (TCAs; imipramine), desmopressin, topical estrogens for females, and alpha-adrenergic antagonists for males are appropriate alternatives. There is emerging evidence about the role of selective serotonin reuptake inhibitors (SSRIs) and serotonin norepinephrine reuptake inhibitors (SNRIs) in treating OAB syndrome. Vanilloids and afferent nerve inhibitors such as capsaicin or resiniferatoxin are in the investigation phases to assess their utility in managing OAB.

The combination of pharmacologic and nonpharmacologic treatment tends to yield superior outcomes and clinical success. "Bladder training" encompasses pelvic floor exercises, scheduled voiding, urge suppression skills, and extensive patient education. Over 70% of patients who are considered cognitively competent experience a meaningful reduction in incontinence episodes over a 2- to 3-month period as a result of employing bladder training and pelvic floor exercises (Ouslander, 2004). Benefit may still be derived from prompted scheduled voiding in patients who are cognitively impaired. In refractory cases of OAB, biofeedback devices that deliver electrical stimulation via vaginal or rectal probes augment the pelvic floor exercises. In severe or refractory patients, surgical interventions, such as neural ablation, slings, and neuromodulating device implantation, may be attempted. This will be further discussed.

Compensatory behaviors such as limiting fluid intake or reducing the frequency of diuretics are not recommended, although patients frequently engage in these behaviors. Self-imposed fluid restriction may precipitate dehydration and subsequent increased fall risks, cognitive impairment, worsened renal function, and changes in drug metabolism. Altering diuretic administration could negatively impact the treatment of other conditions or result in fluid overload. The use of absorbent pads or undergarments may help to mitigate the social stigma aspect of OAB, especially in patients who experience incontinence. Rushing to find a restroom when urgency occurs also predisposes patients to falls and fractures (Box 34.3).

BOX 34.3 Behavioral Modifications

Reduce fluid consumption.
Reduce alcohol consumption.
Reduce caffeine consumption.
Start bladder training.
Perform pelvic floor exercises.

Goals of Drug Therapy

The intended outcome of pharmacologic therapy is primarily resolution of symptoms (urgency, frequency, nocturia), cessation of incontinence episodes (if present), and a full return to previous level of social functioning. In the event of a comorbid mood disorder (depression, anxiety) that emerged as a consequence of OAB, goals of therapy would include resolution of this disorder as well. Patients suffering from OAB are at an increased risk for urinary tract infections, and those with associated incontinence are at risk for perineal skin infections. These corresponding issues may resolve spontaneously upon treatment of the OAB and/or incontinence; however, additional drug therapy may be required (Table 34.4).

TABLE 34.4 Medication Pharmacokinetics and Clinical Considerations

Drug	Metabolism	Interactions	Contraindications	Clinical Considerations
Antimuscarinics				
oxybutynin	Minor substrate of CYP3A4	CYP3A4 inhibitors or inducers Pramlintide may enhance the anticholinergic effects of anticholinergics.	Narrow-angle glaucoma, urinary retention	Xerostomia (29%–71%; dose related) Constipation (7%–15%)
tolterodine	Major substrate of CYP2D6 and 3A4 Minor substrate of CYP2C9 and 2C19	Strong CYP2D6 or 3A4 inhibitors or inducers Systemic azole antifungals may decrease metabolism of tolterodine. Tolterodine may enhance the anticoagulant effect of warfarin.	Urinary retention, narrow-angle glaucoma	Prolonged QTc interval at supratherapeutic doses CYP2D6 poor metabolizers more likely to exhibit QTc prolongation Dosage adjustment for renal impairment Dry mouth (35%; ER capsules, 23%)
trospium	Not fully elucidated; thought to be metabolized by esterase hydrolysis and conjugation	Pramlintide may enhance the anticholinergic effect of anticholinergics.	Bladder flow obstruction, narrow-angle glaucoma	Dosage adjustment of IR trospium in renal impairment Avoid use of ER trospium in patients with renal impairment.
Drug	**Metabolism**	**Interactions**	**Contraindications**	**Clinical Considerations**
solifenacin	Major CYP3A4 substrate	Major inhibitors or inducers of CYP3A4 Grapefruit juice may increase the serum level effects of solifenacin.	Bladder flow obstruction, narrow-angle glaucoma	Dosage adjustment for severe renal impairment (CrCl < 30 mL/min)
darifenacin	Major substrate of CYP3A4 and minor substrate of 2D6 Moderate inhibitor of 2D6 and minor inhibitor of 3A4	CYP3A4 or 2D6 inhibitors or inducers	Uncontrolled narrow-angle glaucoma; urinary retention, paralytic ileus, GI or GU obstruction Concomitant administration of thioridazine	Xerostomia (19%–35%), constipation (15%–21%)
fesoterodine	Parent compound metabolized to active metabolite (5-HMT) by nonspecific esterases 5-HMT metabolized by CYP2D6 and CYP3A4	CYP3A4 or 2D6 inhibitors or inducers	Bladder flow obstruction, narrow-angle glaucoma	Dose adjustment in patients with severe renal impairment (CrCl < 30 mL/min)
OnabotulinumtoxinA				
onabotulinumtoxinA (Botox). No metabolism. Neuromuscular blocking agents and aminoglycoside antibiotics can potentiate the neuromuscular effect of onabotulinumtoxinA.			Hypersensitivity to onabotulinumtoxinA	Black box warning for distant spread (can result in muscle weakness, life-threatening breathing issues)
Serotonin Norepinephrine Reuptake Inhibitors				
duloxetine	Major substrate of CYP1A2 and 2D6 Moderate inhibitor of 2D6	CYP1A2 or 2D6 inhibitors or inducers MAO inhibitors or thioridazine	Concomitant use or within 2 wk of MAO inhibitors; uncontrolled narrow-angle glaucoma	Ulcerogenic potential increased with NSAIDs (increased risk of bleeding) Serotonin syndrome or neuroleptic malignant syndrome risk Not recommended when CrCl <30 mL/min
Alpha-Adrenergic Antagonists				
alfuzosin	Major substrate of CYP3A4	Strong CYP3A4 inhibitors	Strong CYP3A4 inhibitors (itraconazole, ketoconazole, ritonavir)	Avoid concomitant use with other alpha-1-antagonists. Potential to cause dizziness
doxazosin	Major substrate of CYP3A4	Strong CYP3A4 inhibitors	Strong CYP3A4 inhibitors (itraconazole)	Dizziness may occur in up to 28% of patients.
prazosin	Major substrate of CYP3A4	Strong CYP3A4 inhibitors	Strong CYP3A4 inhibitors (itraconazole)	Dizziness
tamsulosin	Major substrate of CYP3A4	Strong CYP3A4 inhibitors	Strong CYP3A4 inhibitors (itraconazole)	Dizziness
terazosin	Major substrate of CYP3A4	Strong CYP3A4 inhibitors	Strong CYP3A4 inhibitors (itraconazole)	Dizziness
silodosin	Major substrate of CYP3A4	Strong CYP3A4 inhibitors	Strong CYP3A4 inhibitors (itraconazole)	Retrograde ejaculation

Anticholinergic/Antimuscarinic Drugs

As a class, antimuscarinic drugs are the mainstay of pharmacologic therapy for OAB and UI. Anticholinergic drugs are considered first-line therapy and typically will be used even after clinical failure or intolerance to an initial anticholinergic medication. The class is divided into tertiary and quaternary amines, differing with respect to lipophilicity, molecular size, and charge. High lipophilicity, small molecular size, and low charge confer upon the tertiary amines (oxybutynin, tolterodine, solifenacin, darifenacin, fesoterodine) easy transfer into the CNS via the blood–brain barrier. The quaternary amine trospium tends to not be as well absorbed and has limited ability to cross the blood–brain barrier (Table 34.5).

TABLE 34.5 Molecular Properties of Antimuscarinic Drugs

Drug	Molecular Classification	Corresponding Molecular Characteristics	Clinical Characteristics
Oxybutynin Tolterodine Solifenacin Darifenacin Fesoterodine	Tertiary amine	High lipophilicity Small molecular size Low charge	Extensive transfer into CNS Increased risk of cognitive adverse effects
Trospium	Quaternary amine	Low lipophilicity Large molecular size High charge	Limited transfer into CNS Reduced risk of cognitive adverse effects

Mechanism of Action

The mechanism of action of each of the medications is relatively similar, with the exception of oxybutynin. Generally, anticholinergics mediate a pharmacologic action by antagonizing the parasympathetic muscarinic receptors in the bladder with relative selectivity for the M_3 and M_1 subtypes. Antagonism of the M_3 muscarinic receptors manifests as a reduction in spontaneous myocyte activity, a decrease in frequency, and a reduction in contraction intensity. They effectively increase bladder capacity, decrease the intensity and frequency of bladder contractions, and delay the initial urge to void. Oxybutynin is both an antimuscarinic and an antispasmodic (secondary to direct muscle relaxation) as well as a local anesthetic.

Oxybutynin boasts a lengthy and robust history of efficacy with respect to OAB and UI. A tertiary amine, oxybutynin is highly lipophilic and easily crosses the blood–brain barrier, thereby conferring higher rates of CNS and anticholinergic adverse effects. The potential for cytochrome P-450 (CYP) enzyme interactions is relatively high as well. Secondary to these adverse effects and interaction potential, oxybutynin may not be well tolerated in all patient populations. Oxybutynin undergoes extensive first-pass metabolism to its active metabolite, N-desmethyl oxybutynin, which is purported to produce most of the pharmacologic activity and adverse effects. Up to 80% of patients will report at least

one significant muscarinic-mediated adverse effect during therapy, up to 20% of whom will subsequently discontinue therapy. Xerostomia, experienced by up to 70% of patients, is dose related but is also the most common reason cited for discontinuing oxybutynin therapy. Despite these inherent limitations, the use of oxybutynin remains prevalent among all available formulations. The extended-release (ER; Ditropan XL) formulation of oxybutynin has been clinically shown to be equally efficacious but is associated with less adverse effects than the conventional formulation. The transdermal oxybutynin patch (Oxytrol) causes roughly 75% less dry mouth as compared to ER tolterodine and is now available without a prescription. The transdermal system releases drug constantly over 96 hours at which time the patch is replaced.

Tolterodine (Detrol) is a competitive antagonist of muscarinic receptors that causes increased residual urine volume and decreased detrusor pressure. It is associated with clinically meaningful reductions in micturition frequency as well as incontinence episodes. In comparison to oxybutynin, tolterodine use yields less dosage changes, adverse effects, and treatment-related therapy discontinuations. Tolterodine ER (Detrol LA) is 18% more effective in reducing the incidence of incontinence as compared to the regular formulation and is responsible for 23% less xerostomia (Robinson & Cardozo, 2010). ER oxybutynin, however, is significantly more efficacious than ER tolterodine in reducing micturition frequency.

Trospium (Sanctura) is a nonselective muscarinic receptor antagonist that improves urinary frequency, episodes of incontinence, urgency, and volume voided. A quaternary ammonium compound, trospium crosses the blood–brain barrier only to a limited extent, which confers a reduced likelihood of cognitive sequelae. Trospium may possess a therapeutic advantage in patients with comorbidities that require drug therapy, given its negligible hepatic metabolism and low risk of drug interactions.

Solifenacin (VESIcare) is a bladder-selective M_3 receptor antagonist that has been shown to be statistically significantly more efficacious than ER tolterodine with respect to urge incontinence, overall incontinence, and urgency. In another pivotal study, solifenacin was shown to reduce episodes of urgency and increase warning time. It is postulated that solifenacin may provide a greater level of efficacy as compared to other drugs within the class. However, despite its bladder selectivity, solifenacin causes dose-related dry mouth in over 20% of patients and xerostomia-related treatment discontinuation in almost 5%, a frequency that is of clinical importance but is lower than other members of this class (Cipullo, 2014).

Darifenacin (Enablex), a tertiary amine, is a highly selective M_3 receptor antagonist that is effective in reducing frequency of micturition, increasing bladder capacity, reducing frequency and severity of urgency, and reducing the number of episodes of incontinence. A comparative advantage associated with darifenacin is its lack of cognitive impairment, as evidenced in multiple randomized controlled trials.

Fesoterodine (Toviaz), a prodrug, is converted to its active metabolite 5-hydroxymethyl

tolterodine (5-HMT), which exerts a pharmacologic effect as a competitive antagonist at the muscarinic receptors. Tolterodine (Detrol) is metabolized to 5-HMT via a CYP2D6-mediated oxidation, and both tolterodine and 5-HMT are responsible for the pharmacologic effect of Detrol. Fesoterodine, however, does not require CYP2D6 activation and therefore may have less potential for pharmacokinetic variability and CYP2D6-specific drug interactions.

The AUA recommends initiating an ER anticholinergic as first-line therapy but does not recommend a specific product.

Time Frame for Response

Expected therapeutic response is variable among members of this class. Generally, a meaningful response would be realized within about 2 weeks. However, evidence suggests that patients taking tolterodine ER experienced reduced micturition, urgency episodes, and incontinence by day 5 of therapy. Trospium may exert a clinical effect as early as day 1 with regard to incontinence, day 3 for urgency, and day 5 for micturition frequency.

Contraindications

Anticholinergic medications are capable of precipitating or worsening urinary retention as well as worsening narrow-angle glaucoma. Both of these conditions, if present in the patient prior to therapy, represent contraindications to the use of antimuscarinics. Antagonism of muscarinic receptors and subsequent down-regulation of acetylcholine activity can result in paralysis of smooth muscle in the bladder or gastrointestinal tract. Additionally, mydriasis can occur with increased intraocular pressure; therefore, anticholinergics should be avoided in patients with narrow-angle glaucoma. Tolterodine, trospium, solifenacin, and fesoterodine require a dosage reduction in the case of severe renal impairment (creatinine clearance [CrCl] less than 30 mL/min). However, the ER formulation of trospium should be avoided in patients with severe renal impairment (Table 34.6).

TABLE 34.6 Antimuscarinic Medication Dosing Considerations

	Oxybutynin	Tolterodine	Trospium	Solifenacin	Darifenacin	Fesoterodine
Usual dose	IR: 5–15 mg orally three times daily ER: 5–15 mg orally once daily Patch: 3.9 mg/patch twice weekly (every 3–4 d)	IR: 2 mg orally twice daily ER: 4 mg orally once daily	IR: 20 mg orally twice daily ER: 60 mg once daily ≥75: 20 mg orally once daily	5–10 mg orally once daily Dosage adjustment with concomitant CYP3A4 inhibitors: Maximum dose 5 mg/d	7.5–15 mg once daily Dosage adjustment with concomitant potent CYP3A4 inhibitors (e.g., azole antifungals, erythromycin, protease inhibitors): 7.5 mg/d	4–8 mg orally daily
Renal insufficiency		**CrCl 10–30 mL/min: IR: 1 mg twice daily ER: 2 mg daily ** *Use with caution*	CrCl ≤30 mL/min: IR: 20 mg once daily at bedtime ER: Use not recommended	CrCl <30 mL/min: Maximum dose 5 mg/d		Severe renal impairment (CrCl <30 mL/min): 4 mg
Hepatic insufficiency		IR: 1 mg twice daily ER: 2 mg daily		Moderate (Child-Pugh class B): Maximum dose 5 mg/d Severe (Child-Pugh class C): Use not recommended	Moderate impairment (Child-Pugh class B): Daily dosage should not exceed 7.5 mg/d. Severe impairment (Child-Pugh class C): Use not recommended	Severe hepatic impairment (Child-Pugh class C): Use not recommended
CYP interactions	CYP3A4 inhibitors or inducers	Strong CYP2D6 or 3A4 inhibitors or inducers Azole antifungals		Major inhibitors or inducers of CYP3A4	CYP2D6 and 3A4 inhibitors	Strong CYP3A4 inhibitors

Adverse Events

The expected adverse event profile includes traditional anticholinergic effects such as xerostomia, constipation, and urinary retention. Antimuscarinic drugs exert an action mainly during the storage phase of the micturition cycle when there is an absence of parasympathetic activity in the detrusor. During the emptying phase of micturition, there is a massive release of acetylcholine, which effectively blunts the drug's action. If this did not occur, the presence of the active drug would undoubtedly decrease the ability of the bladder to contract to promote urinary retention. Prescribing these drugs within the confines of acceptable dosing typically does not precipitate urinary retention; however, overdose or pharmacokinetic interactions may do so.

Interactions

Most antimuscarinic drugs are metabolized by one or more CYP P-450 isoenzymes, the most common of which are CYP3A4 and CYP2D6. Heterozygous or CYP2D6 homozygous patients are considered "extensive metabolizers," which implies an innate ability to appropriately metabolize drugs via this isoenzyme. However, patients who are poor metabolizers with respect to CYP2D6 may be at an increased risk for drug-related toxicity secondary to their inability to fully metabolize CYP2D6-metabolized drugs. Trospium is metabolized exclusively by nonspecific esterases independent of the hepatic CYP P-450 system. Notable drug interactions within the anticholinergic class tend to

involve pharmacokinetic interactions at the enzyme level and typically manifest as increases or decreases in drug metabolism. Solifenacin and tolterodine are capable of causing prolonged QTc, particularly in supratherapeutic dosing. Concomitant administration of other QTc-prolonging medications can potentiate a pharmacodynamic interaction that may result in arrhythmia.

Beta-Adrenoreceptor Agonists

Mirabegron (Myrbetriq) is a selective beta-3-adrenoreceptor agonist that increases bladder capacity and decreases the frequency of micturition without impacting micturition pressure or residual volume. Detrusor relaxation is achieved in part by activation of beta-3-adrenoreceptors by norepinephrine, which subsequently results in activation of adenylyl cyclase, and formation of cAMP, which produces smooth muscle relaxation. Bladder relaxation is crucial during the storage phase of micturition as it allows for compliance and low intravesical pressure during filling. Mirabegron, through its interaction with the beta-3-adrenoreceptor, promotes relaxation during filling and therefore increases bladder capacity, which then influences frequency of micturition. This is the first novel compound for the treatment of OAB, which has been able to produce a therapeutic effect without engaging the muscarinic receptors and producing anticholinergic adverse effects, a limiting factor associated with the mainstay of therapy, the antimuscarinic drugs.

Mirabegron, in daily doses of 25 to 200 mg, was evaluated in several 12-week randomized, placebo-controlled phase III studies, which support its efficacy, safety, and tolerability. Treatment with mirabegron resulted in decreased incontinence episodes, decreases in the number of micturitions, decreases in urgency episodes, and increases in mean volume voided per urination. Therapeutic effects were observed as early as week 4 and persisted throughout the duration of the studies. Meaningful and statistically significant improvements in these micturition parameters and in quality of life measures were observed in patients who were treatment naive and in patients who had failed or were intolerant to the antimuscarinics. Several studies that utilized tolterodine ER 4 mg as an active control reported similar efficacy and tolerability among the mirabegron and tolterodine groups, although no direct statistical comparisons occurred. Rates of xerostomia were significantly higher in patients treated with tolterodine, however. Evaluation of the available literature suggests that mirabegron is similar in efficacy to the antimuscarinics but with a lower incidence of adverse effects.

Dosage

Mirabegron is available as a 25- or 50-mg extended-release 24-hour tablet, which is formulated as an oral-controlled absorption system (OCAS). Generally, 25 mg daily is sufficient to control symptoms of urgency, frequent urination, and UI. An increase to 50 mg daily can be considered dependent upon observed efficacy and tolerability in the individual patient. Maximum daily doses of 25 mg are recommended for patients with severe renal impairment or moderate hepatic impairment. It is not recommended in patients with end-stage renal disease or severe hepatic impairment. Mirabegron is approximately 70% bound to albumin and alpha-1-acid glycoprotein and is extensively metabolized through multiple pathways including dealkylation, glucuronidation, oxidation, and hydrolysis, as well as enzymatically metabolized through CYP3A4 and CYP2D6. Metabolism of mirabegron produces 10 pharmacologically inactive metabolites. The 50-

hour elimination half-life allows for once-daily dosing.

Time Frame for Response

A therapeutic effect is usually realized within the first 8 weeks of therapy, at which point a decision regarding the need to a dosage increase can be considered. Meaningful improvements in parameters of micturition were observed in studies as early as week 4, however.

Contraindications

Mirabegron does not have specifically labeled contraindications; however, dose-related QT prolongation has been observed in clinical studies. Prolongation of the QT interval was observed in female patients on the 200-mg dose of mirabegron, a dose that is supratherapeutic and is not available in the market. Doses of 50 to 100 mg daily did not elicit any electrocardiogram abnormalities in any evaluation. However, patients with QT prolongation or at risk of QT prolongation (taking concurrent medications that prolong QT) should avoid mirabegron.

Adverse Events

Long-term safety and tolerability studies suggest that the rate of treatment-emergent adverse effects is similar between mirabegron and placebo and tends to be mild to moderate in intensity. As compared to tolterodine, mirabegron causes less xerostomia, constipation, urinary retention, and blurred vision. It also does not induce neurological adverse effects such as cognitive impairment, which tends to be associated with the antimuscarinics. Meaningful increases in blood pressure were observed during clinical studies, although hypertension is not considered a contraindication. Monitoring blood pressure is recommended, however.

Interactions

There are no clinically meaningful drug interactions related to the hepatic metabolism with the exception of drugs metabolized by CYP2D6, as mirabegron is a moderate inhibitor of this isoenzyme.

Given mirabegron's efficacy in treatment-experienced and treatment-naive patients as well as its low potential for drug interactions, mild adverse effect profile, and absence of cognitive impairment-related sequelae, mirabegron may become a first-line option. Mirabegron can be considered an appropriate intervention in patients at risk of cognitive impairment and those who are elderly. Treatment discontinuation is a frequent and unfortunate reality with regard to the antimuscarinic drugs, the current treatment of choice. There is no evidence thus far related to treatment adherence with mirabegron, though one of its advantages is its low incidence of adverse effects.

OnabotulinumtoxinA (Botox)

Botulinum toxin serotype A, a purified version of *Clostridium botulinum*, is a neurotoxin, which has demonstrated utility in OAB and DO. Two noninterchangeable products are currently approved and marketed for both neurogenic bladder and urge incontinence: Botox (onabotulinumtoxinA) and Dysport (abobotulinumtoxinA). The preponderance of evaluation and evidence focuses on the Botox product. Generally, the use of injectable botulinum toxin is reserved for patients who have failed more than one of the recommended initial drug therapies (anticholinergics or mirabegron) and are considered refractory. The 2014 AUA guidelines have officially incorporated botulinum toxin into its therapeutic recommendations and consider it a third-line option.

Mechanism of Action

Botulinum toxin, when injected into the detrusor muscle, inhibits calcium-dependent release of acetylcholine, adenosine triphosphate, and substance P and reduces the expression of capsaicin receptors on motor neurons. The resulting desensitization of the motor neurons ultimately causes inhibition of the afferent and efferent pathways that influence DO. In addition to the motor effects, botulinum toxin also modulates the sensory aspect of DO by reducing the expression of vanilloid and muscarinic (M_1, M_2, and M_3) receptors in the suburothelium. The resulting flaccid paralysis in the detrusor reduces bladder pressure, increases bladder capacity, reduces incontinence episodes, and reduces perceived urgency. The effect is permanent and persists until the motor endplate units regenerate after 3 to 24 months, necessitating additional treatment.

Randomized controlled studies have demonstrated onabotulinumtoxinA's sustained efficacy over 6 months in reducing incontinence episodes, improving nocturia, improvement in voiding frequency, improvement in urgency episodes, and improvement in quality of life indicators. Clinical success was achieved in upwards of 70% of patients. Voiding dysfunction and urinary tract infections were the most commonly reported adverse effects.

Optimal dosing and dosing interval have yet to be established; however, there appears to be a balance between efficacy and tolerability at doses of 100 U per injection. Higher doses demonstrated similar efficacy much appreciably higher rates of adverse effects, namely, urinary retention. The duration of therapeutic effect is dependent upon the regrowth of the motor end units on the affected neurons and, therefore, is highly variable. Most patients require retreatment after 6 to 9 months.

Contraindications, Adverse Events, and Interactions

Adverse effects tend to be restricted to urinary tract infections and urinary retention secondary to the localized placement of the botulinum toxin. Urinary tract infection has been observed in 18% to 49% of patients and urinary retention in 6% to 17% of patients.

A condition of treatment, as recommended by the product labeling and the AUA guidelines, is willingness and ability of the patient to self-catheterize. Education on technique should be provided prior to initiating therapy. Systemic adverse effects do not occur unless there is unintended spread of the botulinum toxin beyond the site of injection. A black box warning includes statements related to the blurred vision, dysarthria, muscle weakness, ptosis, dysphagia, and life-threatening breathing difficulties that could indicate unintentional spread of the toxin from its injection site.

Contraindications include sensitivity to the product or patients with existing urinary retention. Botulinum toxins are not metabolized, and therefore, interactions are limited to other drugs that may potentiate the neuromuscular-blocking effects such as anticholinergics, neuromuscular-blocking drugs, and aminoglycoside antibiotics.

Serotonin Norepinephrine Reuptake Inhibitors

Venlafaxine (Effexor) and duloxetine (Cymbalta), SNRIs, have been evaluated as nontraditional therapies for OAB.

Mechanism of Action

Serotonin facilitates urine storage, augmenting parasympathetic innervation and inhibiting sympathetic innervation to the bladder. During the filling phase, glutamate is released and acts upon Onuf nucleus. Onuf nucleus is a discrete confluence of neurons in the anterior horn of the sacral region of the spinal cord, which is involved in the micturition reflex, continence, and muscular contraction during orgasm. The action of glutamate in Onuf nucleus activates the pudendal nerve and subsequent release of acetylcholine, which elicits contraction of the external urethral sphincter. The dense population of the nucleus with serotonin and norepinephrine receptors implies a facilitator role for these monoamines with regard to the micturition reflex and urine storage. Duloxetine enhances urethral sphincter activity and is associated with dose-dependent decreases in episodes of incontinence and improvements in quality of life. It is believed that duloxetine exerts this effect by increasing the availability of serotonin and norepinephrine in the synaptic clefts of Onuf nucleus. Nausea occurs in about 25% of patients but tends to subside by day 7 of treatment. Numerous studies support the use of SNRIs alone or in combination with pelvic floor muscle exercises.

Contraindications, Adverse Events, and Interactions

Duloxetine may not be used concurrently with MAO inhibitors or within 2 weeks of discontinuing an MAO inhibitor. Duloxetine is metabolized in the liver by CYP3A4 and CYP2D6 and therefore is subject to pharmacokinetic interactions with strong inhibitors of these isoenzymes. It is not to be coadministered with thioridazine because there is a significant CYP2D6-mediated interaction that may result in increased concentrations and toxicity in both drugs. Concomitant administration of duloxetine with other medications that have serotonergic or noradrenergic actions may increase the risk of serotonin syndrome or neuroleptic malignant syndrome.

Alpha-Adrenergic Antagonists

The alpha-adrenergic antagonists have proven efficacy and tolerability with respect to treating BPH in males. However, some studies suggest that tamsulosin may reduce bladder pressure, increase the flow rate, and provide symptomatic improvement in patients with OAB and a confirmed obstruction. The extent to which OAB symptoms are relieved is appreciably less than the resolution of symptoms of obstruction. Use in women is controversial because alpha-adrenergic antagonists may precipitate stress incontinence in female patients.

Mechanism of Action

Alpha-adrenergic antagonists, or alpha-blockers, competitively inhibit postsynaptic alpha-1-adrenergic receptors in prostate and bladder tissue. The antagonism reduces the sympathetic-mediated urethral stricture that is associated with BPH or BOO symptoms.

Adverse Events

Postural hypotension is one of the most clinically relevant adverse effects that may occur. All of the drugs in this class have the potential to induce this effect; however, doxazosin precipitates postural hypotension in upwards of 30% of patients. It is of special concern since the majority of patients who would likely be taking an alpha-1-antagonist are elderly and are predisposed to postural hypotension and subsequent falls.

Interactions

The alpha-1-antagonists are metabolized by CYP3A4, and concomitant administration with strong CYP3A4 inhibitors should be avoided. Also, secondary to the potential to cause hypotension, more than one alpha-blocker should not be used concurrently.

Estrogens

Despite the dearth of anecdotal evidence supporting the use of estrogens for symptomatic improvement of OAB and incontinence in females, randomized, controlled trials have yielded contradictory results at best. Unopposed systemic estrogen therapy or combination estrogen/progesterone therapy is associated with an increase in SUI and UUI episodes, as was evidenced by several large multinational studies. Topical estrogen therapy in the form of vaginal estradiol tablets (Vagifem) or the estrogen-releasing vaginal ring (Estring) has, however, demonstrated some symptomatic improvement. The vaginal tablet improved urgency, frequency, urge incontinence, and stress incontinence. The vaginal ring improved urge incontinence, stress incontinence, and nocturia. The therapeutic effect is attributed to increasing the maximum urethral pressure, although some clinicians hypothesize that it is due to reversal of urogenital atrophy and not direct bladder or urethral activity.

Mechanism of Action

Topical estradiol exerts a local action that improves tone and elasticity of female urogenital anatomy by increasing secretion of the cervical mucosa, thickening vaginal mucosa, and proliferation of the endometrium. Both the vaginal tablet and the vaginal ring are indicated for urinary urgency and dysuria.

Contraindications

Patients with undiagnosed vaginal bleeding, a history of breast carcinoma or estrogen-dependent tumors, and thromboembolic disorders (deep vein thrombosis, pulmonary embolism, stroke, myocardial infarction) and patients who are pregnant should not use estrogens.

Adverse Events

Administration of topical estrogens for OAB and incontinence symptoms is not without risk. Well-designed, large-scale, randomized, controlled trials have clearly demonstrated the cardiovascular sequelae that can result from utilizing hormone replacement therapy (HRT) for primary prevention of cardiovascular disease. Since the advent of the Women's Health Initiative study, the use of HRT has dramatically declined. However, in selected individuals, HRT is still used for the treatment of menopause-related symptoms, which include urogenital complaints (vaginal atrophy, dysuria, incontinence).

Risks of administration include the potential for thromboembolic complications, aggravation of existing estrogen-responsive malignancies or development of estrogen-responsive cancers, changes in libido, mood dysregulation, irritability, or syncope.

Antidiuretic Drugs

Mechanism of Action

Desmopressin (1-desamino-8-D-arginine vasopressin; DDAVP), a synthetic vasopressin analogue, had been indicated for nocturnal enuresis in adults and children. It possesses profound antidiuretic properties without any appreciable pressor activity; DDAVP can diurese without impacting blood pressure in a clinically significant way. Exploiting the hypothesis that a relative absence of nocturnal vasopressin and subsequently increased nocturnal urine production underlies the predisposition to suffer from enuresis, DDAVP reduces urine volume and osmolality. In addition to the established indication for enuresis in children, DDAVP has been shown to be efficacious in treating adult patients with nocturia of polyuric origin.

Contraindications and Adverse Events

Patients with hyponatremia or a history of hyponatremia or moderate to severe renal impairment (CrCl less than 50 mL/min) should avoid DDAVP. Adverse effects are mild and rare. However, there is a risk of water retention with or without hyponatremia. Sodium monitoring is recommended in elderly patients prior to treatment and several days into therapy.

Interactions

There are no significant drug interactions associated with DDAVP. Several medications (lithium, TCAs, SSRIs, nonsteroidal anti-inflammatory drugs, carbamazepine) may enhance the toxic effects of DDAVP, but none of the risks are particularly likely.

New and Emerging Therapies

Vanilloid receptors on afferent neurons that innervate the bladder and urethra may be acted upon by capsaicin or resiniferatoxin. Capsaicin-mediated activation of the afferent neurons results in an initial excitation phase immediately followed by a protracted blockade that effectively desensitizes the neurons to normal stimuli. A capsaicin analogue, resiniferatoxin, can also impact the afferent neurons and the Aδ fibers. This transient physiologic "damage" to sensory nerves results in more prolonged retention of urine and improvement in OAB and DO of neurogenic and idiopathic origin.

Botulinum toxin A blocks the release of acetylcholine from the presynaptic neuron, which, in turn, decreases muscle contractility and increases muscle atrophy locally.

Selecting the Most Appropriate Agent

First-Line Therapy

The AUA 2014 guidelines for the management of OAB recommend initiating behavioral therapy in all patients prior to commencing drug therapy. In the absence of contraindications, anticholinergic medications are considered first-line pharmacologic therapy for OAB and symptoms of incontinence. Nonpharmacologic interventions, such as bladder training, typically are recommended prior to initiating drug therapy. Oftentimes, if the behavioral modifications do not suitably resolve the symptoms of OAB, a medication will be added to the nondrug intervention.

Antimuscarinics as a class have an established reputation with regard to efficacy and safety. They effectively reduce bladder pressure, increase bladder capacity and compliance, increase the volume threshold for desire to urinate, and reduce inappropriate bladder contractions. Tolerability issues involving anticholinergic adverse effects (dry mouth, constipation) may limit clinical utility in some patient populations but largely does not significantly impact therapy. There is no unequivocal evidence that recommends the use of one member of this class over another; however, there have been smaller studies that suggest some differential benefits. In terms of efficacy, the larger body of literature supports relative equivalence among antimuscarinics. ER formulations have demonstrated improved efficacy compared to their immediate-release (IR) counterparts. Some recent meta-analyses have insinuated that solifenacin may offer superior clinical efficacy compared to oxybutynin ER and tolterodine ER (Robinson & Cardozo, 2010). When considering the anticholinergic side effect potential, oxybutynin is undeniably responsible for the most xerostomia and constipation. Trospium and darifenacin promote fewer cognitive sequelae than oxybutynin, tolterodine, or solifenacin. Trospium is not metabolized by the CYP P-450 system and therefore is associated with far fewer drug interactions than the rest of this class, which is metabolized primarily by CYP. New evidence suggests that fesoterodine may be more effective than tolterodine in terms of efficacy and improvement in quality of life. Tolterodine is currently the market leader in the majority of countries. The AUA recommends initiating an ER formulation of any of the anticholinergic drugs. If therapeutic failure occurs or tolerability issues arise, it is recommended that another member of the class be initiated before attempting another drug class.

Mirabegron is now also considered an appropriate first-line pharmacologic intervention, according to the guidelines. Mirabegron is a novel entity, which acts upon beta-3-adrenoreceptors in the detrusor muscle to promote relaxation during the filling phase, thereby reducing urgency, increasing the bladder capacity, and decreasing the number of micturitions. Clinical studies have consistently demonstrated efficacy that is similar to that of the anticholinergics and also improved tolerability comparatively, with a remarkably decreased risk of anticholinergic adverse effects and cognitive impairment. The once-daily dosing, coupled with the efficacy and tolerability advantages, low incidence of

drug–drug interactions, and absence of anticholinergic effects, confers upon mirabegron a possible therapeutic advantage.

Second- and Third-Line Therapy

Failure or intolerance to the initial anticholinergic medication generally warrants the trial of a second anticholinergic medication. Since there are some appreciable differences among anticholinergics in terms of side effect profiles and tolerability, a switch to another anticholinergic typically precedes a switch to a different class. The transdermal oxybutynin patch is available without a prescription and may also be considered if oral therapy is not well tolerated but is not recommended as the initial pharmacologic intervention.

Botulinum A toxin is indicated for neurogenic and nonneurogenic DO as well as neurogenic spasm of the urethra due to spinal cord injury or secondary to DO. Injections of 100 U directly into the detrusor muscle promote an effect for 6 to 9 months secondary to the resulting flaccid paralysis of the bladder. Retreatment after dissipation of therapeutic effect is recommended and the interval at which this occurs has not been established. There is a low risk of drug–drug interactions but a relatively significant risk of serious adverse effects such as urinary retention requiring catheterization. Botulinum toxin is recommended after failure of at least two first-line pharmacologic options.

Duloxetine has demonstrated some success in OAB, but to a greater extent with stress incontinence. Incontinence (generally urge incontinence) is part of the OAB symptom constellation and is alleviated by duloxetine treatment. A similar scenario exists for the use of estrogens for OAB. Estrogens are primarily used for SUI and other urogenital symptoms but have demonstrated utility in OAB. Neither the SNRIs nor estrogen is recommended in the guidelines.

Surgical intervention is arguably the last option in terms of management of OAB; it is generally attempted after failure of all reasonable pharmacologic options. This is mostly due to the inherent risks in abdominal or pelvic operation, namely, impacts on renal function, on sexual function, and on any abdominal or pelvic pathology. In addition, surgical intervention is generally most effective in cases of isolated stress incontinence where there is underlying bladder or urethral pathology. In females, surgery usually involves repositioning the urethra so that it is more amenable to pressure changes or providing artificial support or resistance to the urethra by way of a sling. In males, surgery involves implantation of a manually controlled artificial silicone urethral sphincter.

Refractory Overactive Bladder

Depending upon the underlying etiology of OAB, some patients may not be successfully treated with first- or even second-line options. If multiple antimuscarinic drugs fail, as well as appropriate second- and third-line options, more invasive interventions might become necessary. Implantable neurostimulator devices or sacral neuromodulator placement is moderately successful but costly alternatives. Electrical stimulation of the peripheral

nervous system has been shown to positively impact urinary urgency and urge incontinence. Both anal and vaginal transcutaneous stimulation play a role in the treatment of OAB. Direct electrical stimulation of the third and sometimes fourth sacral nerves via a surgically implanted modulator delivers continuous stimulation directly to a nerve with which it is in close contact. Augmentation cystoplasty surgery involves the anastomosis of a segment of bowel to the bisected bladder. This procedure increases bladder capacity and decreases bladder pressure. Serious risks include kidney or bladder infections, new recurrent urinary tract infections, or metabolic abnormalities. Surgical augmentation cystoplasty, neobladder construction, and urinary diversion techniques involve more risk and tend to be reserved for severe, refractory cases.

Another therapeutic consideration is the somewhat controversial dual antimuscarinic drug therapy. This has been studied in both adults and children and has been found to be safe and effective. Dual therapy does not appear to contribute to increased incidence of adverse effects; however, in some patients, the addition of a second anticholinergic drug precipitated postvoid residual volume increases but not urinary retention (Bolduc et al., 2009).

In male patients with OAB in the setting of BOO secondary to BPH, the combination of alpha-adrenergic blockers and 5-α-reductase inhibitors (finasteride, dutasteride) may offer some clinical utility. (see Chapter 33 for further discussion of BPH.)

Special Considerations

Pediatric

Isolated incontinence tends to manifest in young children as nocturia or enuresis. This is generally due to underlying deficits in learned neural control, delayed development of the nervous system, or potentially a more complex issue involving multiple systems. OAB symptoms of urgency or frequency in children commonly occur as a result of fecal impaction or underlying structural abnormalities. Children can present with voiding dysfunction, urgency, frequency, or incontinence. Oxybutynin IR and ER formulations are the only pharmacologic options approved by the U.S. Food and Drug Administration for OAB in children, although tolterodine IR and ER and trospium have been evaluated in clinical trials. All of the medications yielded successful outcomes in terms of reductions in diurnal incontinence, urgency episodes, micturition, and increases in bladder capacity. The adverse effects are similar to those experienced by adults and consisted mainly of dry mouth. Cognitive effects are not significant with respect to memory, cognition, speed of processing, or attention. DDAVP nasal spray has been the cornerstone of therapy for children with enuresis and has demonstrated clinical efficacy, safety, and tolerability.

Geriatric

As was previously mentioned, there is an inherent challenge with regard to OAB in the elderly patient. Numerous nonurinary factors such as anatomic, physiologic, age-related, or iatrogenic elements predispose elderly patients to the development of OAB or the worsening of existing OAB. The incidence of OAB is highest in the elderly population, and yet, the preferred pharmacologic modality for treating this syndrome tends to impact cognition to an extent that may limit utility in this population. Despite these clinical considerations, antimuscarinic therapy is still considered first line. If the adverse effects are intolerable or if the antimuscarinic agent aggravates an existing condition, an alternate medication should be given. If pharmacologic options are exhausted or are not feasible, surgical interventions can be considered in surgical candidates or the syndrome can be managed less aggressively. Less aggressive options include scheduled voiding, bladder training, and the use of absorbent pads or undergarments.

Women

True OAB syndrome affects men and women relatively equally; however, the symptom of incontinence tends to present more frequently in women. Furthermore, within postmenopausal symptomatology, vaginal atrophy and other urogenital changes may underlie urgency, frequency, and urge or stress incontinence that frequently accompanies menopause. SUI affects 78% of women with incontinence episodes (Basu & Duckett, 2009). SUI may be predicated on intrinsic urethral sphincter deficiency or urethral

hypermobility secondary to the loss of vaginal support structures. Antimuscarinic medications are first line; however, in appropriately selected patients, topical estrogens may offer some therapeutic benefit. Duloxetine has been extensively studied in women with stress incontinence secondary to urethral dysfunction or vaginal atrophy. There is an established correlation between SUI and female sexual dysfunction.

Monitoring Patient Response

Despite the seemingly impressive efficacy of anticholinergic drug therapy, there is roughly a 50% placebo response rate, which complicates the assessment of patient response. As the majority of OAB symptomatology is subjective in nature, patient-generated feedback is the most valuable assessment tool with which to measure success. The domains related to the pathology itself that should be assessed include symptoms, symptom severity, and quality of life. If drug therapy has been initiated, drug-specific parameters such as treatment-emergent side effects or drug interactions need to be assessed as well.

There are numerous validated symptom inventories and quality of life assessment tools that have been employed in clinical trials as well as in practice to monitor patient response to treatment. The ICS highly recommends that symptom assessment and quality of life inventories be used throughout the treatment process in order to assess and guide therapy. The OAB-q assesses both the symptoms and quality of life impact in men and women. The reduced version of this scale includes 8 bladder symptom items and 25 health-related quality of life (HRQOL) items, which include symptom bother, coping skills, concerns and worries, sleep, social interaction, and HRQOL total. In females, the Urogenital Distress Inventory (UDI-6), the Incontinence Severity Index (ISI), and the BFLUTS questionnaire are used to assess the symptom of UI specifically. In males, the ICS_{male} and DAN-PSS will assess the symptom of UI. The UDI-6 assesses 19 LUT symptoms as well as the degree of anxiety or bother that is experienced as a result of the incontinence episodes. This scale may have predictive value with respect to urodynamic studies, especially in stress incontinence, BOO, and DO. The ISI is a simple index that generates a numerical product based on frequency and volume of urine loss. The product is associated with the level of severity of the incontinence. BFLUTS evaluates incontinence symptoms and LUT symptoms as well as the degree of bother associated with each. Both the ICS_{male} and DAN-PSS assess LUT symptoms and the extent to which the patient is bothered. Unfortunately, there is no consensus regarding at which point or how frequently these assessment tools should be administered to yield optimal information about treatment response.

Ongoing assessment of potential treatment-related adverse effects is highly recommended. This can be accomplished by clinician-led patient interviews or patient-generated complaints. The drugs most frequently used to treat OAB have the potential to cause bothersome or sometimes serious adverse effects. Since the patient population most often affected by OAB is usually also affected by polypharmacy, multiple medical conditions, predisposition to falls, and predisposition to anticholinergic adverse effects, diligent monitoring of iatrogenic effects is paramount. Upwards of 60% of patients discontinue drug therapy for OAB within 12 months, which underscores the importance of anticipating and then mitigating adverse effects and other barriers to successful treatment (Wagg et al., 2012).

Patient Education and Patient-Oriented Information Sources

Although OAB tends to affect the elderly more frequently than younger patients and may be partially caused or worsened by seemingly normal processes associated with aging, OAB is *not* considered a normal part of aging. Patients need to be made aware of this and their symptoms need to be validated. One of the challenges in diagnosing OAB is the reluctance of patients to complain of the symptoms or the patient's misconception about the symptoms being a normal part of aging. Once a patient is diagnosed with OAB, it is exceptionally important to emphasize that the symptoms need not be tolerated and that ongoing assessment of symptoms and symptom bother is essential to successful treatment.

Once a treatment modality has been mutually agreed upon by the patient and the care provider, the risks and benefits need to be clearly explained to the patient. More often than not, the treatment will consist of a medication and lifestyle changes or bladder training. The medications used to treat OAB (usually anticholinergics) will likely cause at least some minor anticholinergic adverse effects such as dry mouth or constipation. Severe xerostomia can be treated with adequate hydration as well as saliva substitutes. Constipation can be avoided by maintaining adequate hydration or remedied by using a stool softener (docusate) or a stimulant laxative (senna, bisacodyl). Patients should be warned about potentially severe anticholinergic effects such as urinary retention and advised to seek medical attention if symptoms consistent with urinary retention present. Antimuscarinic drugs may potentially augment anticholinergic effects of other anticholinergic medications. Therefore, in the case of multiple physicians, patients should be advised to make their care providers aware of any and all medications prescribed by all members of the health care team.

Aside from the OAB and medication information that may be provided by the patient's care provider, there are numerous reputable sources for patient-oriented information. The American Urogynecology Society maintains a patient-friendly Web site that explains pelvic floor disorders, incontinence, and OAB. It also provides a list of frequently asked questions, tools for patients, bladder diary support, medications and other treatment options, and a search engine for locating a care provider. The National Association for Continence is another reputable Web site that offers useful information regarding underlying causes of OAB, treatment options, frequently asked questions, and a public bathroom finder. The bathroom finder tool is a Google Maps™–powered application that allows the user to input a city or zip code and will then generate a graphical representation of the location of public restrooms.

Nutrition/Lifestyle Changes

Generally before the initiation of drug therapy, patients will be encouraged to adopt some clinician-guided lifestyle changes to minimize the impact of diet or behavior on OAB. It is *not* recommended that patients attempt to remedy OAB on their own by modifying behavior as was previously discussed. Uninformed and unmonitored changes (such as cessation of diuretic use) may detrimentally impact other aspects of the patient's care or may instigate a nascent problem. All of the nutritional or lifestyle changes should be recommended by the care provider and should be monitored; none of these changes should be initiated by the patient.

Compounds that irritate the bladder may exacerbate or precipitate OAB. Tomatoes, artificial sweeteners, grapes, carbonated beverages, strawberries, apple juice, vinegar, weight loss supplements, and spicy foods all may contribute to OAB pathology. Alcohol and caffeine not only act as bladder irritants but also inhibit antidiuretic hormone (ADH) release, which, in turn, will increase the production of urine and contribute to urgency and frequency. Moderation of the consumption of these foods, beverages, or products will likely reduce some of the added pressures that may be contributing to OAB symptoms.

Maintenance of a healthy body weight will also aid in the mitigation of OAB symptoms as excess weight puts increased pressure on the bladder. Pelvic floor exercises and bladder training are also shown to be effective in treating OAB as monotherapy or in combination with medications.

Complementary and Alternative Medications

Numerous natural compounds and botanicals have been evaluated for purposes of treating OAB; however, there is a paucity of evidence to support their use. OAB or urinary dysfunction that is associated with BPH may be further remedied by adjunctive treatment with saw palmetto extract. Saw palmetto or American dwarf plant (*Serenoa repens*) is thought to inhibit 5-α-reductase as its primary pharmacologic action. 5-α-reductase is responsible for the conversion of testosterone to dihydrotestosterone (DHT). DHT is among the androgens that contribute to prostate growth and, in BPH, contributes to pathologic prostate growth. Inhibition of 5-α-reductase opposes the pathologic enlargement of the prostate and subsequently eases the pressure on the urethra at the bladder neck. This effectively reduces or removes the BOO and improves LUT symptoms in males. Saw palmetto extract would not be an appropriate therapeutic option in patients who do not have an underlying BPH-mediated BOO.

To date, three active comparator trials have evaluated the efficacy and safety of saw palmetto extract as compared to 5-α-reductase inhibitors or alpha-1-receptor antagonists. Saw palmetto and finasteride both improved the score on the International Prostate Symptom Score (IPSS), improved quality of life, and increased peak urinary flow rate. Unlike finasteride, saw palmetto did not impact prostate volume or PSA. The trial comparing saw palmetto to tamsulosin did not find a difference between the two groups in terms of IPSS reduction, maximal flow rate, and irritative or obstructive symptoms (Suzuki et al., 2009).

Case Study*

C.J. is a 55-year-old postmenopausal woman presenting with a 2-year history of incontinence. She reports that she often cannot get to the bathroom in time when she feels the urge to urinate. She also experiences incontinence most frequently when she laughs or sneezes. This has caused significant embarrassment and has decreased her social interactions. She drinks four cups of coffee daily. Current prescription medications include hydrochlorothiazide for hypertension. C.J. denies the use of any nonprescription medications or supplements.

Diagnosis: Stress Incontinence

1. List specific goals for treatment for C.J.
2. What drug therapy would you prescribe? Why?
3. What are the parameters for monitoring the success of the therapy?
4. Discuss specific patient education based on the prescribed therapy.
5. List one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What would be the choice for second-line therapy?
7. What OTC and/or alternative medications would be appropriate for this patient?
8. What dietary and lifestyle changes should be recommended for this patient?
9. Describe one or two drug–drug or drug–food interactions for the selected agent.* Answers can be found online.

35 Sexually Transmitted Infections

Virginia P. Arcangelo

Sexually transmitted infections (STIs) are among the most common illnesses in the world. They have far-reaching health, social, and economic consequences. Our knowledge about the global prevalence and incidence of these infections is limited by the quality and quantity of data available from throughout the world. STIs remain a major public health concern in the United States. The economic burden is impressive: Centers for Disease Control and Prevention's (CDC) new estimates show that there are about 20 million new infections in the United States each year, with a total of more than 110 million among men and women. STIs cost the American health care system nearly $16 billion in direct medical costs alone (CDC, 2013).

It is estimated that half of all new STIs in the country occur among young men and women. Those at the highest risk for contracting STIs are those between 15 and 24 years, and gay and bisexual men. Gay and bisexual men have the highest rate of syphilis infections. While most STIs will not cause harm, some have the potential to cause serious health problems, especially if not diagnosed and treated early.

In 2015, the CDC updated the guidelines for treating STIs (Table 35.1). Available from the CDC, these guidelines are one of the most widely used documents published by that organization. The guidelines emphasize the development of management strategies that are adaptable to the managed care environment. Because the guidelines are considered the gold standard for treating STIs, most of the information in this chapter is based on them. The goals of therapy for all STIs are to eradicate the causative organism and prevent complications.

TABLE 35.1 Pharmacotherapy for Sexually Transmitted Infections

Infection	Treatment	Comments
Chlamydial infection	azithromycin 1 g PO once *or* doxycycline 100 mg PO bid for 7 d *Alternative:* erythromycin base 500 mg PO qid for 7 d *or* erythromycin ethylsuccinate 800 mg PO qid for 7 d *or* ofloxacin 300 mg bid for 7 d *or* levofloxacin 500 mg PO for 7 d	Use amoxicillin, erythromycin, *or* azithromycin in pregnancy.
Genital herpes	*Initial episode treatment* for 7–10 d acyclovir 400 mg PO tid *or* acyclovir 200 mg PO 5 times a day *or* valacyclovir 1 g PO bid *Recurrent treatment:* acyclovir 400 mg PO tid for 5 d *or* acyclovir 800 mg bid for 5 d *or* acyclovir 800 mg tid for 2 d *or* famciclovir 125 mg PO bid for 5 d *or* famciclovir 100 mg bid for 1 d valacyclovir 500 mg PO bid for 3 d *or* valacyclovir 1 g once a day for 5 d *Suppressive treatment:* acyclovir 400 mg bid *or* famciclovir 250 mg bid *or* valacyclovir 500 mg or 1,000 mg qd	Treatment can be extended if healing is not complete after 10 d.
Gonorrhea	ceftriaxone 250 mg IM once *PLUS* azithromycin 1 g PO once *or* doxycycline 100 mg PO bid for 7 d *Alternative:* cefixime 400mg once	
Human papillomavirus	*Patient applied:* podofilox 0.5% solution or gel for 3 d and then 4 d of no therapy imiquimod 5% cream three times a week up to 16 wk *Provider applied:* podophyllin resin 10%–25% in compound of tincture of benzoin weekly as needed trichloroacetic acid or bichloracetic acid 80%–90% weekly as needed	Solution applied with cotton swab and gel with finger to visible warts. This is done for 3 d and then 4 d with no therapy and may be repeated four times. Area should be washed with mild soap and water 6–10 h after application. Allow to air-dry. Wash off 1–4 h after application. Apply only to warts and let dry; white "frosting" appears; powder with talc or sodium bicarbonate to remove unreacted acid.
Pelvic inflammatory disease	ceftriaxone 250 mg IM once *or* cefoxitin 2 g IM *and* probenecid 1 g PO once *and* doxycycline 100 mg PO bid for 14 d PLUS doxycycline 100 mg PO bid for 14 d WITH OR WITHOUT metronidazole 500 mg PO bid for 14 d	
Syphilis	*Early primary, secondary, or latent syphilis <1 y* Adult: benzathine penicillin G 2.4 million U, IM single dose Child: 50,000 U/kg, IM, single dose up to 2.4 mil unit *Latent disease >1 y or unknown duration* Adult: benzathine penicillin G 2.4 million U, IM, for 3 doses at 1-wk intervals Child: 500,000 U/kg, IM, for 3 doses at 1-wk intervals *Allergic to penicillin and not pregnant:* doxycycline 100 mg PO bid for 14 d *or* tetracycline 500 mg PO bid for 14 d *Allergic to penicillin and pregnant:* desensitization followed by treatment with penicillin	

From Centers for Disease Control and Prevention. (2006). Sexually transmitted treatment guidelines, 2006. *Morbidity and Mortality Weekly Reports*, 59 (RR-12), 1–110.

The accurate and timely reporting of STIs is integrally important for assessing morbidity trends, targeting limited resources, and assisting local health authorities in partner notification and treatment. STIs, human immunodeficiency virus (HIV), and acquired immunodeficiency syndrome (AIDS) cases should be reported in accordance with state and local statutory requirements. Syphilis, gonorrhea, chlamydia, chancroid, HIV infection, and AIDS are reportable diseases in every state. The requirements for reporting other STIs differ by state, and clinicians should be familiar with state and local reporting requirements.

Reporting can be provider or laboratory based.

Intrauterine or perinatally transmitted STIs can have severely debilitating effects on pregnant women, their partners, and their fetuses. All pregnant women and their sex partners should be asked about STIs, counseled about the possibility of perinatal infections, and ensured access to treatment, if needed.

All pregnant women in the United States should be tested for HIV infection as early in pregnancy as possible. Testing should be conducted after the woman is notified that she will be tested for HIV as part of the routine panel of prenatal tests, unless she declines the test.

CHLAMYDIAL INFECTION

Chlamydial infection is the most prevalent STI in the United States, with 2 to 3 million new cases reported annually. The detection and treatment of this disease is important because the complications can be serious.

CAUSES

Chlamydial infection is caused by *Chlamydia trachomatis*, which shares properties of both bacteria and viruses. The organism is transmitted sexually or perinatally. Repeated infections are common.

In infants, perinatal exposure to the mother's cervix causes the infection. The prevalence is greater than 5% regardless of race, ethnicity, or socioeconomic status. In preadolescent children, sexual abuse must be considered as a causative factor for chlamydial infection; infection of the nasopharynx, urogenital tract, and rectum may persist for greater than 1 year. Because criminal investigation is always a possibility, cultures should be confirmed by microscopic fluoroscopy, which can detect conjugated monoclonal antibodies specific for *C. trachomatis*.

Chlamydial infections occur most frequently in women younger than age 25. All adolescents and young women should be screened for chlamydia yearly, as should any woman who has new or multiple sex partners.

PATHOPHYSIOLOGY

Chlamydial organisms are like viruses in that they are obligate intracellular parasites. They resemble bacteria by containing both deoxyribonucleic acid (DNA) and ribonucleic acid, by dividing by binary fission, and by having cell walls that resemble those of gram-negative bacteria. Species of chlamydial organisms include *Chlamydia psittaci* and *C. trachomatis*, the latter of which has a number of serotypes. These species cause numerous diseases, including lymphogranuloma venereum, blinding trachoma, conjunctivitis, nongonococcal urethritis, cervicitis, salpingitis, proctitis, epididymitis, and newborn pneumonia.

DIAGNOSTIC CRITERIA

The infection may be silent: more than half of infected patients have no clinical signs or symptoms. In symptomatic women, the clinical presentation includes vaginal discharge, mucopurulent cervicitis with edema and friability, urethral syndrome or urethritis, pelvic inflammatory disease (PID), ectopic pregnancy, infertility, and endometritis. Men may report a thin, clear discharge and dysuria. Chlamydial organisms are the major causes of nongonococcal urethritis and epididymitis in young men.

In infants aged 1 to 3 months, chlamydial infection presents in the mucous membranes of the eye, oropharynx, urogenital tract, and rectum and as subacute, afebrile pneumonia; in neonates, it presents as an asymptomatic infection of the oropharynx, genital tract, and rectum. However, chlamydial infection most commonly presents as conjunctivitis 5 to 12 days after birth and is the most frequent identifiable infectious cause of ophthalmia neonatorum. Therefore, for all infants with conjunctivitis who are no older than 30 days, a chlamydial etiology should be considered.

Diagnostic tests for chlamydial ophthalmia neonatorum include tissue cultures and nonculture tests. Ocular exudate should also be tested for *Neisseria gonorrhoeae*.

Chlamydial infection is diagnosed by examination, culture, and antigen detection methods, including direct fluorescent monoclonal antibody staining, enzyme-linked immunosorbent assay, DNA probe assay, and polymerase chain reaction.

INITIATING DRUG THERAPY

Treatment for all STIs consists of antimicrobial therapy followed by preventive education.

Goals of Drug Therapy

Patients are treated to eradicate the organism and prevent transmission to sex partners or to a newborn during birth. Because chlamydial infections often are accompanied by gonococcal infections, patients may be treated for both infections.

Antibiotic Therapy

Antibiotic treatments are prescribed to cure infection and usually relieve symptoms (CDC, 2015). Azithromycin (Zithromax) and erythromycin (E-Mycin), macrolide antibiotics; doxycycline (Vibramycin), a tetracycline antibiotic; and ofloxacin (Floxin), a fluoroquinolone, are drugs of choice for chlamydial infections.

If therapeutic compliance is in question, azithromycin should be used for treatment because it is prepared as a single-dose drug. Doxycycline, however, has been used more extensively and is less expensive. An alternative regimen can be erythromycin, but it is less efficacious and has gastrointestinal (GI) side effects. Other alternatives include fluoroquinolones such as ofloxacin and levofloxacin (Table 35.2).

TABLE 35.2 Overview of Drugs Used to Treat Chlamydial Infections*

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
azithromycin (Zithromax) Adult: 1 g PO single dose Pregnancy: 1 g PO in a single dose Child (≥45 kg, <8 y): 1 g PO in a single dose Child (≥8 y): 1 g PO in a single dose (or doxycycline as below)	GI upset, abdominal pain, pseudomembranous colitis, angioedema, cholestatic jaundice	Hypersensitivity to azithromycin, erythromycin, or any macrolide antibiotic Use with caution with impaired hepatic or renal function.	Do not take with aluminum- or magnesium-containing antacids.
doxycycline (Vibramycin) Adult: 100 mg bid for 7 d Child (≥8 y): 100 mg PO bid for 7 d	Superinfection, photosensitivity, GI upset, enterocolitis, rash, blood dyscrasias, hepatotoxicity	Pregnancy, lactation, hypersensitivity to any of the tetracyclines	Monitor blood, renal, and hepatic function in long-term use. Use of drug during tooth development may discolor teeth. Advise patient to avoid excessive sunlight or ultraviolet light. Caution patient that drug absorption is reduced when taken with food or bismuth subsalicylate.
amoxicillin (Augmentin) Pregnancy: 500 mg tid for 7 d	Hypersensitivity reactions, pseudomembranous colitis, GI upset, rash, urticaria, vaginitis	History of Augmentin-associated cholestatic jaundice, hepatic dysfunction, or allergic reactions to any penicillin	Monitor blood, renal, and hepatic function in long-term use.
ofloxacin (Floxin) 300 mg bid for 7 d	Rash, hives, rapid heartbeat, difficulty swallowing or breathing, photosensitivity, angioedema, dizziness, light-headedness	Pregnancy, hypersensitivity to ofloxacin or quinolones Use with caution with hepatic or renal insufficiency.	Do not take with food. Drink fluids liberally.
levofloxacin (Levaquin) 500 mg daily for 7 d	Same as above	Same as above	Same as above
erythromycin base (E-Mycin) Adult: 500 mg qid for 7 d Pregnancy: 500 mg qid for 7 d or 250 mg qid for 14 d Children: 50 mg/kg/d PO divided into 4 doses daily for 10–14 d	GI upset, pseudomembranous colitis, hepatic dysfunction, cardiac dysrhythmias, CNS disturbances, urticaria, skin eruptions, hearing loss, superinfection and local irritation	Known hypersensitivity to erythromycin Prescribe with caution for patients with impaired hepatic function and children who weigh <45 kg.	Effectiveness of treatment is ~80%; a second course of therapy may be required. Use for prophylaxis of ophthalmia neonatorum and infant pneumonia.
erythromycin ethylsuccinate (E.E.S.) Adult: 800 mg qid for 7 d Pregnancy: 800 mg qid for 7 d or 400 mg qid for 14 d	Same as above	Same as above	Same as above

*In adults, pregnant women, children, ophthalmia neonatorum, and infant pneumonia.

In infants, erythromycin base treatment has an efficacy of 80%. A second course of therapy may be required, and follow-up of the infant is recommended.

Mechanism of Action

Azithromycin and erythromycin bind to bacterial ribosomes to block protein synthesis. The drugs are also bactericidal, depending on their concentration. (For more information on antibiotic actions, see Chapter 8.) Doxycycline is thought to act in a similar way, whereas ofloxacin kills bacteria by blocking DNA gyrase and inhibiting DNA synthesis.

Dosages

A single 1-g dose of azithromycin or 100 mg of doxycycline twice a day for 7 days is the usual initial therapy.

Contraindications

Sensitivity to erythromycin or other macrolides is the main contraindication to therapy.

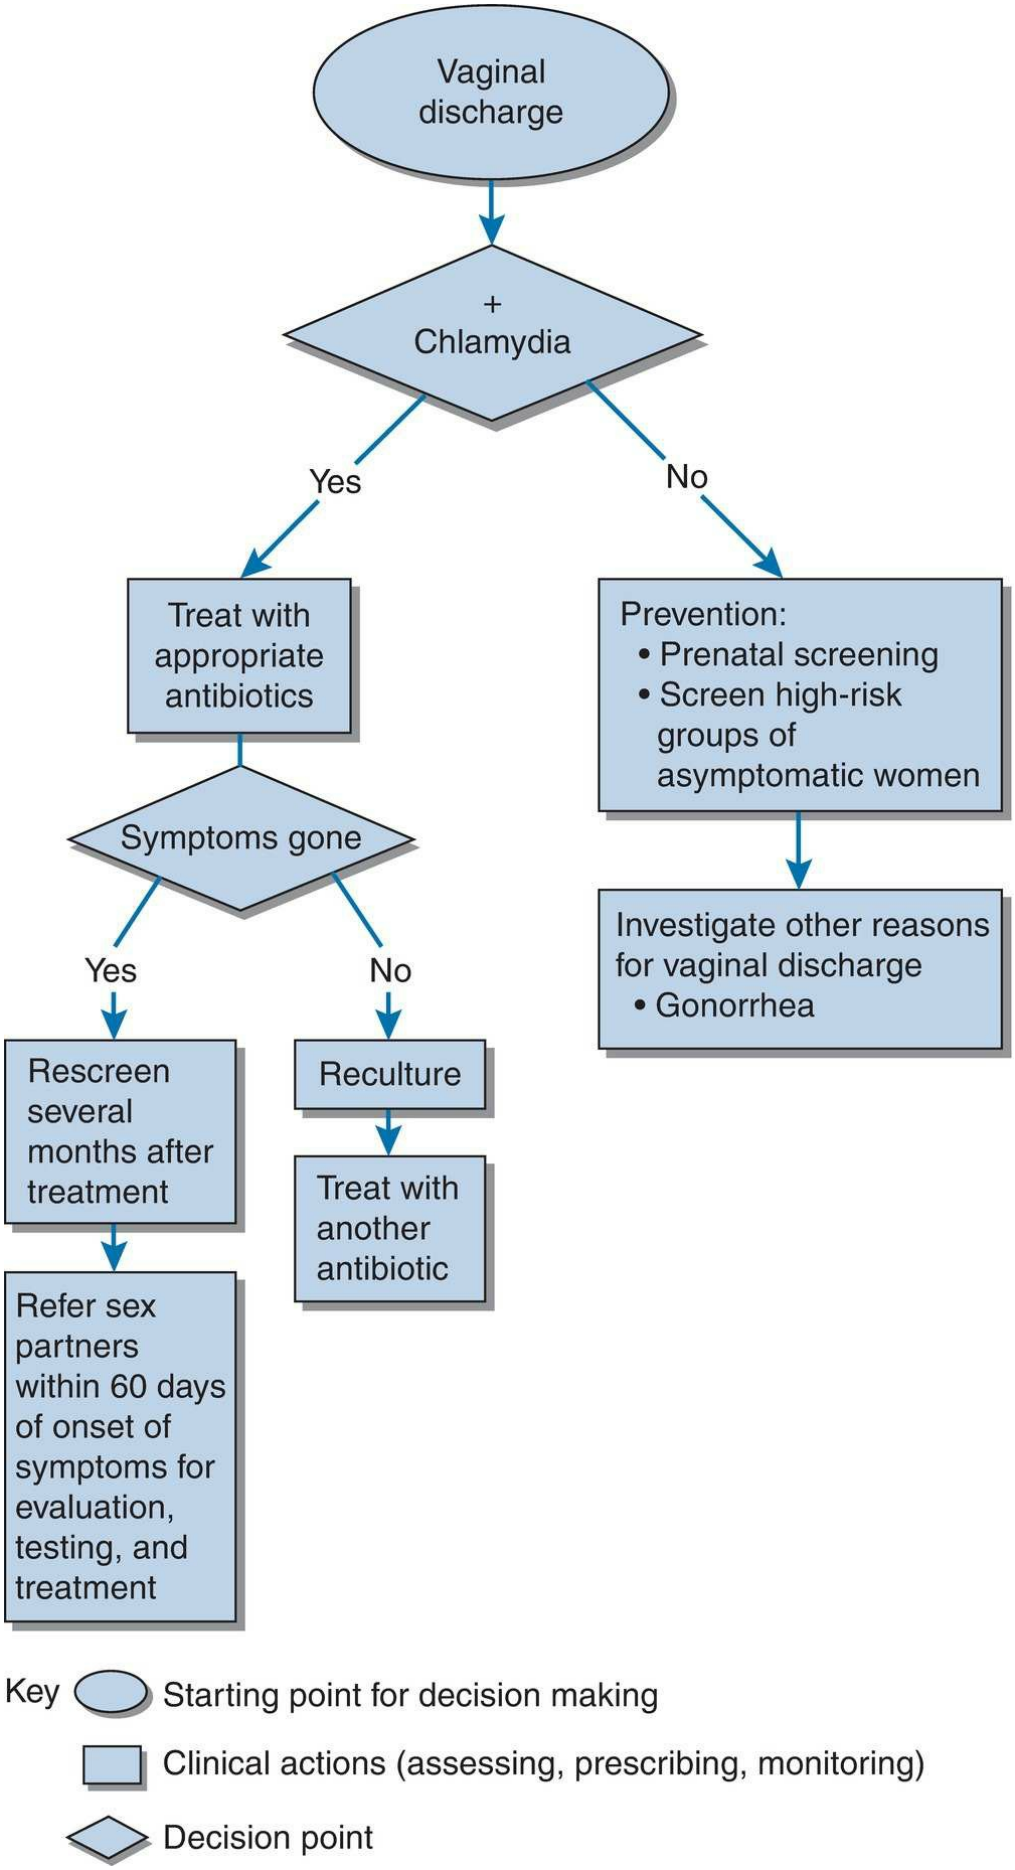
The safety and efficacy of azithromycin in pregnant and lactating women are not known. Doxycycline and ofloxacin are contraindicated in pregnant women.

Adverse Events

In some patients, GI side effects (nausea, vomiting, diarrhea, abdominal discomfort) cause them to discontinue therapy.

Selecting the Most Appropriate Agent

The most appropriate therapy is the one that best matches the needs of the patient in different situations or stages of life. Figure 35.1 and Tables 35.1 and 35.2 summarize treatment options.



Vaginal discharge
+ Chlamydia
Yes
No
Treat with appropriate antibiotics
Prevention:
• Prenatal screening
• Screen high-risk groups of asymptomatic women
Symptoms gone
Investigate other reasons for vaginal discharge
• Gonorrhea
Yes
No
Rescreen several months after treatment
Reculture
Treat with another antibiotic
Refer sex partners within 60 days of onset of symptoms for evaluation, testing, and treatment

Decision point

FIGURE 35.1 Treatment algorithm for chlamydial infection.

Special Population Considerations

Pediatric

To prevent chlamydial infection among neonates, prenatal screening is recommended. In general, patients appropriate for screening include pregnant women younger than age 25 with new or multiple sex partners.

C. trachomatis infection of neonates results from perinatal exposure to the mother's infected cervix. The prevalence of *C. trachomatis* infection among pregnant women does not vary by race/ethnicity or socioeconomic status. Neonatal ocular prophylaxis with silver nitrate solution or antibiotic ointments does not prevent perinatal transmission of *C. trachomatis* from mother to infant. However, ocular prophylaxis with those agents does prevent gonococcal ophthalmia and therefore should be continued.

Initial *C. trachomatis* perinatal infection involves mucous membranes of the eye, oropharynx, urogenital tract, and rectum. *C. trachomatis* infection in neonates is most often recognized by conjunctivitis that develops 5 to 12 days after birth. Chlamydia is the most frequent identifiable infectious cause of ophthalmia neonatorum. *C. trachomatis* also is a common cause of subacute, afebrile pneumonia with onset from ages 1 to 3 months. Asymptomatic infections also can occur in the oropharynx, genital tract, and rectum of neonates.

A chlamydial etiology should be considered for all infants aged 30 days or less who have conjunctivitis. Sexual abuse should be considered for infants and children who test positive for chlamydial infections.

Pregnancy

The recommended regimen for pregnancy is a single dose of azithromycin 1 g or amoxicillin 500 mg orally three times daily for 7 days.

Alternative regimens are erythromycin base 250 mg orally four times a day for 14 days, erythromycin ethylsuccinate 800 mg orally four times a day for 7 days or 400 mg orally four times a day for 14 days, or azithromycin 1 g orally, single dose. Erythromycin estolate is contraindicated during pregnancy because of drug-related hepatotoxicity. Doxycycline is contraindicated in the second and third trimester. All pregnant women who have chlamydia should be retested 3 to 4 weeks and then 3 months after their treatment, which is contrary to the discussion in monitoring patient responses. If infection persists, it can severely affect the mother and neonate.

MONITORING PATIENT RESPONSE

Because therapy with azithromycin or doxycycline is highly efficacious, patients do not need to be retested after treatment is completed, unless they are pregnant (see section "Pregnancy"). If alternative agents, such as erythromycin, are used for treatment, repeat testing for cure is no longer recommended unless therapeutic adherence is in question, symptoms persist, or reinfection is suspected (CDC, 2015).

Screening for *C. trachomatis* should be performed in high-risk groups when the practitioner performs a pelvic examination. High-risk groups include sexually active adolescents and women ages 15 to 24, particularly those who have new or multiple sex partners; those attending family planning clinics, prenatal clinics, or abortion facilities; or those in juvenile detention centers. Screening for high-risk men should be considered when they seek health care.

PATIENT EDUCATION

The patient's sex partner must be treated. The newest guidelines (CDC, 2015) recommend presumptive treatment for all partners. Patients should abstain from sexual intercourse for 7 days after single-dose therapy or until the 7-day regimen is completed. Abstinence should also continue until the patient's sex partner has been treated, to prevent reinfection. Sex partners should be treated if they have had sexual contact with the patient during the 60 days preceding onset of symptoms in the patient or the diagnosis of chlamydial infection. The most recent sex partner should be treated even if the time of the last sexual contact was greater than 60 days before onset or diagnosis.

GONORRHEA

Approximately 820,000 new infections with *N. gonorrhoeae* occur each year in the United States. They are the major causes of PID, tubal scarring, infertility, ectopic pregnancy, and chronic pelvic pain in the United States. Most men seek treatment before serious complications develop, but not soon enough to prevent transmission to others. In women, symptoms may not develop until complications such as PID occur. Screening of men and women at high risk for STIs is an important component of gonorrhea control (CDC, 2015). Patients infected with *N. gonorrhoeae* frequently are coinfected with *C. trachomatis*; this finding has led to the recommendation that patients treated for gonococcal infection also be treated routinely with a regimen that is effective against uncomplicated genital *C. trachomatis* infection. Because the majority of gonococci in the United States are susceptible to doxycycline and azithromycin, routine cotreatment might also hinder the development of antimicrobial-resistant *N. gonorrhoeae*.

CAUSES

Gonorrhea is caused by *N. gonorrhoeae,* a gram-negative diplococcal bacterium. It is transmitted by sexual contact, and the rate of male-to-female transmission is higher than female-to-male or male-to-male. Women with gonorrhea have a high prevalence of other STIs, including chlamydial infection, trichomoniasis, bacterial vaginosis, and herpes genitalis.

Uncomplicated anogenital gonorrhea in women can involve the endocervix, urethra, Skene glands, Bartholin glands, and anus. The endocervix is the most common site of infection. Pharyngeal infection can also occur and is usually asymptomatic.

Pathophysiology

Several strains of gonorrhea have been identified. Gonococcal sensitivity and resistance to antibiotics are clinically significant. Certain strains of the organism are resistant to sulfonamides. Penicillinase-producing *N. gonorrhoeae* and chromosomal-resistant *N. gonorrhoeae* are resistant to penicillin, and tetracycline-resistant *N. gonorrhoeae* is resistant to tetracycline.

Diagnostic Criteria

In the United States, an estimated 820,000 new *N. gonorrhoeae* infections occur each year. Most infections among men produce symptoms that cause them to seek curative treatment soon enough to prevent serious sequelae, but this may not be soon enough to prevent transmission to others. Among women, many infections do not produce recognizable symptoms until complications such as PID have occurred. Up to 30% of women with gonorrheal infection have symptoms. Signs and symptoms include purulent or mucopurulent cervical discharge, dysuria, anal bleeding, menorrhagia, and pelvic discomfort. Men may have discharge and regional lymphadenopathy.

Gonorrhea is diagnosed by examination and culture for *N. gonorrhoeae*. Culture can be obtained from endocervical (women) or urethral (men) swabs, or urine (from both men and women). Diagnosis is confirmed by identification of the organism on culture, positive oxidase reaction, and gram-negative diplococcal morphology on Gram stain.

Initiating Drug Therapy

Preventive education is always offered. Sex partners should be referred for evaluation and treatment of *N. gonorrhoeae* and *C. trachomatis* infection if their last contact with the patient was within 60 days before onset of symptoms or diagnosis of infection. The patient's most recent sex partner should be treated even if the patient's last sexual intercourse was more than 60 days before onset of the symptoms or diagnosis. All patients diagnosed with gonorrhea should be tested for syphilis.

Patients treated for gonococcal infection are also treated for chlamydial infection because patients with gonorrhea are commonly coinfected with *C. trachomatis*. The occurrence of fluoroquinolone-resistant *N. gonorrhoeae* in the United States is rare. Patients with treatment failure should undergo culture and susceptibility testing, and the local health department should be notified (CDC, 2015).

Goals of Drug Therapy

The goal of drug therapy is to eradicate disease and prevent complications and spread of infection to others.

Antibiotics

The CDC describes recommended regimens for uncomplicated gonococcal infections of the cervix, urethra, and rectum (Table 35.3).

TABLE 35.3 Overview of Selected Drugs Used to Treat Uncomplicated Gonococcal Infections in Adults and Children*

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
ceftriaxone (Rocephin) Adult: 125 mg IM in a single dose	Pseudomembranous colitis, rash, GI upset, hematologic abnormalities	Known allergy to cephalosporins Prescribe with caution to penicillin-sensitive patients.	Use for uncomplicated gonococcal infection of the pharynx.
Child: ophthalmia neonatorum: 25–50 mg/kg IV or IM in a single dose, not to exceed 125 mg Child: 125 mg IM in a single dose or 50 mg/kg (maximum dose 1 g) IM or IV in a single dose daily for 7 d or 50 mg/kg (maximum dose 2 g) IM or IV in a single dose daily for 10–14 d Child (<45 kg with bacteremia or arthritis): 50 mg/kg, max 1 g IM or IV in a single daily dose for 7 d Child (>45 kg with bacteremia or arthritis): 50 mg/kg, max 2 g, IM or IV in a single daily dose for 10–14 d		Prescribe with caution to hyperbilirubinemic infants, especially premature infants.	Prescribe prophylactically in infants whose mothers have gonococcal infection.
cefixime (Suprax) 400 mg po in single dose	Pseudomembranous colitis, GI upset, skin rash, headache, dizziness	Known allergy to cephalosporins Prescribe with caution to penicillin-sensitive patients and patients with renal impairment or GI disease Prescribe with caution in patients on dialysis	
azithromycin (Zithromax) 2 g PO Uncomplicated gonococcal infection of the pharynx: 1 g PO in a single dose	GI upset, abdominal pain, pseudomembranous colitis, angioedema, cholestatic jaundice	Hypersensitivity to azithromycin, erythromycin, or any macrolide antibiotic Prescribe with caution in patients with impaired hepatic or renal function.	Take 1 h before or 2 h after meals for greatest absorption. Avoid taking with aluminum- or magnesium-containing antacids. Comes in powder form
doxycycline (Vibramycin) 100 mg PO bid for 7 d	Superinfection, photosensitivity, GI upset, enterocolitis, rash, blood dyscrasias, hepatotoxicity	Pregnancy, lactation, hypersensitivity to any of the tetracyclines	Monitor blood, renal, and hepatic function in long-term use. Because of photosensitivity, patients should avoid sunlight or UV light. Use of drug during tooth development may discolor teeth. Absorption is reduced when drug is taken with food or bismuth subsalicylate (Pepto-Bismol). Prescribe for uncomplicated gonococcal infection of the pharynx.

*Infections of the cervix, urethra, and rectum; uncomplicated gonococcal infection of the pharynx; ophthalmia neonatorum; and gonococcal infection in children.

Cefixime

Cefixime (Suprax) covers an antimicrobial spectrum similar to that of ceftriaxone (Rocephin). A dose of 400 mg orally once is an alternative therapy to ceftriaxone. The advantage of cefixime is that it can be administered orally, and clinical trials have shown a

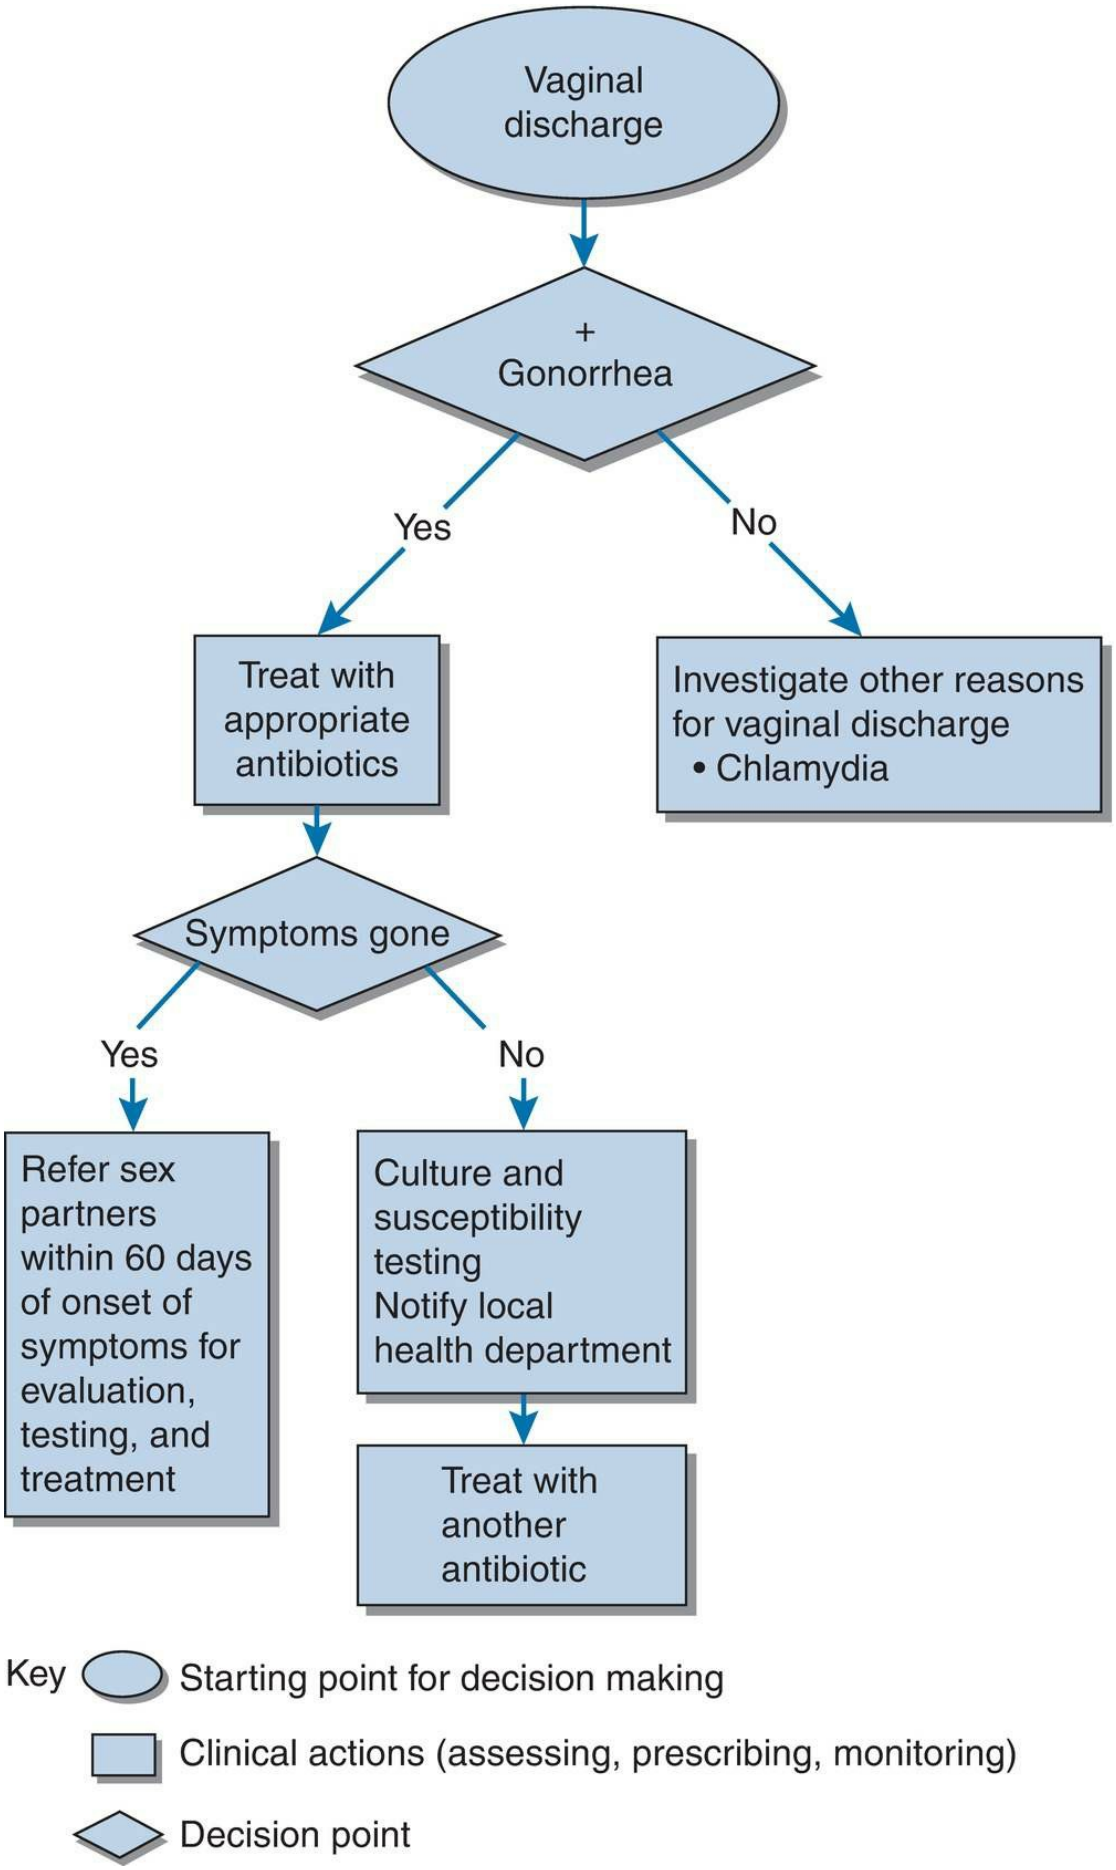
97.1% cure rate for uncomplicated urogenital and anorectal gonococcal infections.

Ceftriaxone

A single injection of 250 mg of ceftriaxone provides sustained, high antibacterial levels in the blood. Extensive clinical experience shows that the drug is safe and effective for treating uncomplicated gonorrhea at all sites, with a cure rate of 99.1% in clinical trials for uncomplicated urogenital and anorectal infections.

The CDC also recognizes other antimicrobials for use against *N. gonorrhoeae*. If there is a severe cephalosporin allergy, a single dose of azithromycin (Zithromax) 2 g orally is effective for uncomplicated gonococcal infection, but it is expensive and causes GI distress. If there is a Zithromax allergy, doxycycline can be considered; however, some isolates are resistant to this class of antibiotic.

The regimen recommended by the CDC for uncomplicated gonococcal infections of the pharynx is summarized in Table 35.1 and Figure 35.2. These infections are more difficult to treat than urogenital and anorectal infections. Few drugs can reliably cure these infections more than 90% of the time. Treatment for gonorrhea and chlamydial infection is suggested, even though chlamydial coinfection of the pharynx is unusual.



Vaginal discharge

Decision point

FIGURE 35.2 Treatment algorithm for gonorrheal infection.

Selecting the Most Appropriate Agent

Therapy for uncomplicated gonococcal infections includes a cephalosporin or fluoroquinolone, as follows:

- Single-dose ceftriaxone 250 mg IM

PLUS:

- Single-dose azithromycin 1 g
- Doxycycline 100 mg orally twice daily for 7 days

The choice is based on the practitioner's assessment of the patient's reliability, allergies, and preferences. If there is a question regarding the patient's reliability, ceftriaxone IM may be the treatment of choice because it is administered in the office.

Special Population Considerations

Pediatric

Gonococcal infection may be transmitted to infants exposed to infected cervical exudate at birth. The infection presents as an acute illness 2 to 5 days after birth. The prevalence in infants depends on the prevalence of infection in pregnant women, whether pregnant women are screened for gonorrhea, and whether newborns receive prophylactic treatment. Manifestations of the infection in newborns include ophthalmia neonatorum, which may result in perforation of the ocular globe and blindness, sepsis with arthritis, and meningitis, rhinitis, vaginitis, urethritis, and inflammation at fetal monitoring sites. Cultures should be taken when typical gram-negative diplococci are identified in conjunctival exudate, and testing for chlamydial organisms should be done in all cases of neonatal conjunctivitis. Presumptive treatment can be given for newborns who are at increased risk for gonococcal ophthalmia or who have conjunctivitis but no gonococci in a Gram-stained smear of conjunctival exudate. Infants with gonococcal ophthalmia should be hospitalized and monitored for signs of disseminated infection. Many physicians prefer to continue therapy until cultures are negative for gonococcal organisms at 48 to 72 hours.

To prevent ophthalmia neonatorum, erythromycin is used as a prophylactic agent, installed in the eyes within 24 hours of delivery; this is required by law in most states, regardless of whether delivery was vaginal or cesarean (Table 35.4).

TABLE 35.4 Prophylaxis for Ophthalmia Neonatorum

Topical Agent	Adverse Events	Contraindications	Special Considerations
erythromycin (Ilotycin) 0.5% ophthalmic ointment in a single application	Sensitivity reactions	Hypersensitivity to erythromycin	Instill into both eyes as soon as possible after birth Use single tubes administration

In preadolescent children, sexual abuse is the most frequent cause of gonococcal infection. Vaginitis is the most common manifestation, followed by anorectal and pharyngeal infections, which are commonly asymptomatic. Standard culture procedures should be used to diagnose the infection, and nonculture gonococcal tests should not be used alone.

Follow-up cultures are not needed if ceftriaxone is used. Only parenteral cephalosporins are recommended for use in children. Quinolones are not approved for use in children because of concerns regarding toxicity. A follow-up culture is needed to ensure that treatment was effective if spectinomycin is used. All children with gonococcal infections should be evaluated for syphilis and chlamydial coinfection.

Monitoring Patient Response

Patients who have had uncomplicated gonorrhea and who were treated with any of the recommended regimens do not need to return for test of cure. If symptoms persist after treatment, the patient is evaluated by culture for *N. gonorrhoeae*, and isolated gonococci should be tested for antimicrobial susceptibility. If infection is identified, its source is usually reinfection rather than treatment failure. In patients treated with spectinomycin for pharyngeal infection, culture should be performed 3 to 5 days after treatment because spectinomycin is not highly effective against these infections.

Patient Education

Patient education concentrates on prevention. All patients should be encouraged to adopt meticulous hygiene and practice safe sex, to insist that partners seek treatment, and to schedule and keep follow-up health care appointments.

Syphilis

In the 1990s, syphilis reemerged in endemic forms in the United States, with a significant increase in the incidence of primary, secondary, and congenital syphilis. The increase has been attributed to greater use of illicit drugs, most notably crack cocaine, and high-risk sexual behavior related to drug use. Approximately 55,000 new cases of primary and secondary syphilis occur annually in the United States (CDC, 2013). Gay and bisexual men are at greatest risk.

Causes

Syphilis is a chronic, infectious disease caused by the spirochete *Treponema pallidum*. Infection may be active, and characterized by symptoms, or inactive (latent). The latent stage has no clinical symptoms. During the latent stage, infections can be detected by serologic testing. Early latent syphilis is defined as latent syphilis acquired within the preceding year. Any other cases of latent syphilis are either late latent syphilis or syphilis of unknown duration (CDC, 2015).

Pathophysiology

T. pallidum is considered a bacterium because of its cell wall and response to antibiotic therapy. *T. pallidum* is not readily grown in vitro and cannot be seen by light microscopy.

Diagnostic Criteria

Patients who contract syphilis may seek treatment for signs or symptoms of primary infection, which include an ulcer or chancre at the infection site. The chancre erupts approximately 3 weeks after exposure. Signs and symptoms of secondary syphilis are low-grade fever, malaise, sore throat, hoarseness, headache, anorexia, rash, mucocutaneous lesions, alopecia, and adenopathy. Signs and symptoms of tertiary infection include cardiac, neurologic, ophthalmic, auditory, or gummatous lesions. Definitive methods for diagnosing early syphilis include dark-field examination and direct fluorescent antibody study of the chancre's exudate or tissue. The serologic tests used to confirm the syphilis diagnosis are nontreponemal and treponemal. The nontreponemal tests are the Venereal Disease Research Laboratory (VDRL) test and the rapid plasma reagin test. The treponemal tests include the fluorescent treponemal antibody absorption test and the microhemagglutination assay for antibody to *T. pallidum*. The two serologic tests are necessary because false-positive nontreponemal test results occur on occasion secondary to certain medical conditions. Treponemal test antibody titers do not correlate accurately with disease activity and should not be used to assess treatment response.

A single test cannot be used to diagnose all cases of neurosyphilis. The diagnosis is made using a combination of tests, including combinations of reactive serologic test results; abnormalities of cerebrospinal fluid (CSF) cell count or protein; or reactive VDRL-CSF with or without clinical manifestations (CDC, 2015).

Initiating Drug Therapy

Although sexual transmission occurs only when mucocutaneous syphilitic lesions, including the rash, are present, people exposed in any stage should be evaluated clinically and serologically. Treatment should be given to those who were exposed within 90 days preceding the diagnosis of primary, secondary, or early latent syphilis in a sex partner, because the partner might be infected even if he or she is seronegative. Treatment should also be given to those who were exposed more than 90 days before the diagnosis of primary, secondary, or early latent syphilis in a sex partner if serologic test results are unavailable and follow-up tests and treatments are uncertain. Patients who have syphilis of unknown duration and who have high nontreponemal serologic test titers are considered to have early syphilis. Sex partners should be notified and treated. Long-term partners of patients with late syphilis should have a clinical and serologic evaluation and should be treated based on the findings.

For all stages of syphilis, penicillin is the preferred treatment. The stage and clinical manifestations of the disease determine the preparation used as well as the dosage and duration of treatment. However, no adequate trials have been performed to determine the optimal penicillin regimen. The only therapy with documented efficacy for syphilis during pregnancy or neurosyphilis is parenteral penicillin G benzathine. Penicillin G has been used for the past five decades to achieve a local cure and to prevent late sequelae.

Goals of Drug Therapy

The goal of treatment for primary and secondary syphilis is cure. The goal of treatment for latent syphilis is to prevent occurrence or progression of late complications. There is limited evidence supporting specific regimens for penicillin, even though clinical experience has shown the effectiveness of penicillin in achieving these goals.

Antibiotics

Penicillin

Adults with primary or secondary syphilis should be treated with penicillin G benzathine (Bicillin). Other choices for unusual situations include doxycycline, tetracycline (Achromycin), ceftriaxone, and erythromycin (Table 35.5).

TABLE 35.5 Overview of Selected Drugs Used to Treat Syphilis

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Nonallergic Adults			
penicillin G benzathine (Bicillin) *Primary, secondary, and early latent infection:* 2.4 million U IM single dose *Late latent infection, infection of unknown duration, or tertiary infection:* 7.2 million U; total 3 doses of 2.4 million U IM each at 1-wk intervals	Hypersensitivity, urticaria, laryngeal edema, fever, eosinophilia, serum sickness–like reactions, anaphylaxis, hemolytic anemia, leukopenia, thrombocytopenia, neuropathy, nephropathy	Hypersensitivity to any penicillin or procaine	Use with caution with patients with allergies or asthma. Do not inject into or near an artery or nerve.
Nonallergic Children			
Primary, secondary, and early latent infection: 50,000 U/kg IM up to adult dose of 2.4 million U in a single dose *Late latent infection, infection of unknown duration:* 50,000 U/kg IM up to adult dose of 2.4 million U administered as 3 doses at 1-wk intervals (total 150,000 U/kg up to adult dose of 7.2 million U)	Same as above	Same as above	Same as above

Mechanism of Action

Penicillins are bactericidal. They disrupt synthesis of the bacterial cell wall and bind to enzyme proteins, interfering with the biosynthesis of mucopeptides and preventing the structural components of the cell wall from leaking out. As such, the bacteria cannot lay protein cross-links in the cell wall. In addition, autolytic enzymes, which promote lysis of bacteria, are activated.

Contraindications

Penicillin is contraindicated in patients with allergies to penicillin, cephalosporin, or imipenem (Primaxin).

Adverse Events

Hypersensitivity, urticaria, laryngeal edema, fever, eosinophilia, anaphylaxis, hemolytic anemia, leukopenia, thrombocytopenia, neuropathy, and nephropathy are some of the adverse effects of the penicillins.

Interactions

Penicillin decreases the effect of oral contraceptives. Hyperkalemia can result from concurrent use of potassium-sparing diuretics, angiotensin-converting enzyme inhibitors, and potassium supplements with parenteral penicillin G.

Doxycycline, Tetracycline, and Others

Nonpregnant patients with latent syphilis who are allergic to penicillin should be treated with doxycycline or tetracycline. Both drugs should be given for 2 weeks if the infection is of less than 1 year's duration; otherwise, they should be given for 4 weeks. Patients who are not pregnant but who are allergic to penicillin and who have primary or secondary syphilis should be treated with doxycycline or tetracycline. For patients who cannot tolerate these, ceftriaxone is recommended. Although erythromycin is less effective than other regimens, it can be used for nonpregnant, compliant patients. Patients whose compliance is questionable or pregnant patients who are allergic to penicillin should be desensitized and treated with penicillin. For more information, see Chapter 8.

Selecting the Most Appropriate Agent

Penicillin G therapy is the first and usually only choice for patients who have syphilis and who are not allergic to penicillin. For patients who are allergic to penicillin and who are not pregnant, first-line therapy relies on doxycycline or tetracycline. There are no proven alternative drugs for pregnant women who have syphilis and who are allergic to penicillin. These women should be desensitized and then treated with penicillin (Figure 35.3).

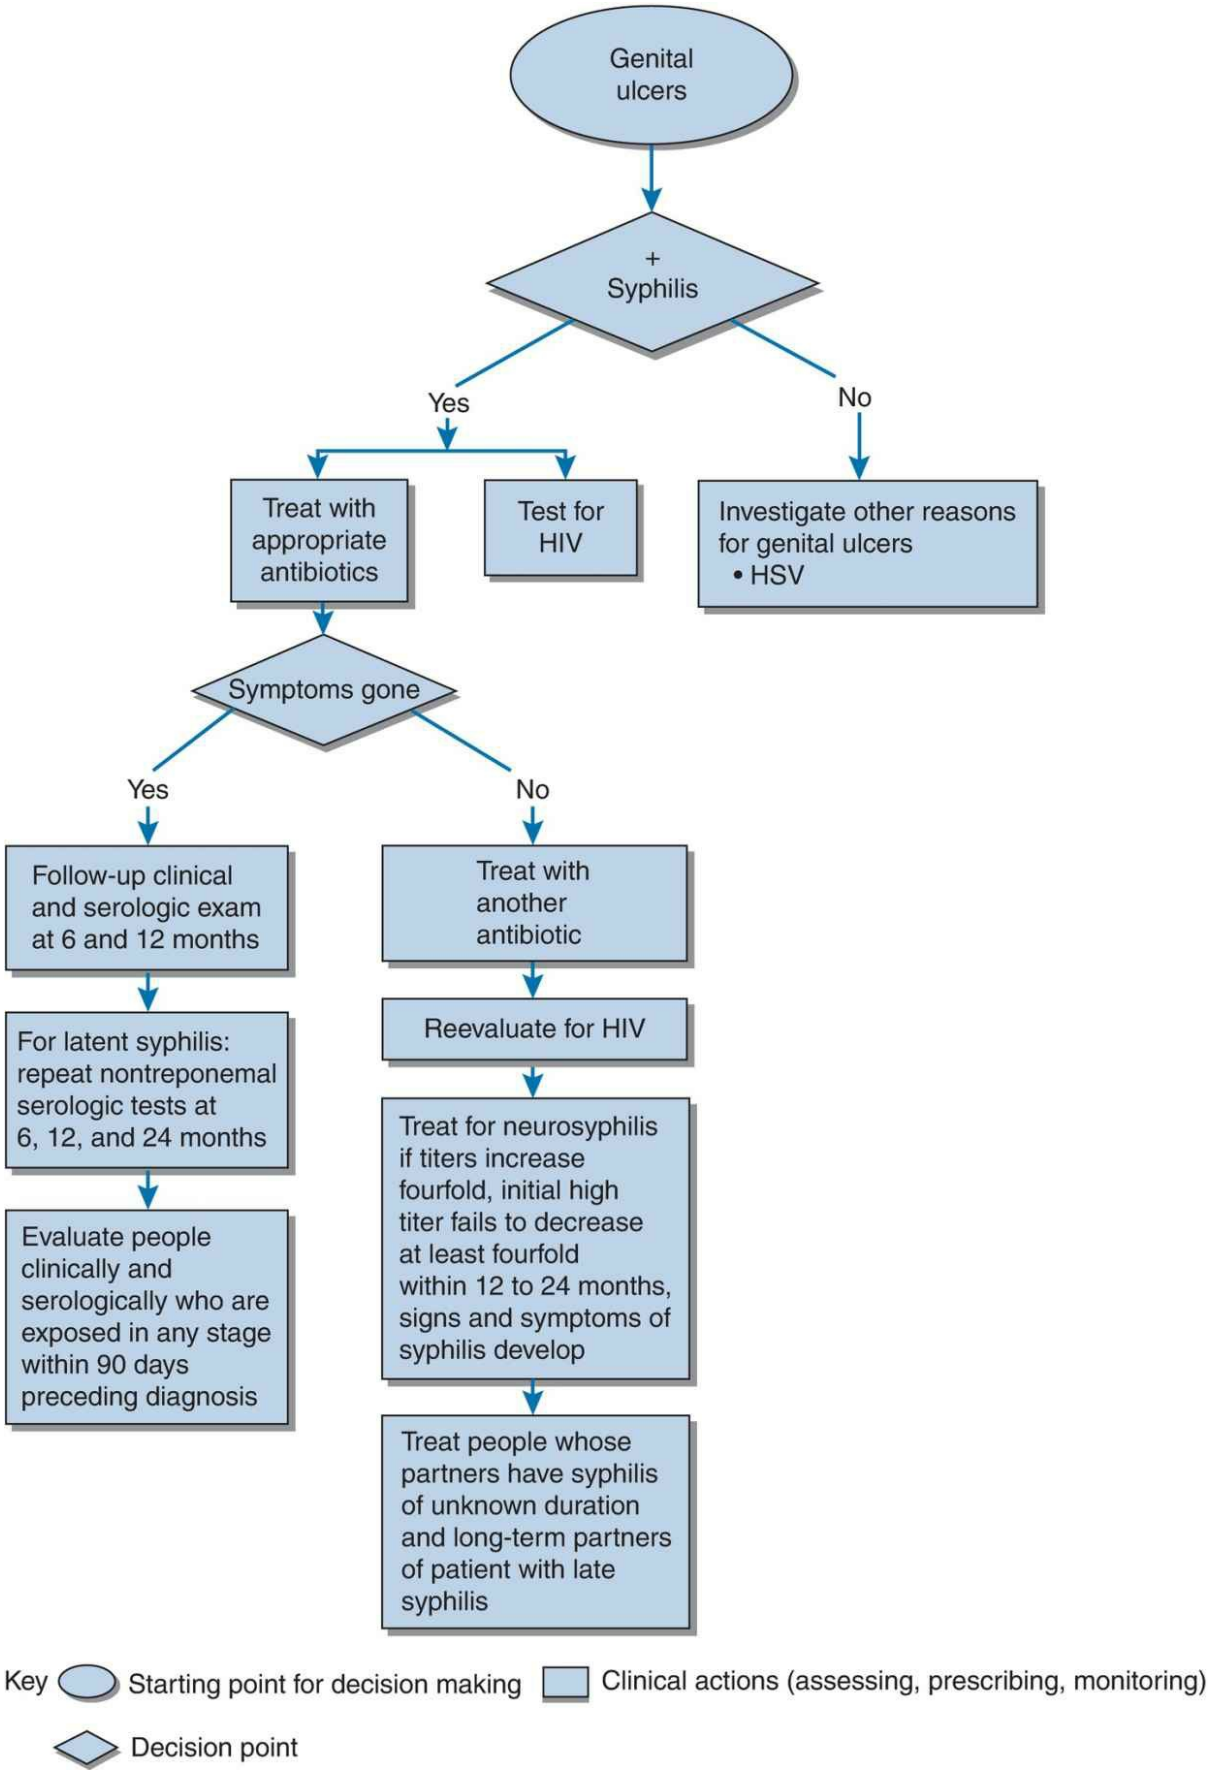

FIGURE 35.3 Treatment algorithm for syphilis.

Special Population Considerations

Pediatric

Children with syphilis should have a CSF examination for asymptomatic neurosyphilis. To assess for congenital or acquired syphilis, birth and maternal records should be reviewed. Children who have primary or secondary syphilis should have an evaluation, consultation with child protection services, and treatment with a pediatric regimen.

Women

Pregnant women should be screened and treated for syphilis to protect the fetus and the newborn from exposure to syphilis. Screening is performed at the time pregnancy is confirmed. If the patient is in a high-risk group, testing should also occur at 28 weeks and at delivery. Pregnant patients who are allergic to penicillin should be desensitized and treated with penicillin.

At-Risk Populations

All patients with syphilis should be tested for HIV infection. In areas where the prevalence of HIV is high, patients with primary syphilis should be retested for HIV after 3 months if the first HIV result was negative.

Monitoring Patient Response

Patients should have a clinical and serologic examination at 6 and 12 months, or more frequently if follow-up results are uncertain. Those who fail to respond to treatment or who were reinfected, those who have signs that persist or recur, or those who have a sustained fourfold increase in nontreponemal test titer values within 6 months after treatment for primary or secondary syphilis should be retreated after evaluation for HIV infection. Treatment with three weekly injections of penicillin G benzathine is recommended if additional follow-up results are uncertain, unless CSF examination identifies neurosyphilis.

Patients with latent syphilis should be evaluated for tertiary disease. All patients with latent syphilis should have quantitative nontreponemal serologic tests repeated at 6, 12, and 24 months.

Patients should be evaluated for neurosyphilis and treated if titer values increase fourfold, an initially high titer fails to decrease at least fourfold within 12 to 24 months, or signs and symptoms related to syphilis develop. Patients with symptoms of neurologic or ophthalmic disease should be evaluated for neurosyphilis and syphilitic eye disease and treated appropriately according to the results (Table 35.6).

TABLE 35.6 Overview of Drugs Used to Treat Neurosyphilis

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
aqueous crystalline penicillin G 18–24 million U/d, give as 3–4 million U IV q4h for 10–14 d	Similar to penicillins	Hypersensitivity to penicillin	This penicillin preparation is the drug of first choice in treating neurosyphilis; second-line therapy is procaine penicillin.
procaine penicillin (Bicillin with probenecid, Benemid) 2.4 million U IM/d, plus probenecid 500 mg PO qid, both for 10–14 d	Similar to other penicillins *Probenecid:* Headache, dizziness, GI upset, hypersensitivity reactions, acute gouty arthritis, nephrotic syndrome, uric acid stones	Hypersensitivity to penicillin or probenecid Children <2 y: blood dyscrasias, uric acid kidney stones	If compliance can be ensured, avoid IV, intravascular, or intra-arterial administration. *Probenecid:* Use caution in prescribing for patients with peptic ulcer.

Patient Education

Teaching patients about preventive strategies is important in deterring the transmission of disease. All patients with a diagnosis of syphilis should be advised to undergo HIV testing as well.

Genital Herpes Simplex Virus Infection

In the United States, genital herpes simplex (HSV) is the most prevalent genital ulcer disease with approximately 50 million persons infected. It is associated with a higher risk of HIV infection. More than 500,000 new cases occur each year. Most infected people remain undiagnosed. They have mild or unrecognized infections that shed the virus in the genital tract intermittently. Although some first episodes of genital herpes may be characterized by severe disease requiring hospitalization, many people are unaware they have the infection or are asymptomatic when transmission occurs. The disease can be controlled, not cured. It recurs periodically. Viral infections, for which curative therapy is not available, have been stable or increasing in prevalence. With 500,000 new cases each year, herpes simplex virus (HSV) is one of the most common viral STIs.

Causes

Genital herpes simplex is caused by HSV, which has two serotypes: HSV-1 (genital) and HSV-2 (anorectal). The infection is transmitted by contact with an infected person by kissing or sexual intercourse, or during vaginal birth. Recurrent outbreaks may be triggered by injury to the infected area, an illness that alters immune status, emotional stress, or menses.

Pathophysiology

Recurrent genital herpes is usually caused by HSV-1, while anorectal is HSV-2. After the virus enters the body through a susceptible mucosal surface, it resides and remains dormant in the cells of the nervous system until activated later. Exacerbations of varying frequency may or may not occur. In general, recurrent outbreaks are less severe than the initial episode.

Diagnostic Criteria

A diagnostic evaluation for herpes includes a health history and physical examination. In addition to serologic testing for HSV, patients should have a serologic test for syphilis. HIV testing should be considered as well. Specific tests for genital herpes include culture or antigen test for HSV. In addition, a POCkit HSV-2 test can be performed.

The patient seeking treatment may report any one of three genital HSV syndromes. The first is primary infection, which is the first infection with genital HSV characterized by no preexisting antibodies to either HSV-1 or HSV-2. Symptoms include genital pain, vesicles, fever, malaise, regional adenopathy, and, in women, lesions on the cervix. The second syndrome is nonprimary first episode infection, which is the first clinically evident infection in women who have had a previous infection with the heterologous strains. The symptoms include fewer lesions, few constitutional symptoms, and a shorter, milder course. The third syndrome is recurrent infection, which usually has no constitutional symptoms, a shorter duration of viral shedding, and a shorter healing time.

Initiating Drug Therapy

The only effective therapy for genital herpes is drug therapy. Patient education is an important measure for preventing spread of the disease.

Goals of Drug Therapy

Treatment goals for first clinical episodes, recurrent episodes, and daily suppressive therapy aim to control the symptoms of the herpes episodes. The drugs *do not eradicate* the latent virus, and once discontinued, they do not affect the risk, frequency, or severity of recurrences. Treatment trials show acyclovir (Zovirax), valacyclovir (Valtrex), and famciclovir (Famvir) to be beneficial for treating genital herpes. The use of topical acyclovir is discouraged because it is substantially less effective than the systemic drug. The recommended acyclovir dosing regimens have been approved by the U.S. Food and Drug Administration and reflect substantial clinical experience and expert opinion for initial and recurrent episodes (Table 35.7).

TABLE 35.7 Overview of Selected Drugs to Treat Genital Herpes

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
acyclovir (Zovirax) *First clinical episode:* 400 mg tid for 7–10 d or 200 g five times a day for 7–10 d *Recurrence:* 400 mg tid for 5 d or 200 mg five times a day for 5 d or 800 mg bid for 5 d Daily *suppressive therapy:* 400 mg bid *Severe disease:* 5–10 mg/kg IV q8h for 5–7 d or until clinical resolution occurs	GI upset (nausea, vomiting), headache, CNS disturbances, rash, malaise, vertigo, arthralgia, fatigue, viral resistance	Hypersensitivity to acyclovir Use with caution with renal impairment, pregnancy, breast-feeding mothers.	Do not exceed maximum dose.
famciclovir (Famvir) *First clinical episode:* 250 mg tid for 7–10 d *Recurrence:* 125 mg bid for 5 d *Daily suppressive therapy:* 250 mg bid	Headache, fatigue, GI upset With chronic use: pruritus, rash, laboratory test abnormalities, paresthesias	Hypersensitivity to famciclovir Pregnancy, lactation Use with caution in patients with renal dysfunction.	Easy to administer for prolonged treatment May be affected by drugs metabolized by aldehyde oxidase
valacyclovir (Valtrex) *First clinical episode:* 1 g PO bid for 7–10 d *Recurrent episodic infection:* 500 mg PO bid for 5 d *Daily suppressive therapy:* 500 mg PO qd (<9 episodes a year) or 1,000 mg PO qd	GI upset, headache, dizziness, abdominal pain	Hypersensitivity to valacyclovir Do not use in children. Use with caution with renal impairment, pregnancy, lactation.	Valacyclovir 500 mg qd is less effective than other valacyclovir regimens in patients with ≥10 episodes yearly. Be alert for renal or CNS toxicity in patients taking other nephrotoxic drugs.

Antivirals: Acyclovir, Famciclovir, and Valacyclovir

The three first-line systemic agents used to control genital herpes infections are acyclovir, famciclovir, and valacyclovir. These drugs inhibit viral DNA replication and are highly effective.

Acyclovir, which has low bioavailability, works only in the cells infected by HSV. Famciclovir, a prodrug of penciclovir, is well absorbed. It is converted to penciclovir by first-pass metabolism. Valacyclovir, a prodrug of acyclovir, is converted rapidly by first-pass metabolism to acyclovir. It has a 50% bioavailability; it also deactivates viral DNA polymerase.

Because antiviral medications are excreted by the renal system, caution should be used in patients with renal disease. They should also be prescribed cautiously for pregnant patients and are contraindicated in breast-feeding patients. These antivirals interact with probenecid, which increases the effect of the antiviral agent, and with zidovudine (Retrovir), which may cause drowsiness. For a detailed discussion of the roles that acyclovir, famciclovir, and valacyclovir play in controlling HSV-1 and HSV-2, see Chapter 13.

Selecting the Most Appropriate Agent

Therapy progresses from selecting treatment for the first clinical episode of infection to prescribing an antiviral agent for suppressive therapy (Figure 35.4).

Decision point

FIGURE 35.4 Treatment algorithm for genital herpes.

First-Line Therapy

Treatment for the first clinical episode of genital herpes includes antiviral therapy and counseling about the natural history of the virus, sexual and perinatal transmission, and methods to reduce transmission. Antiviral therapy for the initial outbreak includes the following:

- Acyclovir 400 mg three times daily for 7 to 10 days
- Acyclovir 200 mg five times a day for 7 to 10 days
- Famciclovir 250 mg three times a day for 7 to 10 days
- Valacyclovir 1.0 g two times a day for 7 to 10 days

The choice is based on the cost of medication, patient preference, or scheduling issues.

Second-Line Therapy (Recurrent Episodes)

Most patients with genital herpes infection have recurrent episodes of genital lesions. Episodic or suppressive antiviral therapy may shorten the duration of lesions or prevent recurrences. Episodic therapy is beneficial for recurrent disease if the treatment is started during the prodromal phase or within 1 day after onset of the lesions. When given episodic treatment, the patient should also be given additional antiviral therapy so the treatment can be initiated at the first sign of prodrome or genital lesions. Recurrent episodes are treated with:

- Acyclovir 400 mg three times a day for 5 days
- Acyclovir 800 mg two times a day for 5 days
- Acyclovir 800 mg three times a day for 2 days
- Famciclovir 125 mg two times a day for 5 days
- Famciclovir 1,000 mg twice a day for 1 day
- Valacyclovir 500 mg two times a day for 3 days
- Valacyclovir 1.0 g once a day for 5 days

Third-Line Therapy (Suppressive Therapy)

Third-line therapy is also known as suppressive therapy for HSV. The frequency of recurrent symptoms, or outbreaks, can be reduced by 75% or more with daily suppressive therapy, although suppressive therapy does not eliminate subclinical viral shedding. This therapy is used for patients with more than six episodes a year. Acyclovir has documented safety and efficacy for use for as long as 6 years, and valacyclovir and famciclovir for 1 year. Discontinuation of therapy should be discussed with the patient after 1 year of continuous suppressive therapy to determine the rate of recurrence and the patient's psychological

adjustment. In many patients, the frequency of recurrence decreases over time.

Asymptomatic viral shedding is reduced but not eliminated with suppressive treatment with acyclovir. Therapy is not discontinued in patients who are HIV positive.

Suppressive therapy is as follows:

- Acyclovir 400 mg two times a day
- Famciclovir 250 mg two times a day
- Valacyclovir 500 or 1,000 mg once a day

Valacyclovir 500 mg once a day may be less effective than other regimens for prolonged suppression.

Severe or Complicated Disease

For patients with severe disease or complications requiring hospitalization, intravenous (IV) therapy is indicated. The recommended regimen is acyclovir 5 to 10 mg/kg body weight IV every 8 hours for 5 to 7 days or until clinical resolution is attained.

Special Population Considerations

Pediatric

The risk of HSV infection in the neonate is not completely eliminated with cesarean delivery. Infants exposed to HSV during birth should be followed carefully. Before clinical signs develop, the CDC recommends that the infant have surveillance cultures of mucosal surfaces to detect HSV infection. Infants born to women who acquired genital herpes near term should receive acyclovir therapy. Infants with neonatal herpes should be treated with acyclovir 30 to 60 mg/kg/d for 10 to 21 days.

Women

During pregnancy, the first clinical episode of genital herpes may be treated with oral acyclovir. IV administration of acyclovir is indicated for life-threatening maternal HSV infection. Acyclovir is not recommended for routine administration in pregnant women who have a history of recurrent genital herpes. The safety of systemic acyclovir and valacyclovir in pregnant women is unknown.

Women who acquire genital herpes close to the time of delivery (30% to 50%) are at high risk for transmitting the disease to the neonate. Those who have recurrent herpes at term or those who acquire genital HSV during the first half of pregnancy (3%) are at low risk for transmitting the disease to the neonate.

Sex partners who are symptomatic should have an evaluation and treatment similar to patients who have genital lesions. Most people who have genital HSV infection have no history of genital lesions. Therefore, asymptomatic sex partners of patients with newly diagnosed genital herpes should be interviewed regarding histories of typical and atypical genital lesions and encouraged to perform examinations and seek medical attention immediately if lesions appear.

Monitoring Patient Response

Response to therapy is monitored by symptom relief and resolution of lesions.

Patient Education

Patients should inform their sex partners that they have genital herpes and should abstain from sexual activity when lesions or prodromal symptoms are present. The practitioner can also discuss use of condoms with sex partners. Patients should also be counseled about transmission of HSV during asymptomatic periods. A diagnosis of genital herpes can be devastating to the individuals involved, so counseling should include helping patients cope with their infection and prevention of transmission.

Effective episodic treatment of recurrent herpes requires initiation of therapy within 1 day of lesion onset or during the prodrome that precedes some outbreaks. The patient should be provided with a supply of drug or a prescription for the medication with instructions to initiate treatment immediately when symptoms begin.

The risk of neonatal infection should be discussed with both sexes, and women who are pregnant should advise their health care providers about the infection. Patients should also be advised that episodic antiviral therapy may shorten the duration of lesions during recurrent episodes and that recurrent outbreaks can be ameliorated or prevented with suppressive antiviral therapy. Prevention of neonatal herpes should be emphasized during late pregnancy and counseling provided regarding unprotected genital and oral sexual contact at this time.

Patients who have genital herpes should be educated about the natural history of the disease, with emphasis on the potential for recurrent episodes, asymptomatic viral shedding, and the attendant risks of sexual transmission. All persons with genital HSV infection should be encouraged to inform their current sex partners that they have genital herpes and to inform future partners before initiating a sexual relationship. Persons with genital herpes should be informed that sexual transmission of HSV can occur during asymptomatic periods. Asymptomatic viral shedding is more frequent in genital HSV-2 infection than genital HSV-1 infection and is most frequent in the first 12 months of acquiring HSV-2.

Pelvic Inflammatory Disease

It is estimated that PID affects 1 million women each year. Approximately 250,000 of these women are hospitalized and more than 150,000 major surgical procedures are performed. The disease is associated with significant long-term consequences, including tubal factor infertility, ectopic pregnancy, and chronic pelvic pain. Risk factors for PID include previous episodes of PID, presence of *N. gonorrhoeae, C. trachomatis*, or bacterial vaginosis in the lower genital tract, multiple sex partners, use of an intrauterine contraceptive device, adolescence, sexual intercourse during the last menstrual period, douching, and cigarette smoking. Oral contraceptives are thought to afford some protection against PID.

Causes

The most common etiologic agents for PID are *N. gonorrhoeae* and *C. trachomatis*. Other microorganisms that are part of the vaginal flora can also cause PID, as well as *Mycobacterium hominis* and *Ureaplasma urealyticum*.

Pathophysiology

PID consists of several inflammatory disorders of the upper female genital tract that include any combination of endometritis, salpingitis, tubo-ovarian abscess, and pelvic peritonitis. It is an ascending infection that spreads from the lower genital tract to the endometrium, to the fallopian tubes, and to the peritoneal cavity.

Diagnostic Criteria

In all settings, no single historical, physical, or laboratory finding is sensitive and specific enough to make the diagnosis of acute PID. Many cases of PID are not recognized because they are asymptomatic or because the patient or health care provider fails to recognize mild or nonspecific symptoms.

The following diagnostic criteria are from the CDC (2015) guidelines. Empiric treatment of PID should be given to sexually active young women and others who are at risk for STIs if all of the following minimum criteria are present with no other causes for the illness: lower abdominal tenderness, adnexal tenderness, and cervical motion tenderness. Additional criteria may be used to enhance the specificity of the minimum criteria, including oral temperature exceeding 101°F (38.3°C), abnormal cervical or vaginal discharge, elevated erythrocyte sedimentation rate, elevated C-reactive protein, and laboratory documentation of cervical infection with *N. gonorrhoeae* or *C. trachomatis*. In selected cases, the following definitive criteria for diagnosing PID are warranted: histopathologic evidence of endometritis on endometrial biopsy; transvaginal sonography or other imaging techniques showing thickening, fluid-filled tubes with or without free pelvic fluid or tubo-ovarian complex; and laparoscopic abnormalities consistent with PID.

Initiating Drug Therapy

Treatment for PID is prescribed when the patient's signs and symptoms meet the diagnostic criteria. Treatment includes empiric, broad-spectrum coverage of likely pathogens, including *N. gonorrhoeae, C. trachomatis*, anaerobes, gram-negative facultative bacteria, and streptococci. The CDC (2015) recommends patients be hospitalized when surgical emergencies cannot be excluded and when the patient is pregnant; does not respond clinically to oral antimicrobials; cannot tolerate an outpatient oral regimen; has severe illness, nausea and vomiting, or high fever; has a tubo-ovarian abscess; or is immunodeficient. There are no efficacy data that compare parenteral with oral regimens, and clinical experience should guide the decision to switch from parenteral to oral therapy, which may occur within 24 hours of clinical improvement.

Goals of Drug Therapy

In addition to ameliorating infection or preventing the progression of disease, the goal of drug therapy is to preserve the patient's reproductive health or at least minimize the effects of infection. Treatment should begin as promptly as possible because prevention of long-term sequelae has a direct correlation with immediate antibiotic coverage. Factors to consider in selecting treatment include drug availability and cost, patient acceptance, and antimicrobial susceptibility.

Antimicrobials and Appropriate Treatment Choices

For the most part, antimicrobial regimens for PID are those used for patients with chlamydial and gonorrheal infections. Refer to the sections on chlamydial infection and gonorrhea in this chapter, and also see Table 35.8 for an overview of drug therapy in PID and Figure 35.5 for a synopsis of the treatment. For women with PID of mild or moderate severity, parenteral therapy and oral therapy appear to have similar clinical efficacy.

TABLE 35.8 Overview of Selected Drugs to Treat Pelvic Inflammatory Disease

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
cefoxitin (Mefoxin) Mefoxin plus probenecid (Benemid) 2 g IV q6h Mefoxin plus doxycycline (Vibramycin) 100 mg PO for 14 d	*cefoxitin:* Pseudomembranous colitis, thrombophlebitis, rash, pruritus, eosinophilia, fever, dyspnea, hypotension, GI upset *doxycycline:* Superinfection, photosensitivity, GI upset, enterocolitis, rash, blood dyscrasias, hepatotoxicity	Hypersensitivity to cefoxitin or cephalosporins Pregnancy, lactation, hypersensitivity to any of the tetracyclines	Prescribe with caution to penicillin-sensitive patients and those with GI disease. Monitor blood, renal, and hepatic function in long-term use. Avoid sunlight or UV light. Use of drug during tooth development may cause dental discoloration. Absorption is reduced when taken with food or bismuth subsalicylate.
doxycycline (Vibramycin) 100 mg PO bid for 14 d or clindamycin (Cleocin) 450 mg PO qid for 14 d	Same as above	Same as above	Parenteral therapy may be discontinued 24 h after patient improves clinically. Clindamycin is used with tubo-ovarian abscess rather than doxycycline.
ofloxacin (Floxin) 400 mg PO bid for 14 d	Rash, hives, rapid heartbeat, difficulty swallowing or breathing, photosensitivity, angioedema, dizziness, light-headedness	Pregnancy Hypersensitivity to ofloxacin or fluoroquinolones	Use with caution with hepatic or renal insufficiency. Do not take with food.
metronidazole (Flagyl) 500 mg PO bid for 14 d	CNS stimulation, phototoxicity, GI upset, insomnia, headache, dizziness, tendinitis or tendon rupture, local reactions	Hypersensitivity to metronidazole Pregnancy, lactation	Take on empty stomach with full glass of water and maintain adequate hydration throughout therapy. Avoid excessive sunlight or UV light. Monitor blood, renal, and hepatic function in long-term use. Use with caution with CNS disorders that increase seizure risk and in renal or hepatic impairment.
ceftriaxone (Rocephin) 250 mg IM once	Pseudomembranous colitis, rash, GI upset, hematologic abnormalities	Known allergy to cephalosporins	Prescribe with caution to penicillin-sensitive patients.

Decision point

FIGURE 35.5 Treatment algorithm for pelvic inflammatory disease (PID).

Special Population Considerations

So that the mother and fetus can be closely monitored, pregnant women with suspected PID should be hospitalized and treated with parenteral antibiotics.

Monitoring Patient Response

Patients treated with oral or parenteral therapy should demonstrate substantial clinical improvement within 3 days after therapy has been initiated. Those who do not improve in this period usually require additional diagnostic tests or surgical intervention. The patient should be seen after 1 week of antibiotic therapy to check for residual pelvic abnormalities. Outpatient oral or parenteral therapy also requires a follow-up examination performed within 72 hours, using the criteria for clinical improvement.

Patient Education

If *N. gonorrhoeae* or *C. trachomatis* is present, the practitioner needs to explain to patients with PID that their sex partners should be examined and treated if they have had sexual contact with the patient during the 60 days before the onset of the patient's symptoms. Male partners of women with PID caused by *C. trachomatis* or *N. gonorrhoeae* are often asymptomatic and should be treated empirically with regimens that are effective against both infections.

Human Papillomavirus Infection

The detection of human papillomavirus (HPV) infection has increased in frequency in the genital tracts of men and women. Genital warts, known as *condylomata acuminata,* have been detected with widely increasing frequency as well. About 14 million new cases of HPV are diagnosed each year, and the prevalence of this disease is estimated to be 79 million cases (CDC, 2013).

Causes

There are over 100 identified types of HPV, which 40 are genital. The sexual transmission of HPV is well documented, with the highest prevalence in young, sexually active adolescents and adults. Risk factors include the presence of other STIs, an increased number of sex partners, and use of oral contraceptives without other protection.

Pathophysiology

Most HPVs cause no symptoms, are subclinical, or remain unrecognized. Warts that are visible in the genital tract are usually caused by HPV types 6 or 11, which also cause warts (that cannot be seen externally) on the uterine cervix and in the vagina, urethra, and anus. These viruses, which can produce symptoms, have also been associated with conjunctival, nasal, oral, and laryngeal warts. They are rarely associated with invasive squamous cell carcinoma of the external genitalia. Genital warts can be painful, friable, or pruritic, depending on their size and anatomic location.

Cervical dysplasia has been strongly associated with other HPV types in the anogenital region, including types 16, 18, 31, 33, and 35. These are found occasionally in visible genital warts and have been associated with external genital squamous intraepithelial neoplasia and vaginal, anal, and cervical intraepithelial dysplasia and squamous cell carcinoma. Visible genital warts can be infected simultaneously with multiple HPV types. The body's immune system clears most HPV naturally within 2 years (about 90%), though some infections persist.

Diagnostic Criteria

Genital warts are diagnosed definitively by biopsy, which is needed only if the diagnosis is uncertain, if the lesions do not respond to standard therapy, if the disease worsens during therapy, if the patient is immunocompromised, or if the warts are pigmented, indurated, fixed, and ulcerated. The literature does not support HPV nucleic acid tests for use in the routine diagnosis or management of visible genital warts. For women who have exophytic cervical warts, high-grade squamous intraepithelial lesions must be ruled out before initiating treatment for genital warts (CDC, 2006).

Initiating Drug Therapy

There is no evidence that current treatments eradicate or affect the natural history of HPV infection or the development of cervical cancer. Removal of warts may or may not decrease infectivity. Warts that are not treated may resolve on their own, remain unchanged, or increase in number and size. Treatment is guided by patient preference, cost of treatment and available resources, experience of the health care practitioner, wart size and number, anatomic location of wart, wart morphology, convenience, and adverse effects. No single treatment is ideal for all patients, nor is one superior to another.

Visible genital warts may be self-treated by the patient if they are accessible or by the health care practitioner. Nonpharmacologic therapies include surgery or laser therapy. Carbon dioxide laser is used for extensive warts or intraurethral warts and for patients who do not respond to other treatments. Pharmacotherapy may include podophyllin resin (Podofin), imiquimod (Aldara), trichloroacetic acid (TCA), bichloracetic acid (BCA), or intralesional interferon (Intron A).

Goals of Drug Therapy

The primary goal in treating visible genital warts is the removal of symptomatic warts and prevention of HPV transmission. Removal can induce wart-free periods in most patients. Often, genital warts are asymptomatic. Pharmacologic therapy may include podofilox (Condylox), imiquimod, TCA, and BCA (Table 35.9).

TABLE 35.9 Overview of Selected Drugs and Procedures Used to Treat Genital Warts

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Patient Applied			
podofilox solution or gel (Condylox) 0.5% bid for 3 d followed by 4 d of no therapy; repeat cycle as needed for a total of 4 cycles.	Mild or moderate pain or local irritation	The safety of podofilox during pregnancy has not been established.	Apply solution with cotton swab or apply gel with finger. Total wart area should not exceed 10 cm^2, and total volume of podofilox should not exceed 0.5 mL/d.
imiquimod cream (Aldara) 5% cream applied three times a week for up to 16 wk	Mild to moderate local inflammatory reactions	The safety of imiquimod during pregnancy has not been established.	Apply with finger at bedtime. Wash area with mild soap and water 6–10 h after application of cream. May clear area of warts in 8–10 wk or sooner.
Practitioner Applied			
cryotherapy	Pain, necrosis, blistering	Use of cryoprobe in the vagina is not recommended because of risk of vaginal perforation and fistula formation.	Repeat applications every 1–2 wk. Use local anesthetic. Indicated for urethral meatus warts, anal warts, oral warts
podophyllin or resin in compound tincture of benzoin 10%–25% (Podofin)	Local irritation	The safety of podophyllin during pregnancy has not been established. Use with caution vaginally because of potential systemic absorption.	Apply small amount to each wart and allow site to air-dry. Limit to ≤0.5 mL of podophyllin or ≤10 cm^2 of warts per therapy session. Wash off preparation 4 h after application to reduce local irritation. Repeat application weekly if necessary. With vaginal warts, allow to dry before removing speculum and treat with ≤2 cm^2 per session. For warts on the urethral meatus, treatment area must be dry before preparation comes in contact with normal mucosa.
trichloroacetic acid or bichloracetic acid 80%–90%	Can spread rapidly and damage adjacent tissue; pain		Apply small amount only to warts and allow site to dry. White "frosting" will develop. Use talc with baking soda to remove unreacted acid if an excess amount is applied. Repeat treatment weekly as needed. Indicated for vaginal warts

Podofilox and Podophyllin Resin

Visible genital warts can be self-treated by the patient with podofilox. The patient must be able to identify and reach the warts to be treated. Podofilox in 0.5% solution or gel is safe, inexpensive, easy to use, and efficacious on mucosal surfaces.

A stronger preparation for application only by the health care provider is podophyllin resin, which may be administered at a 10% to 25% concentration in a compound with tincture of benzoin. The CDC does not recommend use of podophyllin by the patient because of rare but potential toxicity involving systemic absorption, bone marrow suppression, or serious GI upset. The preparation is applied weekly as needed. Again, to guard against potential toxicities, the CDC recommends washing the preparation from the application site 1 to 4 hours after application. The most common adverse effect, which

indicates the preparation is working, is local irritation. The preparation has not been established as safe for use during pregnancy.

Imiquimod

Like podofilox, imiquimod may be self-administered by the patient. This antimitotic preparation enhances the immune response to HPV. Imiquimod can be topically applied three times weekly for 3 to 4 months. As with podophyllin, the imiquimod site should be washed with mild soap and water 6 to 10 hours after application. Warts should disappear in 8 to 10 weeks. During imiquimod therapy, sexual contact should be avoided to prevent viral transmission. Adverse effects include a local inflammatory reaction. The safety of use during pregnancy has not been established.

Trichloroacetic Acid (TCA) and Bichloracetic Acid (BCA)

TCA and BCA are applied by the health care provider. These are strong 80% to 90% acids that flow onto the wart site quickly, and the fluid can spread equally quickly. Application requires particular care and skill. The acid is applied only to the warts and left to air-dry. A white "frosting" appears at the site. The practitioner can use talc or sodium bicarbonate powders to neutralize acid that falls on healthy tissue. TCA and BCA can be used effectively on keratinized areas and are safe for use during pregnancy. They are associated with low systemic toxicity.

Intralesional Interferon

Interferon is ineffective when used systemically. However, the use of intralesional interferon appears to be effective, and recurrence rates after therapy are comparable to those with other treatment modalities. Intralesional therapy appears to be effective because of interferon's antiviral or immunostimulating effects.

Selecting the Most Appropriate Agent

Treatment of genital warts should be guided by the preference of the patient, the available resources, and the experience of the health care provider. No definitive evidence suggests that any one of the available treatments is superior to the others, and no single treatment is ideal for all patients or all warts. Most patients have 10 or fewer genital warts. These warts respond to most treatment modalities. Factors that may influence selection of treatment include wart size, wart number, and anatomic site of wart, wart morphology, patient preference, and cost of treatment, convenience, adverse effects, and provider experience. Many patients require a course of therapy rather than a single treatment. In general, warts located on moist surfaces or in intertriginous areas respond better to topical treatment than do warts on drier surfaces. Figure 35.6 outlines the most appropriate patient- or practitioner-applied drug therapies in the most appropriate order.

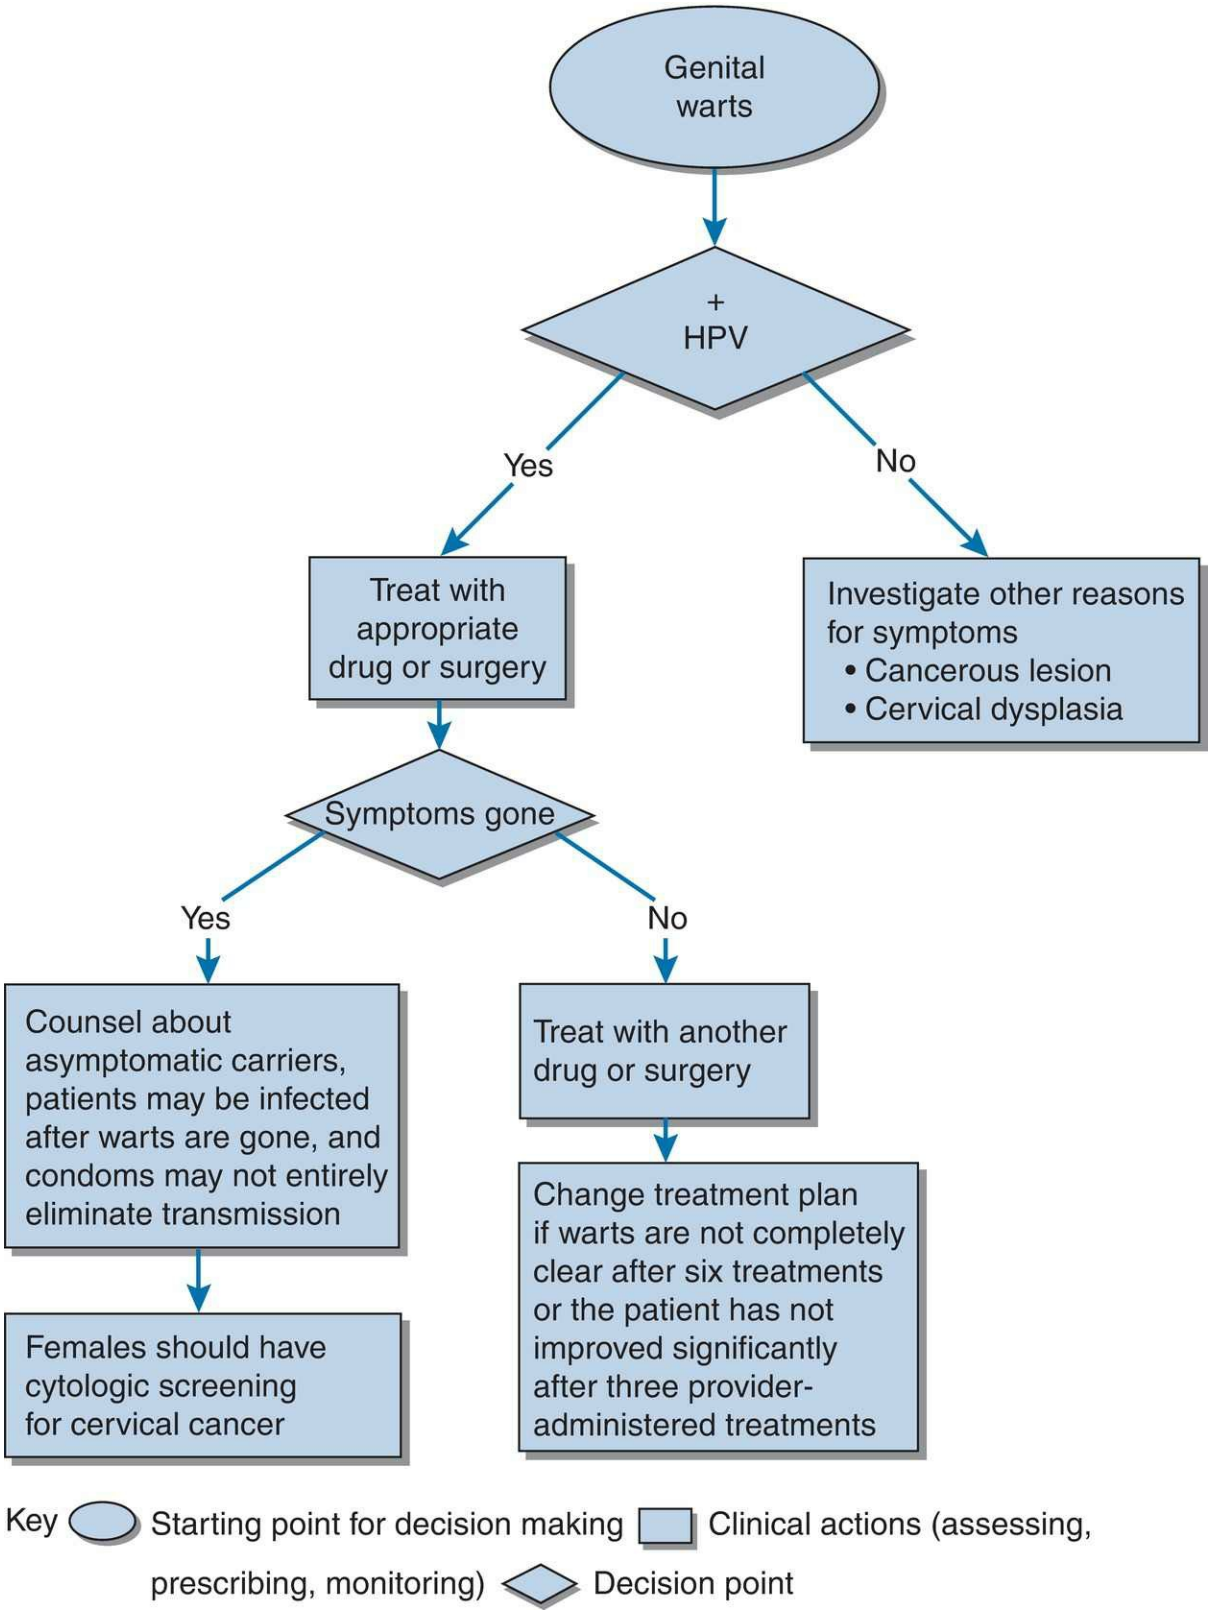

FIGURE 35.6 Treatment algorithm for genital warts.

Special Population Considerations

Pediatric

Laryngeal papillomatoses in infants and children are caused by HPV 6 and HPV 11. The prevention value of cesarean section is unknown, and the route of transmission is not completely understood.

Women

Many experts recommend removing warts during pregnancy because they can proliferate and become friable.

Monitoring Patient Response

If the warts are not completely clear after six treatments or the patient has not improved significantly after three practitioner-administered treatments, the treatment plan should be changed. Evaluation of the risk/benefit ratio of treatment should occur throughout the course of therapy to avoid overtreatment. Women with genital warts should have cytologic screening for cervical cancer.

Once warts are eradicated, follow-up evaluations are not mandatory. Patients should monitor for recurrences, especially in the first 3 months. Patients who have concerns regarding recurrences can have a follow-up evaluation 3 months after treatment. Earlier follow-up visits may help to verify a wart-free state and monitor or treat complications and can be used for patient education and counseling.

Patient Education

Most sexually active men and women will get HPV at some point in their lives. This means that everyone is at risk for the potential outcomes of HPV and many may benefit from the prevention that the HPV vaccine provides. HPV vaccines are routinely recommended for 11- or 12-year-old boys and girls and protect against some of the most common types of HPV that can lead to disease and cancer, including most cervical cancers. CDC recommends that all teen girls and women through age 26 get vaccinated, as well as all teen boys and men through age 21 (and through age 26 for gay, bisexual, and other men who have sex with men). HPV vaccines are most effective if they are provided before an individual ever has sex.

The practitioner needs to provide precise instruction and guidance for applying topical antimitotic preparations, such as by showing how to apply podofilox solution with a cotton swab and the gel with a finger to visible warts. Patients should also be informed that HPV organisms persist despite resolution of lesions. Sex partners do not need to be examined because reinfection is most likely minimal and treatment to reduce transmission is not realistic in the absence of curative therapy. However, partners should be counseled about having a partner with genital warts and should be informed that the patient may remain infectious even when the warts are gone. The use of condoms may not eliminate the risk of transmission.

Patients should be warned that ablative therapies may cause scarring in the form of persistent hypopigmentation or hyperpigmentation. Depressed or hypertrophic scars rarely occur. Disabling chronic pain syndromes can also occur but are rare.

Case Study*

J.R. is a 36-year-old white, middle-class woman who has been sexually active with one partner for the past 2 years. She and her partner have no history of STIs, but her partner has a history of fever blisters. She reports genital pain, genital vesicles and ulcers, and fever and malaise for the last 3 days. Examination reveals adenopathy and vaginal and cervical lesions.

Diagnosis: Genital Herpes

1. List specific goals for treatment for J.R.
2. What drug therapy would you prescribe? Why?
3. What are the parameters for monitoring the success of the therapy?
4. Discuss specific education for J.R. based on the diagnosis and prescribed therapy.
5. List one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What, if any, would be the choice for second-line therapy?
7. What OTC or alternative medicines would you recommend?
8. What dietary and lifestyle changes should be recommended for this patient?
9. Describe one or two drug–drug or drug–food interactions for the selected agent.* Answers can be found online.

36 Osteoarthritis and Gout

Sarah F. Uroza Lauren K. McCluggage Carol Gullo Mest

Osteoarthritis (OA), formerly known as *degenerative joint disease*, is the most common joint problem in the United States. Based on U.S. data from 2005, OA affects approximately 14% of adults older than age 25 and one third of adults older than age 65. Although prevalent, OA is often undiagnosed because clinical signs and symptoms are typically attributed to the normal aging process. In population-based studies in which asymptomatic patients were screened, the incidence of radiographic-defined OA was consistently higher than the incidence of symptomatic OA in the hands, knees, and hips.

OA is a progressive disease that can result in chronic pain, restricted range of motion, and muscle weakness, especially if a weight-bearing joint is affected. The joints commonly affected by OA include the knees, hips, cervical and lumbar spine, distal interphalangeal (DIP) joints, and the carpometacarpal joint at the base of the thumb.

Causes

There are two forms of OA. *Primary*, or idiopathic, OA arises from physiologic changes that occur with normal aging. *Secondary* OA usually results from traumatic injuries or inherited conditions and may present as hemochromatosis, chondrodystrophy, or inflammatory OA.

There are several modifiable and nonmodifiable risk factors that contribute to the development of OA. Of all the risk factors, obesity is the greatest in the development of OA of the knees and hips, especially in women. This is due to mechanical stress on weight-bearing joints. There may also be a metabolic effect of excess fat on articular cartilage that may account for some of the significance of obesity as a systemic risk factor. Other modifiable risk factors include prior joint injury and occupations that require excessive mechanical stress or heavy lifting. For patients with a past knee injury, the lifetime risk of knee OA is 57% compared to 45% in patients with no previous injury.

The nonmodifiable risk factors include gender, age, race, and genetics. Women have a higher overall risk for developing OA, but men tend to have disease onset at an earlier age. Increasing age is a risk factor until age 75, at which point the risk equilibrates. OA of the DIP and carpometacarpal joints is more common in White women; OA of the knees occurs more frequently in African American women. Genetics may determine approximately one fourth of knee OA cases and one half of hip and hand OA cases.

Pathophysiology

OA must be differentiated from other forms of arthritis because the physiologic changes specific to the condition dictate disease management. Although most forms of arthritis, including OA, result in degeneration of articular cartilage, the subsequent formation of new bone is a change specific to OA.

The physiologic changes associated with OA begin with deterioration of the articular cartilage, which reduces joint friction during movement by diffusing mechanical stress to the underlying bone. Normal articular cartilage is smooth and is supported by subchondral bone. The subchondral bone serves as a flexible base to absorb mechanical force.

Articular cartilage consists of chondrocytes, connective tissue cells that are embedded in an extracellular matrix. The matrix is made up of collagen, water, and proteoglycans (macromolecules). The proteoglycans provide elasticity and flexibility to the matrix, which allows the articular cartilage to resist direct pressure. In OA, there is a reduction in proteoglycans in the extracellular matrix, leading to a decrease in resiliency to mechanical stress. In time, the articular cartilage becomes friable. The underlying subchondral bone responds to this change through a process termed *remodeling*. Remodeling involves the production of new bone that is thicker than the original bone. If remodeling occurs at the joint margins, an osteophyte (bone spur) may develop. The adjacent cortical bone becomes fortified with new bone, resulting in an irregular narrowing of the joint space. Sclerosing and cyst formation may ensue.

In addition to cartilaginous changes, concomitant changes in the synovial fluid must be considered. Synovial fluid, the main lubricant of joints, is produced and excreted from the cartilage. Destruction of the proteoglycans in OA renders the mechanism of synovial release ineffective, thereby further impairing the smooth mechanical operation of the joint. Figure 36.1 demonstrates the mechanism of cartilage destruction.

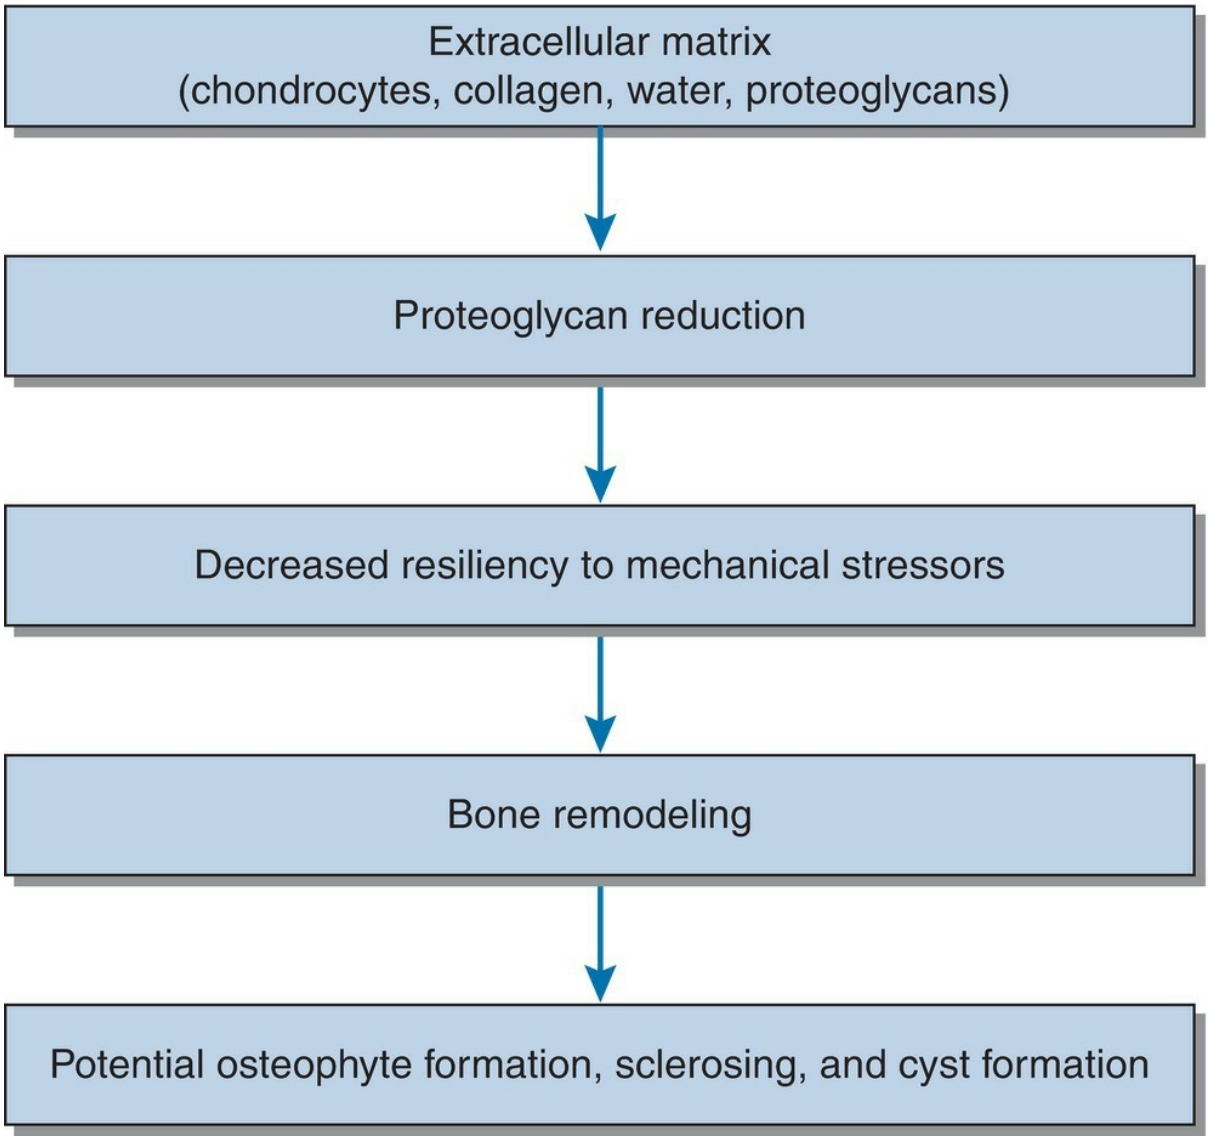

FIGURE 36.1 Destruction of cartilage in osteoarthritis.

Diagnostic Criteria

Joints commonly affected by OA include the hip, knee, hand, and cervical and lumbosacral spine. The American College of Rheumatology (ACR) published criteria for the diagnosis of OA of the knee (1986), hip (1991), and hand (1990) (Box 36.1). Often, a thorough history and physical examination provide enough data to diagnose OA. The most common symptom is joint pain; the patient in an early stage of OA usually describes the pain as insidious, intermittent, and mild. As the disease progresses, the patient may describe the pain as more constant and more disabling. Most patients report remittance of pain with rest and exacerbation of pain with joint movement.

BOX 36.1 Diagnostic Criteria for Osteoarthritis

- Hand: Pain, aching, or stiffness and three of the following:
  - Hard tissue enlargement of >2 joints
  - Hard tissue enlargement of >2 DIP joints
  - <3 swollen MCP joints
  - Deformity of >1 selected joint
- Hip: Pain and 2 of the following
  - ESR < 20 mm/h
  - Radiographic femoral or acetabular osteophytes
  - Radiographic joint space narrowing
- Knee
  - Clinical diagnosis: Knee pain and three of the following
  - >50 years old
  - Stiffness < 30 minutes
  - Crepitus
  - Bony tenderness
  - Bony enlargement
  - No palpable warmth
  - Clinical and radiographic diagnosis: Knee pain + osteophytes and one of the following:
  - >50 years old
  - Stiffness < 30 minutes
  - Crepitus
  - Clinical and laboratory diagnosis: Knee pain and five of the following:
  - Age > 50 years old
  - Stiffness < 30 minutes
  - Crepitus
  - Bony tenderness

- Bony enlargement
- No palpable warmth
- ESR < 40 mm/h
- RF < 1:40
- Synovial fluid signs of OA (clear, viscous, or WBC count < 2,000/mm^3)

MCP, metacarpophalangeal joint; ESR, erythrocyte sedimentation rate.

Although the symptoms of OA are localized, associated pain may be referred. For example, it is common for OA of the hip to be referred to the medial knee. Another symptom associated with OA is crepitus, a painless "crackling" in the joint. Crepitus most commonly affects the knee, but it may be heard in other joints affected by OA as well. As OA progresses to later stages of articular damage, deformity of the joint may be observed. The deformity usually appears as an enlargement of the joint, which may result from either increased bone production or synovitis. Other deformities resulting from OA of the knee include varus (bow-legged knees) and valgus (knock-kneed legs).

OA of the cervical spine may present with pain that radiates to the supraclavicular or upper trapezius areas. Depending on the level of nerve involvement, symptoms may progress to include pain in the distal upper extremities. OA of the lumbar spine may produce symptoms of neurogenic claudication.

On physical examination, decreased range of motion is the most common finding. This finding may be absent in the early stages of the disease but gradually progresses as the condition worsens. In later stages of the disease, joint contractures may occur, resulting in varus and valgus deformities. Patients with severe OA of the hip may present with gait disturbances.

Because OA is a progressive disease, complications such as joint effusion and enlargement may occur. Occasionally, radicular problems may occur secondary to changes in the cervical vertebrae.

Joint enlargement due to the formation of osteophytes may be observed. Osteophyte formation in the DIP joint is called *Heberden nodes*; in the proximal interphalangeal joint, it is referred to as *Bouchard nodes*.

Radiologic findings in OA may be used to confirm the suspected diagnosis. Narrow joint spaces with osteophyte formation are common findings.

Initiating Drug Therapy

Before initiating drug therapy, the practitioner should recommend appropriate physical activity or physical therapy. The goals of physical therapy are to reduce pain, improve motion, and maintain functional ability (Box 36.2). In addition, for hip and knee OA, overweight patients should be counseled on the need for weight loss.

BOX 36.2 Nonpharmacologic Therapies for Osteoarthritis

- Moist heat to help diminish muscle spasm and relieve stiffness
- Weight loss if the patient is overweight
- Exercises to strengthen the muscles surrounding the involved joint(s) and a fitness program to maintain flexibility of the involved joint through swimming, walking, cycling, and isometric exercises
- Use of assistive devices to help with ambulation and activities of daily living

The goals of pharmacotherapy for OA are to maintain function, prevent further joint damage, and diminish associated pain. The degree of joint involvement and the severity of the symptoms usually dictate proper interventions for individual patients.

Acetaminophen

First-line pharmacotherapy for OA is geared toward analgesia, specifically with acetaminophen (Tylenol). Due to acetaminophen's cost-effectiveness and safety, it is currently the first-line treatment recommended in guidelines by the ACR, the European League Against Rheumatism (EULAR), and others.

Mechanism of Action

Acetaminophen exerts its action within the central nervous system (CNS). It is thought to inhibit central cyclooxygenase (COX), which results in decreased prostaglandin synthesis. Through this prostaglandin inhibition, acetaminophen exerts analgesic and antipyretic effects but does not have anti-inflammatory effects.

Dosage

The recommended dose is 650 mg every 4 to 6 hours or 1,000 mg every 6 to 8 hours around the clock. The key to acetaminophen dosing for OA is to schedule the dose regardless of the patient's pain. To be most effective, it must be taken regularly.

The recommended dose of up to 4 g/d is safe for patients with normal liver function. Higher doses have been associated with hepatotoxicity. Patients with a history of liver disease or who are chronic alcohol drinkers should not take more than 1,800 to 2,000 mg/d. All patients should be counseled regarding the need to avoid other products that contain acetaminophen.

Time Frame for Response

If taken as scheduled, patients can experience pain relief within 1 week of initiation.

Contraindications

The only absolute contraindication to acetaminophen use is hypersensitivity to acetaminophen. Acetaminophen should be used cautiously in patients with hepatic disease or who drink more than three alcoholic drinks daily.

Adverse Events

Acetaminophen is typically well tolerated with the most common adverse events being dizziness and rash. For patients who take more than the recommended daily dose, acetaminophen can induce hepatic failure as a result of the accumulation of the hepatotoxic metabolite acetylimidoquinone. Also, patients need to be educated about the risk of accidental overdose with combination products that also contain acetaminophen. Renal toxicity has also been observed with chronic overdosages.

Interactions

With chronic doses of greater than 1.3 g daily, acetaminophen can increase the international normalized ratio (INR) of a patient on warfarin. If a patient is on chronic acetaminophen and warfarin, the INR should be monitored more frequently upon initiation and discontinuation of acetaminophen. Isoniazid may increase the risk of hepatotoxicity of acetaminophen.

Nonsteroidal Anti-inflammatory Drugs

Second-line therapy for OA includes nonsteroidal anti-inflammatory drugs (NSAIDs), the most commonly used class of drugs in the world. NSAIDs are further classified according to their chemical structure (Table 36.1). Although these classes have subtle differences, they all basically act by inhibiting COX. These drugs may be prescribed if patients do not respond well to acetaminophen or if an inflammatory process has begun.

TABLE 36.1 Overview of Selected Nonsteroidal Anti-inflammatory Agents Used to Treat Osteoarthritis and Rheumatoid Arthritis

Generic (Trade) Name	Dosage	Contraindications	Special Considerations	Short, Intermediate, or Long Acting
Acetic Acid NSAIDs				
etodolac (Lodine)	IR: 600–1,000 mg/d PO in 2 or 3 divided doses ER: 400–1,000 mg/d PO	Pregnancy and lactation; use cautiously with allergies, renal, hepatic, CV, and GI conditions.		Intermediate
indomethacin (Indocin)	50–200 mg/d PO in 2–3 divided doses	Same as above, and also GI bleeding with history of proctitis or rectal bleeding	Decreased diuretic effect with loop diuretics; potential decreased antihypertensive effect with beta blockers; increased CNS adverse effects due to lipophilicity	Short
nabumetone (Relafen)	750–2,000 mg/d PO in 1–2 divided doses	Pregnancy and lactation; use cautiously with allergies, hepatic, CV, and GI conditions; significant renal impairment	May be taken in divided dose	Long
sulindac (Clinoril)	300 mg/d PO in 2 divided doses	Pregnancy and lactation; use cautiously in patients with asthma, chronic urticaria, CV dysfunction, hypertension, GI bleeding, peptic ulcer, impaired hepatic or renal function.	May take with meals if GI upset occurs.	Intermediate
tolmetin (Tolectin)	600–2,000 mg/d PO in 3–4 divided doses	Pregnancy, lactation; use cautiously with allergies, renal, hepatic, CV, and GI conditions	May affect results (false positive) of proteinuria tests using acid precipitation tests; patient should have ophthalmic examination periodically during long-term therapy.	Intermediate

Generic (Trade) Name	Dosage	Contraindications	Special Considerations	Short, Intermediate, or Long Acting
Enolic Acid NSAIDs				
piroxicam (Feldene)	10–20 mg/d PO	Pregnancy and lactation; use cautiously with allergies, renal, hepatic, CV, and GI conditions	Because therapeutic response progresses over several weeks, evaluate response after 2 wk. NSAID with the longest half-life.	Long
Fenamic Acid NSAID				
meclofenamate (Meclomen)*	200–400 mg/d PO in 3–4 divided doses	Same as above	Patient should have ophthalmic examination periodically during long-term therapy.	Short
Phenylacetic Acid NSAIDs				
diclofenac sodium (Voltaren) diclofenac potassium (Cataflam)	OA: 100–150 mg/d PO in 2–3 divided doses RA: 100–200 mg/d PO in 2–4 divided doses	Significant renal impairment, pregnancy, lactation; use cautiously with impaired hearing; allergies; hepatic, CV, and GI conditions.	NSAID with the shortest half-life	Short
Propionic Acid NSAIDs				
fenoprofen (Nalfon)	800–3,200 mg/d PO in 3–4 divided doses	Same as above	Patient should have ophthalmic examination periodically during long-term therapy.	Short
ibuprofen (Motrin)	1,200–3,200 mg/d PO in 3–4 divided doses	Same as above	Therapeutic response may occur over several weeks.	Short
naproxen (Naprosyn)	500–1,500 mg/d PO in 2 divided doses	Same as above	May take with meals if GI upset occurs.	Intermediate
Salicylic Acid NSAIDs				
diflunisal (Dolobid)	500–1,500 mg/d PO in 2–3 divided doses	Pregnancy and lactation; use cautiously with allergies, renal, hepatic, CV, and GI conditions.		Intermediate
aspirin (Bayer, others)	2.4–3.6 g/d PO in 4–6 divided doses; maximum daily dose is 5.4 g	Allergy to salicylates, other NSAIDs, tartrazine, hemophilia, and other bleeding disorders, pregnancy (possibly teratogenic), and more; do not use in children after illness because of association with Reye syndrome.	Increased risk of bleeding when taken concomitantly with anticoagulants and other NSAIDs Consult package insert for extensive list of interacting drugs and effects.	Short
COX-2 Selective NSAIDs				
celecoxib (Celebrex)	200–400 mg/d PO in 2 divided doses	Allergy to the drug or to sulfonamides, NSAIDs, or aspirin; significant renal impairment; pregnancy, lactation	Elimination of the drug occurs primarily through hepatic metabolism; therefore, patients with symptoms suggesting liver dysfunction should be carefully monitored.	Intermediate

*Brand name only available in Canada.

Mechanism of Action

There are two mechanisms by which NSAIDs exert their anti-inflammatory action. One is by inhibiting the conversion of arachidonic acid to prostaglandin, prostacyclin, and thromboxanes—all of which are mediators of pain and inflammation. The other is by interfering with protein kinase activation (especially when taken at higher doses).

COX is the enzyme that converts arachidonic acid to prostaglandin G_2. The COX enzyme is present in two forms, COX-1 and COX-2. Most NSAIDs nonselectively inhibit both COX-1 and COX-2, except for celecoxib, which is more selective for COX-2. COX-1 enzymes are found in the gastrointestinal (GI) tract and kidney and produce protective prostaglandins, which is why most research focuses on preserving the activity of COX-1. COX-2 is produced at nonspecific sites of inflammation as well as in the kidneys. Inhibition of COX-2 produces anti-inflammatory and analgesic effects without affecting the GI tract. COX-2 produces protective prostaglandins in the kidney that are responsible for maintaining adequate blood perfusion via vasodilation of the afferent arteriole. Therefore, inhibition of either COX-1 or COX-2 can result in decreased renal perfusion and impaired kidney function.

Dosage

Dosing of NSAIDs is variable. The drugs are classified into short-, intermediate-, and long-acting categories. NSAIDs require five half-lives to reach peak therapeutic levels and five half-lives to be fully excreted. Categories with a longer half-life require longer periods to reach therapeutic levels.

Some common agents used to treat OA are diclofenac, ibuprofen, and the COX-2 inhibitor celecoxib. Diclofenac is given at 50 mg twice daily, and ibuprofen is usually given at 400 mg four times daily. The typical dose of celecoxib is 100 mg twice daily or 200 mg once daily. Patients should be encouraged to use the prescribed NSAID consistently for 2 to 3 weeks to determine its effectiveness. Table 36.1 gives information about other agents and dosing considerations.

Time Frame for Response

Patients' responses to NSAIDs are quite variable. Patients who do not respond to one NSAID may respond to another, even one in the same class. This response variability is also seen in the side effect profile of NSAIDs. The practitioner should be familiar with several of the NSAIDs from each class and should try to individualize therapy based on symptom management and side effects.

Contraindications

NSAIDs are contraindicated in patients allergic to aspirin, in patients with alcohol dependence, or in pregnant patients. Further, since celecoxib contains a sulfa moiety, it is contraindicated in patients with a sulfa allergy. Caution should be used when prescribing NSAIDs to patients with renal or hepatic impairment or the elderly. Due to the increase in cardiovascular adverse events, all NSAIDs carry a black box warning emphasizing that they are contraindicated for perioperative pain treatment in patients undergoing coronary artery bypass graft surgery.

Adverse Events

NSAIDs have gained a reputation as innocuous agents because of their over-the-counter (OTC) availability and widespread use. However, this class of drugs is far from benign, and patient education materials should highlight potential adverse events. The side effect profile of NSAIDs is quite extensive.

Visual changes, weight gain, headache, dizziness, nervousness, photosensitivity, weakness, tinnitus, easy bruising or bleeding, and fluid retention are adverse events that have been associated with use of NSAIDs. Again, cautious use and frequent monitoring, particularly of elderly patients, is of paramount importance for safe NSAID use. The most common adverse events of NSAIDs occur in the GI and renal systems.

Adverse GI events may run the gamut from minor GI irritation to ulcers, GI bleeding, perforation, and gastric outlet obstruction. These GI effects are why NSAIDs remain a second-line approach to OA treatment. Concomitant use of misoprostol (Cytotec) has been shown to decrease the incidence of ulcer disease and GI complications. Misoprostol, a prostaglandin analog, is given at 200 mg four times daily. Its use should be limited to patients at high risk for GI complications (age > 65, comorbid medical conditions, history of peptic ulcer disease or upper GI bleeding, oral glucocorticosteroids, or anticoagulants).

Studies of the treatment of GI effects as a result of NSAIDs have compared the efficacy of proton pump inhibitors and histamine-2 (H_2) receptor antagonists. Yeomans et al. (1998) determined that omeprazole (Prilosec), a proton pump inhibitor, healed existing ulcers and prevented further ulcer development more effectively than did ranitidine (Zantac), an H_2 receptor antagonist. Similarly, Hawkey et al. (1998) found omeprazole and misoprostol equally successful at treating ulcers and other GI symptoms associated with NSAID use. However, omeprazole was better tolerated and was associated with an improved relapse rate.

Another option for patients experiencing GI adverse events with nonselective NSAIDs is celecoxib. In a study conducted by Chan et al. (2010), patients randomized to celecoxib had a lower incidence of upper or lower GI events compared with patients treated with diclofenac plus omeprazole.

Patients with renal disease, congestive heart failure (CHF), cirrhosis, and volume depletion may experience renal aberrations, particularly related to renal blood flow. These adverse events underscore the need for frequent monitoring of patients on long-term

NSAID therapy.

Controversy surrounds the issue of increased risk of cardiovascular events, including thrombotic events, myocardial infarction, and stroke due to NSAID use. This increased risk led to the market removal of two COX-2 selective agents, rofecoxib and valdecoxib. All NSAIDs have a black box warning regarding this increased risk and warn that patients with cardiovascular disease risk factors may be at an increased risk. In multiple analyses, naproxen seems to have little to no increased cardiovascular risk, whereas diclofenac consistently demonstrates an increased risk.

Interactions

NSAIDs have the potential to increase bleeding so they need to be used cautiously with other anticoagulants, specifically warfarin. Also, due to the risk of hypertension, NSAIDs may counteract the effect of antihypertensives. If possible, patients with hypertension should not be on NSAIDs. The combination of NSAIDs and angiotensin-converting enzyme inhibitors or angiotensin receptor blockers may result in decreased renal function and should be avoided. For patients who take aspirin daily, ibuprofen must be taken 30 minutes to 2 hours after or 8 hours before the aspirin in order for the aspirin to be cardioprotective. If taken concurrently with lithium, NSAIDs may increase the drug concentrations of lithium and caution is advised.

Nonacetylated Salicylates

Nonacetylated salicylates (Box 36.3) are especially beneficial in patients who are sensitive to the GI irritation caused by long-term aspirin use. Diflunisal (Dolobid), the most commonly used nonacetylated salicylate, is an effective COX-1 inhibitor with anti-inflammatory and analgesic properties, but its antipyretic activities are weak. In terms of symptom relief, the nonacetylated salicylates are probably as effective as aspirin in treating inflammatory disorders.

BOX 36.3 Nonacetylated Salicylates

- Diflunisal
- Sodium salicylate
- Choline salicylate
- Magnesium salicylate
- Choline magnesium trisalicylate
- Salsalate

Analgesics

When the pain associated with OA progresses and is no longer responsive to acetaminophen or NSAIDs, analgesics are the next option. Analgesics can also be used in patients who cannot tolerate acetaminophen or NSAIDs or in whom they are contraindicated. Analgesics only decrease pain and have no effect on inflammation. These drugs should be prescribed for a limited time because of potential dependence and withdrawal symptoms. Analgesics used for OA other than tramadol and tapentadol, detailed below, include codeine in combination with acetaminophen.

Tramadol

Mechanism of Action

Tramadol exerts multiple effects to induce pain relief. It is a mu opioid receptor agonist similar to other opioids such as morphine. By binding to the mu opioid receptor, ascending pain pathways are inhibited, resulting in decreased pain sensation. In addition, tramadol also inhibits the reuptake of serotonin and norepinephrine. These neurotransmitters are also involved in the ascending pain pathway.

Dosage

Tramadol is available as an immediate-release tablet (Ultram), extended-release tablet (Ultram ER), and in combination with acetaminophen (Ultracet). For the immediate-release tablet, patients can take 50 to 100 mg every 4 to 6 hours as needed for pain with a maximum daily dose of 400 mg. For patients taking the extended-release tablet, the starting dose is 100 mg daily with an increase every 5 days to the maximum of 300 mg/d. All forms of tramadol need to be dose adjusted for renal and hepatic dysfunction.

Time Frame for Response

Patients may feel a decrease in pain as soon as 1 hour after taking an immediate-release tramadol dose with a maximum effect at 2 hours. The extended-release tablet takes about 12 hours for the maximum effect to be seen.

Contraindications

Patients with an opioid dependency should not take tramadol since it has opioid effects. Also, patients with acute intoxication with alcohol, hypnotics, central-acting analgesics, opioids, or psychotropic drugs should not be given tramadol. Tramadol has the ability to lower the seizure threshold. Therefore, tramadol should not be used in patients with a history of seizures and needs to be used cautiously with other medications that may lower the seizure threshold.

Adverse Events

Unlike NSAIDs, tramadol does not produce serious GI adverse events nor does it aggravate existing hypertension, CHF, or renal disease. The most common side effects of tramadol include nausea, dizziness, drowsiness, and sweating. Due to the opioid receptor agonism, tramadol has the potential to exert similar adverse events as other opioids, such as constipation, dependency, euphoria, and respiratory depression.

Interactions

Tramadol is metabolized by CYP2D6, and any medication that inhibits or induces this enzyme will interact with tramadol. Also, because it inhibits serotonin reuptake, tramadol has the potential to induce serotonin syndrome when used in combination with other serotonergic agents, such as selective serotonin reuptake inhibitors, tricyclic antidepressants, monoamine oxidase (MAO) inhibitors, or linezolid.

Tapentadol

Mechanism of Action

Similar to opioids, tapentadol is an agonist for the mu opiate receptor. In addition, tapentadol also inhibits the reuptake of norepinephrine.

Dosage

For patients starting tapentadol (Nucynta), the recommended dose for the first day of therapy is 50 to 100 mg every 4 to 6 hours as needed with the option of giving the second dose as soon as 1 hour after the first dose, if needed. After the first day of therapy, the recommended dose is 50 to 100 mg every 4 to 6 hours as needed with a maximum daily dose of 600 mg. The dosing interval should be increased to every 8 hours or longer in patients with moderate hepatic impairment. Tapentadol is not recommended in patients with severe hepatic or renal impairment (clearance less than 30 mL/min).

Tapentadol is also available in an extended-release formulation. For opioid-naïve patients, the recommended starting dose is 50 mg by mouth twice daily. The dose can be increased by 50 mg per dose every 3 days to a maximum daily dose of 500 mg.

Time Frame for Response

Patients are likely to experience pain relief within 1 to 2 hours of taking the dose. The ER formulation peaks after 3 to 6 hours of ingestion.

Contraindications

Due to the opioid receptor agonism, tapentadol is contraindicated in patients with impaired pulmonary function who are not in a monitored setting. Also, patients with

paralytic ileus should avoid use due to the risk of opioid-induced constipation. Last, since tapentadol inhibits norepinephrine reuptake, it cannot be used within 14 days of a MAO inhibitor.

Adverse Events

The adverse event profile of tapentadol is similar to that of other opioids and tramadol. The most common adverse events are dizziness, somnolence, constipation, nausea, and vomiting. There is a risk of respiratory depression and CNS depression.

Interactions

Tapentadol needs to be used cautiously with other CNS depressants due to additive effects. As mentioned above, tapentadol and MAO inhibitors cannot be used within 14 days of each other. Using tapentadol with serotonergic agents increases the risk of serotonin syndrome.

Ethanol may increase the tapentadol concentrations if patients are taking the extended-release product. Therefore, patients taking extended-release tapentadol need to refrain from alcohol and any medication containing ethanol.

Duloxetine

Mechanism of Action

Duloxetine is a serotonin and norepinephrine reuptake inhibitor. By enhancing serotonin and norepinephrine, duloxetine works in the CNS to reduce pain transmission. Duloxetine is a relatively balanced serotonin and norepinephrine reuptake inhibitor.

Dosage

The FDA-approved dosing for chronic musculoskeletal pain is 30 mg by mouth daily for 7 days and then increase to 60 mg by mouth daily, which is the listed maximum dose for this indication. However, the trials that resulted in duloxetine's approval for this indication increased the dose to 120 mg by mouth daily in patients not having an adequate response to the 60 mg dose.

Time Frame for Response

The benefit of duloxetine was seen as early as 4 weeks in the clinical trials. Time points sooner than this were not assessed, so it is not known if its effect starts sooner.

Contraindications

Due to the risk for serotonin syndrome, duloxetine should not be started while a patient is on a monoamine oxidase inhibitor (MAOI) or within 14 days of stopping an MAOI. Also,

starting duloxetine while a patient is receiving linezolid and intravenous methylene blue may increase the risk of serotonin syndrome and is contraindicated.

Adverse Effects

Some of the precautions and warnings associated with duloxetine risk include hepatotoxicity, orthostatic hypotension, serotonin syndrome, abnormal bleeding, and activation of mania. These are considered the more rare but serious adverse effects. More common adverse effects seen in the clinical trials include nausea, constipation, somnolence, and hyperhidrosis.

Interactions

Duloxetine is metabolized through CYP1A2 and CYP2D6; therefore, medications that inhibit these enzymes may cause increased duloxetine concentrations. Due to the serotonergic effects of duloxetine, there is a risk for serotonin syndrome if other serotonergic agents are used concomitantly. Heavy alcohol use should be discouraged due to an increased risk of hepatotoxicity.

Topical Agents

Capsaicin

Mechanism of Action

For the relief of arthritic pain, capsaicin exerts its effect through the depletion of substance P. Initially, capsaicin releases substance P from the peripheral sensory neurons. However, with repeated use, substance P becomes depleted, and capsaicin prevents reaccumulation of substance P. Substance P is a chemomediator responsible for pain transmission from the periphery to the CNS. Therefore, by depleting peripheral neurons of substance P, the pain impulse will not be transmitted centrally.

Dosage

Capsaicin is available as an OTC product in a patch, cream, gel, liquid, or lotion. The directions for the patch are to apply it to the affected area three to four times a day for 7 days. The patch can remain on the area for up to 8 hours. The cream, gel, liquid, and lotion forms should be applied at least three times a day for maximal efficacy.

Time Frame for Response

The maximal effect is seen after 2 to 4 weeks of continual use.

Contraindications

There are no absolute contraindications for topical capsaicin. Patients should be advised to not apply capsaicin to broken or irritated skin.

Adverse Events

The most common adverse event is burning and irritation at the application site. The burning typically subsides within days of continual use. Due to the initial release of substance P, patients may experience some pain with initial use and should be advised to expect this.

Topical NSAIDs

Diclofenac is currently the only commercially available topical NSAID. It is available as a 1.5% solution (Pennsaid) for the relief of OA pain of the knee and as a 1% topical gel (Voltaren) for the relief of OA pain in joints amenable to topical therapy.

Mechanism of Action

The mechanism of action for topical diclofenac is the same as for oral NSAIDs. The benefit

is that minimal diclofenac is absorbed when applied topically, which then decreases the risk of adverse events. Data has shown that only 6% to 10% of the topical gel and 2% to 3% of the solution is absorbed.

Dosage

The dosage of topical diclofenac is dependent on the formulation and location. For the gel, if used on the lower extremities, 4 g should be applied four times a day; if used on the upper extremities, 2 g should be applied four times a day. The entire total daily dose should not exceed 32 g/d. For the topical solution, 40 drops should be applied to the affected knee(s) four times a day. The solution should be applied in 10-drop increments to limit spillage. It can be first applied to the hand and then rubbed on the knee. Regardless of formulation, it is imperative that the entire affected area be covered to achieve maximal effect.

Contraindications

Topical diclofenac carries the same warnings and contraindications as oral NSAIDs, although the risk is less. Also, topical diclofenac is contraindicated on nonintact or damaged skin.

Adverse Events

The most common adverse events are application site reactions and include pruritus, rash, dry skin, pain, and exfoliation.

Interactions

Topical diclofenac should be used cautiously with medications that interact with oral NSAIDs since some of the topical medication is absorbed.

Corticosteroids

If symptoms of OA are restricted to one or two joints that have not responded to first- or second-line treatment, intra-articular corticosteroids may be helpful. Aseptic technique and a local anesthetic are required. The amount of drug injected depends on the size of the joint. Careful technique that avoids the surrounding soft tissues is imperative to avoid tissue atrophy. The side effect of localized pain may be treated with an NSAID or another appropriate analgesic. Injection of corticosteroids usually produces symptom relief within a few days, and the relief may last up to several months. Because of the potential for cartilage destruction and osteonecrosis with repeated injections, this therapy should be used judiciously.

Selecting the Most Appropriate Agent

In 2012, the ACR published guidelines for the treatment of hand, hip and knee OA. In these guidelines, it is specified that patient specific characteristics need to be assessed and care should be individualized. In selecting therapies for OA, the prescriber should consider patient variables such as age, childbearing status, progression of arthritis, and underlying illnesses. These guidelines provide recommendations for initial therapy but do not provide recommendations for subsequent treatment sequences if initial therapy fails.

With the 2012 ACR guidelines, multiple agents were listed as first-line therapies based on the location of the OA (Table 36.2). For hand OA, the initial recommended treatments are topical capsaicin, topical NSAIDs, oral NSAIDs, and tramadol. For knee OA, initial recommended treatments include acetaminophen, oral NSAIDs, topical NSAIDs, tramadol, and intra-articular corticosteroid injections. For patients 75 years or older, topical NSAIDs are preferred over oral NSAIDs. Also, if a patient has a history of upper GI ulcer within a year, the recommendation is to use a COX-2 selective NSAID in addition to a proton pump inhibitor. For patients who have a history of upper GI ulcers greater than a year prior to initiating therapy, a selective NSAID can be used or a nonselective NSAID with a proton pump inhibitor. The ACR recommendations for hip OA are similar to that of knee except they do not recommend topical NSAIDs as initial therapy.

TABLE 36.2 Guideline Recommendations for the Treatment of OA

	ACR	EULAR	OARSI
Hand	Initial treatment options: • Topical capsaicin • Topical NSAIDs • Oral NSAIDs	1st line: topical NSAIDs, capsaicin 2nd line: APAP 3rd line: NSAIDs IA steroids for painful flares	
Hip	Initial treatment options: • APAP • Oral NSAIDs • Tramadol • IA steroids	1st line: APAP 2nd line: NSAIDs +/– gastroprotection 3rd line: opioid +/– APAP IA steroids for flares unresponsive to analgesia and NSAIDs	1st line: APAP 2nd line: oral NSAIDs 3rd line: weak opioid analgesics Moderate to severe pain unresponsive: IA steroids
Knee	Initial treatment options: • APAP • Oral NSAIDs • Topical NSAIDs • Tramadol • IA steroids	1st line: APAP, topical NSAIDs, capsaicin 2nd line: NSAIDs +/– gastroprotection 3rd line: opioid +/– APAP IA steroids for flares with effusions	Without comorbidities • IA steroids • Topical NSAIDs • Oral NSAIDs • capsaicin • duloxetine • APAP With comorbidities • IA steroids • Topical NSAIDs

ACR, American College of Rheumatology; APAP, acetaminophen; EULAR, European League Against Rheumatism; IA, intra-articular; NSAIDs, nonsteroidal anti-inflammatory drugs; OARSI, Osteoarthritis Research Society International.

Also the EULAR has guidelines for the treatment of hip (2005), knee (2003), and hand (2007) OA. These guidelines outline first-line and subsequent treatment recommendations.

The Osteoarthritis Research Society International (OARSI) has published guidelines regarding the treatment of hip and knee OA. Table 36.2 compares the recommendations of these three guidelines. Figure 36.2 outlines a general treatment algorithm for patients with hip or knee OA.

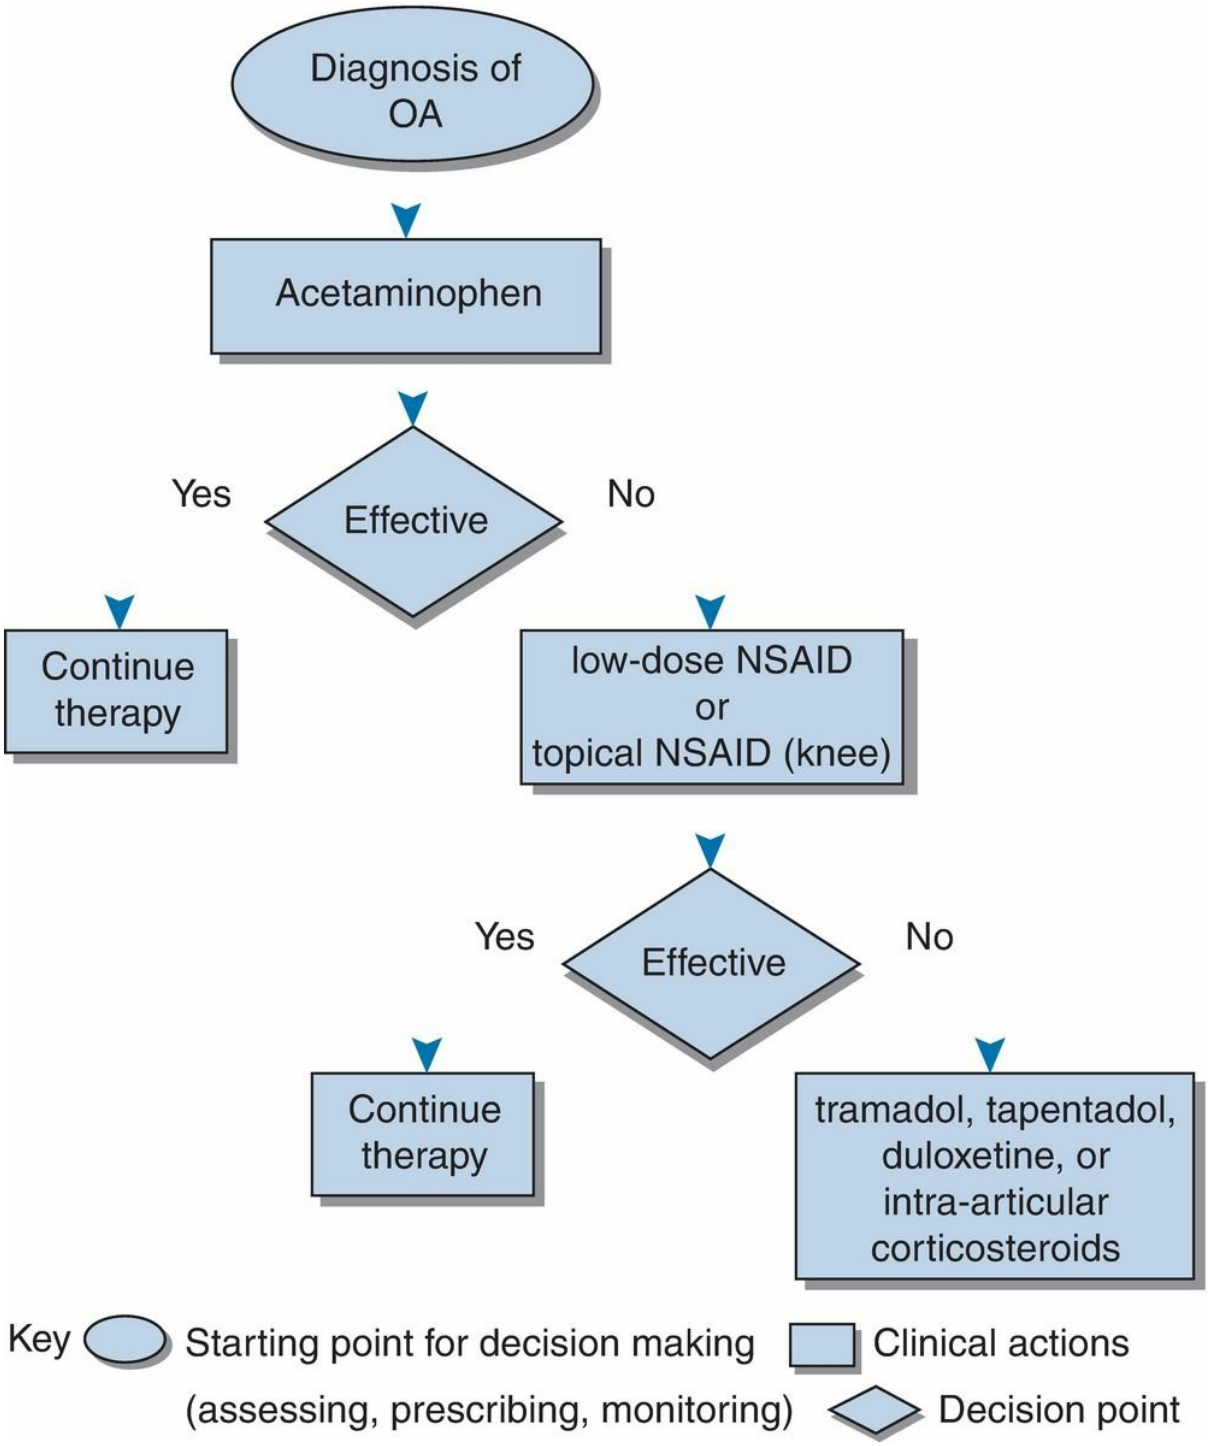

FIGURE 36.2 Treatment algorithm for OA.

First-Line Therapy

Historically, acetaminophen 1 gram every 6 to 8 hours has been the first-line treatment for OA due to its effectiveness in reducing the pain of OA within 4 weeks and lasting for up to 2 years. However, there is conflicting data regarding the analgesic effect of acetaminophen compared to NSAIDs for OA pain. Many trials indicate that NSAIDs are superior, especially in patients with more severe disease; however, NSAIDs are associated with more adverse reactions. The EULAR continues to recommend acetaminophen as first-line therapy for hip and knee OA. Due to the relative safety of acetaminophen compared to NSAIDs, a trial of acetaminophen for most patients with OA remains first line.

Second-Line Therapy

For patients without risk factors for GI disturbance, if acetaminophen therapy fails to provide relief, ibuprofen or a similar nonselective NSAID should be considered for second-line therapy as monotherapy or in combination with acetaminophen. Since there is no evidence that one NSAID is more effective than another, the choice of the specific NSAID should be based on the cost and convenience of therapy. For patients at increased risk for GI disorders, such as peptic ulcer disease, a COX-2 inhibitor may be a better second-line choice. Alternatively, the use of a traditional NSAID coupled with a proton pump inhibitor may be sufficient to provide analgesia along with gastric protection.

Third-Line Therapy

For patients who have failed to obtain pain control with acetaminophen or NSAIDs or those in which these therapies are contraindicated, opioid or nonopioid analgesia can be tried. The addition of codeine to acetaminophen may further reduce pain, but often, patients discontinue this combination due to the side effects associated with codeine (constipation, drowsiness). Tramadol or tapentadol may be tried, realizing that patients may experience similar adverse effects as they do to opioids. Duloxetine is another alternative to analgesics that can be tried as monotherapy or as adjunct to acetaminophen or NSAIDs. Most of the data regarding the use of duloxetine is for knee OA and showed modest improvement in pain scores.

Intra-articular steroids may be useful when an effusion is present and there are clear signs of local inflammation.

Special Populations

Geriatric

For elderly patients, the practitioner usually prescribes an NSAID with a shorter half-life in a smaller dosage than for a younger adult. Patients over age 65 should be considered at risk for GI hemorrhage and treated with either a COX-2 inhibitor or a combination of a nonselective NSAID and a gastric protective agent, such as misoprostol or a proton pump inhibitor.

Women

Many of the NSAIDs are pregnancy category C agents during the first 30 weeks of gestation. After gestational week 30, most NSAIDs are categorized as class D agents, indicating that there is evidence of harm to the fetus and should only be used in life-threatening illnesses.

Monitoring Patient Response

In addition to routine questions about the efficacy of the drug (e.g., pain relief), baseline and ongoing monitoring for specific drug therapy should be done. If a patient is taking acetaminophen, baseline liver function tests should be checked and monitored periodically. Monitoring for NSAID therapy includes a complete blood count (CBC), urinalysis, and serum creatinine. These studies should be repeated at 1 to 3 months and then every 3 to 6 months thereafter for the duration of therapy. In patients at risk for GI hemorrhage, the clinician should consider evaluating the patient for stool occult blood, anemia, and other signs of bleeding.

Patient Education

Drug Information

For patients taking acetaminophen, they need to be educated that it is most effective if taken around the clock regardless of pain. Also, patients need to be cognizant of other products that may contain acetaminophen and ensure they are not exceeding the daily limit. Last, for patients taking scheduled acetaminophen, alcohol intake should be minimized or avoided.

Patients taking NSAIDs need to be aware of their potentially harsh effects on the GI system, ranging from mild GI discomfort to gastric bleeding. The practitioner may emphasize strategies for dealing with some of these adverse events, including taking NSAIDs with food or milk or at meals. Patients should be reminded that a specific NSAID should be used regularly for 2 to 3 weeks before switching to another NSAID. This period is needed to assess whether the medication is effective.

Patients receiving a corticosteroid injection for joint pain need to be informed that a single joint should not be injected more frequently than every 6 months. Patients should be cautioned to limit activity of the injected joint for several days after the injection. Otherwise, the reduced pain perception of the joint may allow the patient to cause further joint damage, enhancing the progression of OA.

Patient-Oriented Information Sources

The National Institute of Arthritis and Musculoskeletal and Skin Diseases (NIAMS) is a government-sponsored group that provides information on OA and its treatment (http://www.niams.nih.gov/hi/topics/arthritis/oahandout.htm). This information is also available in Spanish. The Arthritis Foundation (http://www.arthritis.org/about-arthritis/types/osteoarthritis/) provides information on the web and in print.

Nutrition/Lifestyle Changes

The practitioner should provide the patient with information about the continued use of physical therapy, exercise, and weight loss. All of the guidelines stress the importance of nonpharmacologic recommendations in the treatment of OA.

Complementary and Alternative Medications

Glucosamine, a form of an amino acid, is a naturally occurring substance in the body. It is believed to be involved in the development and repair of cartilage. Exogenous replacement of this substance is thought to help build on existing cartilage. Evidence-based reviews of this agent suggest that moderate improvements in pain relief and function can be achieved when administered at 1,500 mg/d. This effect is thought to be similar in magnitude to that of low-dose NSAIDs or acetaminophen.

Chondroitin, a large protein-like molecule that can impart elasticity to collagen, has shown similar, but slightly less, efficacy compared to glucosamine. The dosage of chondroitin used in most of the studies was 800 to 1,200 mg/d.

The most common adverse effects associated with these products are GI discomfort, including diarrhea, heartburn, nausea, and vomiting. A concern exists that glucosamine may negatively affect blood glucose; however, this has not been proven in trials. Also, because of its uncertainty, glucosamine is not recommended in patients with poorly controlled diabetes. Since they are considered food supplements, there is little U.S. Food and Drug Administration regulation, and the preparations may vary in potency and effectiveness.

Trials that have examined the use of glucosamine and chondroitin for the treatment of OA have failed to consistently show a benefit of the combination versus placebo. In a subgroup analysis of the GAIT trial conducted by Clegg et al. (2006), patients with moderate to severe symptoms, the use of combination glucosamine and chondroitin resulted in decreased pain scales. However, this was a subgroup analysis that has not yet been verified with a subsequent trial. The ACR guidelines conditionally recommend against the use of glucosamine for the treatment of hip and knee OA.

Gout

Historically, gout has been called the "disease of kings." For years, it was believed that gout was caused by an overindulgence in food and alcohol that only the rich could afford. While dietary factors can play a role, they are not the only risk factor leading to the development of gout.

Gout is the most common form of inflammatory arthritis in the United States. The incidence of gout in America has increased over the last 20 years and is now estimated to affect 8.3 million Americans (4%). This increase is thought to be due to the improved diagnosis but also the increasing number of patients with obesity, hypertension, thiazide diuretic use, and alcohol intake.

Gout is an inflammatory condition that results from monosodium urate crystals precipitating in the synovial fluid between joints due to hyperuricemia. The monosodium urate crystals form due to hyperuricemia either from overproduction or underexcretion of uric acid. The most common joint affected is the metatarsophalangeal joint. Other common affected joints include the midtarsal joints, ankles, knees, fingers, wrists, and elbows.

Causes

The overproduction or underexcretion of uric acid in the body leads to hyperuricemia. Hyperuricemia is defined as serum urate concentrations greater than 6.8 mg/dL. At levels greater than 6.8 mg/dL, serum uric acid concentrations exceed the natural saturation point, which leads to the development of monosodium urate crystals. These crystals precipitate in patients' joints causing pain, arthritis, and inflammation.

The underexcretion of uric acid through insufficient renal clearance is the most common cause of hyperuricemia. Patients with diseases that can affect the kidneys (i.e., diabetes, chronic kidney disease [CKD], etc.) or those taking drugs that can alter uric acid excretion such as thiazide diuretics and aspirin can also have insufficient renal clearance of uric acid leading to hyperuricemia.

Genetic and dietary factors play a role in the overproduction of uric acid. Typically, dietary factors alone will not cause a significant enough increase in serum urate levels to cause hyperuricemia. Foods and beverages associated with increasing urate levels can cause an acute elevation in patients who are already experiencing hyperuricemia due to genetic overproduction or renal underexcretion leading to a gout attack. A further discussion of dietary modifications that can be made to decrease gout attacks can be found in the Nutrition/Lifestyle Changes section of this chapter.

There are many other factors that can play a role in the development of gout. Female sex hormones increase the excretion of uric acid in premenopausal women. This may explain why gout is seen more in male patients than in female patients. As female patients go through menopause and sex hormones change, this can decrease their excretion of uric acid leading to postmenopausal women developing gout. Gout is also associated with advancing age in men, obesity, and comorbidities such as hypertension, CHF, and organ transplantation. A full list of risk factors for the development of gout can be found in Box 36.4.

BOX 36.4 Risk Factors for the Development of Gout

- Males
- Advancing age
- Menopausal women
- Obesity
- Dietary factors
    - Organ meat
    - Seafood

    - Sweetened Beverages
    - Fructose
    - Ethanol
- Drugs
    - Thiazide diuretics
    - Loop diuretics
    - Cyclosporine
    - Aspirin (<1 g/d)
- Insulin resistance
- Renal insufficiency
- Hypertension
- Congestive heart failure
- Organ transplantation

Pathophysiology

When hyperuricemia leads to the development of monosodium urate crystals being released into joint spaces, these crystals are phagocytized by macrophages. This phagocytosis causes the activation and release of IL-1β. IL-1β binds to synovial endothelium and causes the release of proinflammatory cytokines. Neutrophils are recruited to the synovium, which causes further release of IL-1β and other proinflammatory cytokines that perpetuates the gouty arthritis inflammatory process.

In some cases, the monosodium urate crystals alone may not be sufficient to trigger the activation and release of IL-1β from macrophages. In these cases, they require additional stimulation from free fatty acids or lipopolysaccharides to release IL-1β. When patients consume alcohol or a large meal, this can increase the free fatty acid concentration in the body and trigger the release of IL-1β.

Chronic gout and acute inflammation from gouty flares can lead to chronic pain, joint damage, and potential disability. As the disease progresses, joints may look deformed due to the development of tophi. Tophi are nodules created by monosodium urate crystals in a matrix of lipids, proteins, and mucopolysaccharides, and they may form in joint spaces. Tophi are most commonly found in the metatarsophalangeal joint, but they can also be found in other common joints affected by gout and throughout the body. Tophi can protrude through the skin and resemble a chalky substance. These urate crystals can also be found in other areas of the body, such as soft tissue, vertebrae, or skin. When they are located outside of the common joints, these crystals can mimic other disease states.

Diagnostic Criteria

Diagnosis of gout usually occurs clinically when a patient is experiencing rapid monoarticular arthritis, typically in the first metatarsophalangeal joint. This arthritis is accompanied by swelling and redness of the joint. The ACR diagnostic criteria that were developed in 1977 are still the most widely used form of diagnosis for patients with gout. Patients experiencing six or more of the clinical, laboratory, or radiologic criteria found in Box 36.5 are considered to have gout.

BOX 36.5 ACR Diagnostic Criteria for Gout

More than one acute arthritis attack
Maximum joint inflammation develops within 1 day
Monoarticular arthritis attack
Joint redness
Pain or swelling of first metatarsophalangeal joint
Unilateral first metatarsophalangeal joint attack
Unilateral tarsal joint attack
Suspected tophus
Hyperuricemia
Radiography of asymmetric swelling within a joint
Radiography of subcortical cysts without erosions
Monosodium urate crystals in joint fluid during attack
Negative culture for organisms within joint fluid during an attack

Confirmation of a gout diagnosis can be made by aspirating monosodium urate crystals from the synovial fluid of the inflamed joint, but this is a painful and often unnecessary procedure if the patient is already displaying characteristic symptoms. Radiography can also be done using ultrasounds, MRIs, or computed tomography, but often it takes over 10 years of untreated chronic gout before crystals can be seen using one of these methods.

Initiating Drug Therapy

The treatment of gout can be divided into treatment of chronic gout and treatment of acute gout attacks. The goals of drug therapy in chronic gout are to decrease the serum urate level to less than 6 mg/dL and to decrease the occurrence of acute gout attacks. The goal of less than 5 mg/dL may be preferred in patients with multiple risk factors or with a history of frequent acute gout attacks. Decreasing the serum urate level will help to reach the clinical goal of less pain and inflammation in the joints. For an acute gout attack, the goals are to relieve pain, terminate the attack, and maintain joint function.

The sections that follow are divided based on chronic gout treatment and acute gout attack treatment.

Chronic Gout

Urate-lowering therapies (ULT) are the primary pharmacologic treatment for chronic gout. Often, gout flares can occur when initiating ULT due to the redistribution of uric acid. To prevent these gout flares, patients should take NSAIDs or colchicine for the first 6 months of therapy. After 6 months, the number of gout flares should decrease due to the initiation of ULT. At this time, NSAIDs and colchicine can be discontinued until it is required for gouty flares.

Xanthine Oxidase Inhibitors

According to the 2012 ACR guidelines, the first-line therapy for the management of chronic gout is xanthine oxidase inhibitors (XOIs). There are currently two XOIs on the market, allopurinol and febuxostat. While allopurinol has been the mainstay of therapy for years, it does have an increased risk for hypersensitivity reactions and must be dose adjusted in patients with kidney failure. When febuxostat came to the market in 2010, it gave those patients at risk of developing hypersensitivity reactions or with kidney impairment another option for chronic gout treatment.

Mechanism of Action

XOIs decrease uric acid levels by selectively inhibiting xanthine oxidase. Xanthine oxidase is the enzyme responsible for the conversion of hypoxanthine to xanthine to uric acid. Hypoxanthine and xanthine are then excreted in the urine with little risk of precipitation. By inhibiting the conversion to uric acid, uric acid levels are decreased, thereby reducing the risk of crystallization and a gout attack.

Dosage

Allopurinol is initially dosed 100 mg once daily and should be gradually titrated by 100 mg/d in 2- to 5-week increments until uric acid is less than 6 mg/dL. The usual dosage is 300 mg daily either once daily or taken in divided doses up to four times daily. The max dose is 800 mg/d. Patients with stage 4 or worse CKD should start at 50 mg/d and titrate up to a therapeutic dosage.

Febuxostat is dosed 40 mg once daily and may be increased to the FDA-approved max dose of 80 mg once daily in patients who do not achieve a serum uric acid level less than 6 mg/dL after 2 weeks. According to the ACR guidelines and international standards, febuxostat can be increased up to 120 mg daily in refractory cases. Febuxostat is metabolized through the liver and can be used in patients with mild to moderate kidney impairment without dose reduction.

Time Frame for Response

Serum urate levels can begin to fall as early as 2 weeks following initiation of chronic gout therapy. Serum uric acid levels should be drawn every 2 to 5 weeks during dose titration until desired level is reached, which may take up to 6 months. Once goal serum uric acid levels are achieved, the patient should have levels drawn every 6 months throughout treatment.

Contraindications

Pegloticase should not be administered with allopurinol or febuxostat. Using both agents could increase the risk of infusion site reactions or anaphylaxis with the pegloticase. Allopurinol should not be used with didanosine as it may increase the serum concentrations of didanosine leading to toxicity. Allopurinol and febuxostat can inhibit the metabolism of azathioprine and mercaptopurine leading to toxic doses and should not be used concurrently.

Adverse Events

Common adverse reactions that can occur with the use of XOIs include rash, arthralgias, and GI complications, which can be reduced by taking the medication with food. Allopurinol and febuxostat have been associated with liver function abnormalities. Liver function tests should be performed at baseline periodically throughout treatment.

Allopurinol, although generally well tolerated, does have a risk of hypersensitivity reactions. Allopurinol hypersensitivity syndrome consists of a rash (Stevens-Johnson syndrome and toxic epidermal necrolysis), fever, impaired liver and kidney function, leukocytosis, and eosinophilia. The risk of allopurinol hypersensitivity syndrome increases in patients with kidney dysfunction or those of certain ethnic populations that are more genetically predisposed to the reaction. Prior to initiating allopurinol, Koreans with stage 3 or worse CKD, Han Chinese, and Thai patients should receive genetic testing for the HLA-B*5801 allele. Patients that report HLA-B*5801 positive should be prescribed alternative therapy to allopurinol. Patients should be counseled to report a rash immediately to their health care provider.

Interactions

The use of ACE inhibitors, thiazide, and loop diuretics along with allopurinol may increase the levels of allopurinol and increase the risk of allopurinol hypersensitivity syndrome. Before initiating allopurinol with patients on antineoplastic agents, interactions should be evaluated. Multiple antineoplastic agents are affected by allopurinol, and the effects can range from noneffective antineoplastic treatment to toxicity. INR levels should be monitored when patients are taking both allopurinol and warfarin as allopurinol may increase bleeding risk due to decreased warfarin metabolism.

As previously mentioned, both allopurinol and febuxostat inhibit the metabolism of mercaptopurine and azathioprine. Concurrent use should be avoided if possible. Febuxostat

is contraindicated with these agents. However, allopurinol can be used, but the azathioprine or mercaptopurine dose needs to be reduced to 1/3 to 1/4 of the typical dose and monitored closely for toxicity.

Probenecid

If at least one XOI is contraindicated or not tolerated well, practitioners should use probenecid for the treatment of chronic gout.

Mechanism of Action

Probenecid increases the excretion of serum uric acid by competitively inhibiting the reabsorption of uric acid at the proximal convoluted tubule.

Dosage

The initial dose is 250 mg twice daily for 1 week, and the dose is then increased to 500 mg twice daily if needed. The dose can be increased in 500-mg increments every 4 weeks to a maximum of 2 g/d. Once serum uric acid levels are within normal limits and no gout attacks have occurred for 6 months, the dose can be reduced by 500 mg every 6 months.

Time Frame for Response

As with the XOIs, serum uric acid levels will begin to decrease within 2 weeks but may take up to 6 months to see full effect.

Contraindications

Probenecid should not be given during an acute gout attack as it could exacerbate the symptoms when initiated. It also should not be given to patients who have been diagnosed with blood dyscrasias, uric acid kidney stones, children less than 2 years old, or anyone who has a past medical history of a reaction with probenecid. Patients should also not use ketorolac while taking probenecid, because it may increase the concentration of ketorolac leading to toxic symptoms such as nausea, gastric ulcers, headache, and edema.

Adverse Events

There are many adverse effects associated with probenecid. Serious reactions that can occur include hemolytic anemia and aplastic anemia in patients with G6PD deficiency, hepatic necrosis, and anaphylaxis. Other less serious but common reactions include headache, dizziness, anorexia, nausea vomiting, gingival soreness, urinary frequency, renal colic, nephrotic syndrome, dermatitis, pruritus, flushing fever, and gout exacerbations.

Interactions

Avoid the use of probenecid with antibiotics including penicillin derivatives,

cephalosporins, and fluoroquinolones as probenecid may increase the concentrations of the antibiotics increasing the risk of adverse effects and toxicities associated with these drugs. The use of methotrexate with probenecid may result in methotrexate toxicity including leukopenia, thrombocytopenia, anemia, and nephrotoxicity. Using citalopram with probenecid may increase citalopram concentrations, increasing the risk of QT prolongation, and its use with lorazepam can also increase lorazepam concentrations leading to toxicity. The use of probenecid with aspirin and other salicylates may reverse the uricosuric effect of probenecid. As with XOIs, probenecid should not be used with pegloticase due to an increased risk of anaphylaxis and infusion reactions of the pegloticase.

Pegloticase

Pegloticase is used as last-line therapy for patients with chronic gout that has not successfully been treated with either XOIs or probenecid. It must be administered intravenously in a health care facility every 2 weeks and costs more than $5,000 per dose.

Mechanism of Action

Pegloticase is a pegylated recombinant form of uricase. Uricase is an enzyme typically absent in humans but is found in high levels in primates. Uricase converts uric acid to allantoin, which is an inactive, water-soluble metabolite of uric acid allowing uric acid to be easily excreted by the kidneys.

Dosage

The recommended dose for pegloticase is 8 mg IV over at least 2 hours every 2 weeks. Before beginning pegloticase infusions, patients should discontinue the use of any oral antihyperuricemic agents and should not begin taking oral medications for chronic gout throughout the course of therapy.

Gouty flares can occur from initiating a new therapy and can be prevented by using NSAIDs or colchicine. It is recommended to begin this prophylaxis at least 1 week prior to initiating pegloticase and to continue for 6 months.

Patient should also be pretreated with antihistamines and corticosteroids prior to the infusion. This will help patients with any infusion reactions and potential anaphylaxis.

Time Frame for Response

The reduction of uric acid concentrations can be seen as soon as 1 day after the infusion. For patients who are responders to pegloticase, the reduction can be maintained for at least 6 months.

Contraindications

Pegloticase is contraindicated in patients with glucose-6-phosphate dehydrogenase

deficiency.

Adverse Events

As with all of the chronic gout medications, pegloticase can cause potential gout flares within the first few months of treatment. Prophylaxis for these gout flares is recommended for the first 6 months of treatment with colchicine or an NSAID.

Injection site reactions such as, bruising, urticaria, erythema, and pruritus are also common. Administering antihistamines and corticosteroids with each infusion can decrease these injection site reactions in most patients.

Some patients also experience GI-related symptoms such as nausea, vomiting, and constipation with pegloticase.

Antipegloticase antibodies form in 92% of patients and anti-PEG antibodies in 42%. These antibodies may result in a loss of response to pegloticase as early as 4 months into treatment.

Pegloticase does hold a black box warning for hypersensitivity and anaphylaxis reactions. Anaphylaxis has been reported during and after administration. Due to these reactions, patients should receive pegloticase infusions in a health care facility while being closely monitored during and for a period of time after administration. Most reactions occur within 2 hours of administration, but some patients have had delayed hypersensitivity reactions. The risk of these infusion reactions increases in patients whose uric acid level is greater than 6 mg/dL. Health care practitioners should monitor serum uric acid levels prior to infusion and discontinuing treatment if patients' concentrations are greater than 6 mg/dL on two consecutive measurements.

Interactions

Patients taking pegloticase should discontinue all other chronic gout medications. Allopurinol, febuxostat, and probenecid may increase the levels of pegloticase and increase the risk of infusion reactions and anaphylaxis.

Selecting the Most Appropriate Drug

In 2012, the ACR developed guidelines for the management of gout and the treatment of hyperuricemia (Khanna, 2012a). In addition to outlining the treatment options, they defined which patients should be initiated on chronic ULT. The criteria for initiating long-term ULT include patients with a diagnosis of gouty arthritis and one of the four following criteria: tophi or tophus, two or more gouty attacks yearly, CKD stage 2 or worse, or past urolithiasis. For those meeting criteria for chronic ULT, the options include XOIs, probenecid, and pegloticase.

First-Line Therapy

The initiation of either allopurinol or febuxostat should be used as first-line therapy for chronic gout. The ACR did not provide preference of one agent over the other. These agents can effectively lower serum uric acid in patients who are underexcretors or overproducers. If a patient has an intolerance or adverse effect to one XOI, the other one can be substituted. The XOIs are considered first-line agents due to their efficacy and relative safety.

As previously mentioned, regardless of the agent selected, patients need to be initiated on acute gout prophylaxis when chronic ULT is started. This acute gout prophylaxis could include NSAIDs or colchicine and should be continued for 6 months.

Second-Line Therapy

If at least one XOI is contraindicated or not tolerated well, probenecid is the second-line agent. Probenecid is associated with more drug interactions and cannot be used in patients with a history of urolithiasis.

If a patient is on a XOI at maximal appropriate dose and the goal serum urate concentration is not achieve, probenecid can be added to the XOI and titrated to goal.

Third-Line Therapy

For patients who are on both a XOI and probenecid and are unable to achieve their uric acid goal and continue to have disease activity, pegloticase can be initiated after discontinuation of other ULT.

Acute Gout

Patients with chronic gout will commonly experience gout attacks. Making dietary modifications and discontinuing the usage of medications that can induce gout attacks, weight loss, and controlling other diseases states will help decrease the frequency of attacks, but they will occur in gout patients. When an acute gout attack occurs, patients can rest the joint and apply ice as needed to help with the pain. They can also use short courses of NSAIDs, corticosteroids, or colchicine to reduce the pain.

NSAIDs

NSAIDs can help decrease inflammation and pain during acute gout attacks. Naproxen, indomethacin, and sulindac are the three NSAIDs indicated for the treatment of acute gout. NSAIDs should be initiated at onset of the gout attack and continued for 24 hours after the resolution of symptoms. The usual course of treatment is 3 to 7 days. See the discussion of NSAIDs in the OA section of this chapter for more information about NSAIDs. See Table 36.3 for appropriate dosing for acute gout attacks.

TABLE 36.3 NSAID Dosing for Acute Gout

Drug	Dose
naproxen	750 mg initially followed by 250 mg every 8 h until attack subsides
indomethacin	50 mg three times daily until pain is tolerable then reduce dose
sulindac	200 mg twice daily

Systemic Corticosteroids

Systemic corticosteroids can be given to patients to help decrease inflammation during an acute gout attack. Most patients will tolerate a short duration of oral corticosteroids; those that do not may benefit from an intramuscular dose. If a patient's gout attack is focused in 1 to 2 large joints, the clinician may choose to provide an intra-articular dose alone or in addition to oral corticosteroids.

Mechanism of Action

Corticosteroids decrease inflammation by suppressing the migration of polymorphonuclear leukocytes. Leukocytes cause a further release of IL-1β and other proinflammatory

cytokines that lead to the inflammation associated with gouty arthritis.

Dosage

For oral doses, patients can take prednisone or methylprednisolone. Patient taking prednisone should use 0.5 mg/kg for 5 to 10 days or 0.5 mg/kg for 2 to 5 days and then taper 7 to 10 days. Clinicians can also choose to use a methylprednisolone dose pack. This dose pack contains (21) 4-mg tablets. These are tapered from six tablets on day 1, five tablets on day 2, and so forth until the patient is only taking one tablet on day 6.

For patients unable to take oral corticosteroids, an intramuscular dose of methylprednisolone 0.5 to 2 mg/kg for one dose can be given. This dose can be repeated as clinically indicated.

For patients experiencing pain in 1 to 2 large joints, an intra-articular dose of triamcinolone acetonide can be given. The dose is dependent on the size of the joint being treated. Large joints such as knees can be given 40 mg of triamcinolone, medium joints such as wrist ankles and elbows can be given 30-mg injections, and smaller joints can be given 10-mg injections.

Time Frame for Response

Patients should start to feel pain relief in 1 to 2 days. It may take up to a week for complete resolution.

Contraindications

Oral corticosteroids should be used with caution in patients with suppressed immune systems, diabetes, uncontrolled HTN, cardiovascular disease, and psychiatric disorders. If patients are requiring a corticosteroid and have one of these conditions, they may be a good candidate for an intra-articular dose as these will have less of a systemic effect.

Adverse Events

Adverse effects of corticosteroids are extensive. By limiting the duration of treatment, many of the more chronic adverse effects will be avoided. However, even using corticosteroids for 5 to 10 days may results in acute adverse effects. These acute adverse effects include hyperglycemia, hypertension, fluid retention, CNS stimulation, and dyspepsia. Patients at risk for these conditions need to be monitored closely while on corticosteroids.

Interactions

Interactions associated with corticosteroids are more severe when associated with long-term treatment. With the short-term use of corticosteroids being used to treat gout, there are few interactions. The interactions that should be monitored are with specific disease states. Diabetic patients should monitor their blood sugar more closely as corticosteroids may

cause an increase in blood sugar levels. Patients with hypertension, CHF, and fluid retention should also monitor their blood pressure and symptoms as corticosteroids can cause edema leading to worsening HTN and CHF. Corticosteroids also cause immunosuppression so use caution in patients where immunosuppression needs to be avoided.

Colchicine

Colchicine has been used for the treatment of gout, Mediterranean fever, and multiple cardiovascular diseases for centuries. Although colchicine has had widespread use for many years, it was only approved by the FDA in 2009 under the unapproved drugs initiative. With this approval, there were changes to the dosing regimen and a new focus on safety related to comorbidities and drug–drug interactions.

Mechanism of Action

Colchicine inhibits the activation, degranulation, and migration of neutrophils to the area of a gout attack. This then decreases the inflammation and pain associated with a gout attack.

Dosage

For acute gout attacks, patients should be given their first dose within 24 hours of symptom onset. Colchicine is not recommended if symptoms started more than 36 hours prior. Patients should take 1.2 mg at first sign of gout flare followed by 0.6 mg 1 hour later. They can then take 0.6 mg daily or BID starting 12 hours later and continue until the attack resolves. Patients with severe renal failure (CrCl < 30 mL/min) should have the dose reduced to 0.3 mg daily. These patients should be monitored closely for adverse effects and should not repeat treatment more than once every 2 weeks.

Prophylactic doses of colchicine to prevent gout attack during initiation of chronic gout treatment are 0.6 mg once or twice daily for up to 6 months after achieving target serum urate levels. If a patient is receiving prophylactic dosing and experiences a gout attack, they can begin the acute gout dose. They should wait 12 hours from their last dose of acute gout treatment before resuming the prophylactic dosing.

When patients are also taking P-glycoprotein (P-gp) or CYP3A4 inducers, their dosing needs to be altered to prevent colchicine toxicities. See Table 36.4 for dosage adjustments with P-gp or CYP3A4 inducers (Figure 36.3).

TABLE 36.4 Prophylactic Colchicine Dosing Dependent on Interactions

Usual Treatment	Strong 3A4 Inhibitor	Moderate 3A4 Inhibitor	P-gp Inhibitor	CrCl < 30 mL/min
0.6 mg twice daily	0.3 mg daily	0.3 mg BID or 0.6 mg daily	0.3 mg daily	0.3 mg daily
0.6 mg daily	0.3 mg every other day	0.3 mg daily	0.3 mg every other day	

	CYP 3A4 Inhibitors	P-glycoprotein inhibitors
Strong Inhibitors 	Clarithromycin	Cyclosporine
	Telithromycin	Ketoconazole
	Nefazodone	Tacrolimus
	Indinavir	Amiodarone
	Saquinavir	Clarithromycin
	Ritonavir	Verapamil
	Atazanavir	Telaprevir
	Ketoconazole	Ranolazine
	Itraconazole	Itraconazole
	Grapefruit juice	Grapefruit juice
	Erythromycin	Saquinavir
	Fluconazole	Lovastatin
	Verapamil	Simvastatin
	Diltiazem	Atorvastatin
	Fluoxetine	Erythromycin
	Cimetidine	
	Atorvastatin	
Weak Inhibitors	Amiodarone	

FIGURE 36.3 Drug interactions with colchicine.

Time Frame for Response

Colchicine begins to provide its pain relief within 18 to 24 hours. It can take up to 48 hours to have its full anti-inflammatory effect.

Contraindications

Patients who have renal or hepatic impairment or those taking P-gp inhibitors or strong CYP3A4 inhibitors should use caution and possible lower doses of colchicine. Patients with both renal and hepatic impairments and also taking a P-gp inhibitor or strong CYP3A4 inhibitor should not take colchicine as it may cause fatal colchicine toxicity.

Adverse Events

The most common adverse effects of colchicine are GI effects in particular diarrhea. Some patients also experience pharyngolaryngeal pain, fatigue, and headache when being treated for gout flares. Other more uncommon but serious adverse effects of colchicine include blood dyscrasias and neuromuscular toxicity including rhabdomyolysis.

Interactions

Colchicine is a substrate of the efflux transporter P-gp, and it is mainly metabolized by CYP3A4. Because of these pharmacokinetic properties, colchicine has many drug interactions with P-gp and CYP3A4 inhibitors. If P-gp or CYP3A4 inhibitors are coadministered with colchicine, it can cause increased concentrations of colchicine, which can potentially be fatal. In addition to its anti-inflammatory effects, colchicine inhibits cell mitosis. Inhibition of cell mitosis can lead to organ system dysfunction and failure. Cardiac effects are most commonly seen in patients who have taken increased concentrations of colchicine. Since many drugs are P-gp and CYP3A4 inhibitors, it is important to be aware of the strength of the inhibition. This will help the clinician to judge if the drug should be avoided, if the dose should be adjusted, or if the patient should just be monitored while taking the drugs concomitantly. Figure 36.3 lists common drug interactions with colchicine and the degree to which the drug inhibits P-gp or CYP3A4. Table 36.4 lists the dose adjustments for colchicine based on the clinician's assessment of the drug interaction and renal function.

Selecting the Most Appropriate Drug

The ACR created guidelines for the treatment of acute gout attacks in 2012 (Khanna, 2012b). Prior to determining appropriate therapy, the patient's attack needs to be classified as mild, moderate, or severe. This is determined based on the patient's reported pain score with mild being less than or equal to 4, moderate being 5 to 6, and severe being greater than or equal to 7. Also, the location needs to be considered. The ACR breaks down the extent of the attack into one or few small joints, 1 or 2 large joints (ankle, knee, wrist, elbow, hip or shoulder), or polyarticular (4 or more joints). Based on the location and severity of pain, the appropriate treatments can be determined.

First-Line Therapy

For patients with mild to moderate pain in small joints or 1 to 2 large joints, initial therapy includes NSAIDs, systemic corticosteroids, or colchicine. If the pain started more than 36 hours prior, then colchicine is no longer a preferred agent. For patients with diabetes, heart failure, hypertension, or other conditions predisposing them to adverse effects of corticosteroids, steroids would not be the preferred agent. Patients may want to also supplement pharmacologic treatment with topical ice applied to the affected joint(s) as needed.

For patients with severe pain or polyarticular attacks, combination therapy is recommended as initial therapy. Box 36.6 lists common combinations recommended for acute gout treatment.

BOX 36.6 Combination Therapy for Acute Gouty Arthritis

Colchicine + NSAID
Oral corticosteroid + colchicine
Intra-articular steroid + (NSAID or colchicine or oral corticosteroid)

Second-Line Therapy

If monotherapy is not effective, the patient can switch to another first-line therapy or switch to combination therapy (Box 36.6). NSAIDs and corticosteroids are not recommended as a combination due to the overlap in toxicities and should be avoided in the treatment of gout.

Special Considerations

Ethnic/Genomics

As mentioned in the discussion of allopurinol, Korean, Han Chinese, and Thai patients have a higher probability of having an allopurinol hypersensitivity reaction due to the HLA-B*5801 genetic allele. All Han Chinese and Thai patients and Korean patients with stage 3 or worse CKD should be genetically tested for the HLA-B*5801 allele before beginning allopurinol therapy. If the patients test positive, they should be given alternative therapy to allopurinol.

Monitoring Patient Response

Patients should have their serum urate levels monitored during the titration of XOIs or probenecid every 2 to 5 weeks. Once target serum urate level is achieved (less than 6 mg/dL or less than 5 mg/dL), the patients should be monitored every 6 months.

It is very common for patients with gout to also have hypertension and renal insufficiency, so it is important that they also undergo appropriate assessments for their renal and cardiovascular systems. Baseline lab tests should include complete blood cell count, urinalysis, serum creatinine, blood urea nitrogen, and serum uric acid measurements.

Nephrolithiasis occurs in approximately 10% to 25% of patients with primary gout. The solubility of uric acid crystals increases when the urine pH becomes more alkaline. Acidic urine saturated with uric acid crystals may result in spontaneous stone formation. Patients should be warned about this complication and should be treated appropriately if stones occur.

Patient Education

To prevent acute gout attacks, patients can follow some nutritional and lifestyle modifications listed below. During an acute attack, patients should be counseled to elevate, ice, and rest the affected joint(s).

Drug Information

Patient-Oriented Information Sources

The ACR Web site has a section targeted to patients (https://www.rheumatology.org/practice/clinical/patients/diseases_and_conditions/gout.as). There is a page regarding gout that includes basic facts and lists of other resources for patients.

Nutrition/Lifestyle Changes

Dietary modifications can help to decrease the risk and frequency of acute gout attacks. Decreasing purine-rich foods, sweetened beverages, and alcohol will help decrease the serum urate levels. Box 36.7 has a full list of foods to decrease or avoid the consumption of in patients with gout. Patients should also increase their consumption of water, vegetables, and nonfat dairy as they have been shown to lower the risk of gout. Improving overall health status through weight loss and smoking cessation and closely monitoring and treating comorbidities, such as coronary artery disease, obesity, diabetes, hyperlipidemia, and hypertension, can also help decrease the risk of gout and prevent gouty flares.

BOX 36.7 Foods and Beverages That Can Increase Serum Urate Levels

Red meat: (specifically organ meat)
Kidney
Liver
Sweetbreads
Seafood:
Sardines
Shellfish
High-fructose corn syrup:
Sodas or sports drinks
Foods containing high levels
Alcohol
Especially beer
Also wine and spirits

Complementary and Alternative Medicine

Studies have shown that vitamin C inhibits uric acid synthesis and lowers serum uric acid

levels. In a 2011 meta-analysis by Juraschek et al. (2011) of 13 trials, researchers studied the effect of oral vitamin C supplementation on serum uric acid levels. This trial showed that a mean dose of 500 mg/d of vitamin C reduced serum urate levels 0.32 mg/dL. This dose is well over the recommended dietary allowance for vitamin C (90 mg/d men; 75 mg/d women) but is still under the maximum tolerable intake of 2 g/d. Vitamin C along with dietary modifications may be an option for some patients who do not tolerate pharmacologic therapy or wish to have an additional benefit with their pharmacologic therapy.

Case Study*

G.P., a 66-year-old, right-handed white man, seeks treatment for swelling and decreased range of motion in the right knee. He tells you he retired at age 65 after 40 years of assembly-line work. He reports that his physical activity has decreased and his weight has increased 20 pounds since retiring. His hobbies include woodworking and playing cards and playing with his two grandchildren. He denies tobacco use and alcohol use.

Although he describes several years of joint pain that gradually worsened, his activities were not limited until approximately 6 months ago, when he noted an insidious onset of swelling in the right knee. Over the years, he has sporadically taken acetaminophen, aspirin, and ibuprofen to control the pain. He reports that none of the drugs provided better relief than the others. His medical history is remarkable for hypertension and three episodes of gout.

Diagnosis: Osteoarthritis

1. List specific goals of treatment for G.P.
2. What drug therapy would you prescribe, and why?
3. What are the parameters for monitoring success of the therapy?
4. Discuss specific patient education based on the prescribed therapy.
5. List one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What would be the choice for second-line therapy?
7. What over-the-counter and/or alternative medications would be appropriate for G.P.?
8. What lifestyle changes should be recommended for G.P.?
9. Describe one or two drug–drug or drug–food interactions for the selected agent.* Answers can be found online.

37 Rheumatoid Arthritis

Lauren K. McCluggage Carol Gullo Mest

Rheumatoid arthritis (RA) is a chronic autoimmune inflammatory disease characterized by symmetric polyarthritis and joint changes, including erythema, effusion, and tenderness. The course of RA is characterized by remissions and exacerbations. RA can affect several organs, but it usually involves synovial tissue changes in the freely movable joints (diarthroses). RA most commonly affects small joints, including the wrists, second through fifth metatarsophalangeal joints, proximal interphalangeal joints, and metacarpophalangeal joints. RA may also affect large joints, including the elbows, shoulders, neck, hips, knees, and ankles.

In 2008, approximately 0.6% of the adult population in the United States had RA, with the prevalence in women about twice of that in men (Helmick et al., 2008). New onset of RA is seen throughout the life span, including infancy, but most cases occur in the fifth or sixth decade. Recent data have shown that diagnosis is occurring later in life, and the overall prevalence is decreasing. Previous data have shown that patients with RA have a higher rate of disability and mortality compared to patients of similar age without RA. However, with the increased use of disease-modifying antirheumatic drugs (DMARDs), especially early in the disease process, these risks appear to have normalized (Kroot et al., 2000).

Causes

The cause of RA continues to be the subject of research. Theories of causation include genetic factors, infectious agents, environmental factors, and an antigen–antibody response. It is unlikely that a single factor is responsible for all cases of RA.

Pathophysiology

The major physiologic changes associated with RA include synovial membrane proliferation followed by erosion of the subarticular cartilage and subchondral bone. Although the precise etiology of RA is unknown, mounting evidence points to a series of immunologic events. It is unclear whether an infectious, viral, or genetic agent prompts these events.

Specific major histocompatibility complex class II alleles and human leukocyte antigen are seen more frequently in patients with RA. These molecules are responsible for processing and presenting antigenic material to $CD4^+$ T cells. The exact antigen that initiates the following cascade is unknown but could be an exogenous or endogenous protein. T-cell activation stimulates monocytes, macrophages, and synovial fibroblasts to produce proinflammatory cytokines, including tumor necrosis factor (TNF) alpha, interleukin (IL)-1, and IL-6. During this process, matrix metalloproteinases are also released, causing major destruction in the joint cartilage. The activated T cells stimulate B cells, which then produce immunoglobulins, including rheumatoid factor (RF) and anti–citrullinated protein antibody (ACPA). The activation of the macrophages, monocytes, and synovial fibroblasts along with the release of cytokines stimulates angiogenesis in the synovial membrane. TNF-alpha is a key inflammatory mediator because it induces further production of proinflammatory cytokines and stimulates expression of adhesion molecules on endothelial cells. The expression of adhesion molecules promotes recruitment of leukocytes and more inflammatory cells. The result is a self-perpetuating inflammatory cycle.

Early Phase

In the early phase of RA, the synovium becomes more vascularized, and proliferation and hypertrophy begin. This results in the synovial tissue becoming edematous and exhibiting frond-like villi. As leukocytes proliferate, the synovial fluid becomes less viscous.

Progression

As RA progresses to the chronic form, continued hyperplasia and hypertrophy of the synovial lining occur. The thickness of the synovial lining increases up to fivefold from the normal one or two cell layers. The proliferation of the synovium persists, with lymphocytic tissue and plasma cells forming around blood vessels. This proliferative tissue extends into the joint space, joint capsule, ligaments, and tendons.

Severe, Chronic Rheumatoid Arthritis

In severe RA, pannus forms as a result of the release of lysosomal enzymes. Pannus is granulation tissue composed of lymphocytes, plasma cells, fibroblasts, and macrophages. Growing much like a tumor, pannus can invade the cartilage, activate chondrocytes, and release enzymes that can degrade cartilage and bone. This destructive process begins at the synovium and extends to the unprotected area at the junction of the cartilage and subchondral bone. These inflammatory cells can erode surrounding tissue, tendons, and cartilage. When pannus invades the joint margins, decreased range of motion and ankylosis may ensue. Pannus is a specific feature of RA, differentiating it from other forms of arthritis.

Diagnostic Criteria

In 2010, the American College of Rheumatology (ACR) and the European League Against Rheumatism (EULAR) collaborated on defining classification criteria for RA (Table 37.1). The goal of the criteria is to identify patients early who have a high probability of persistent RA and in whom early treatment would be beneficial. The emphasis of the classification criteria is on new patients with synovitis not explained by other conditions. Components of these criteria include joint involvement, serologic testing, acute phase reactants, and duration of symptoms.

TABLE 37.1 2010 American College of Rheumatology/European League Against Rheumatism Classification Criteria for Rheumatoid Arthritis

	Score
Target population (Who should be tested?): patients who	
1. Have at least one joint with definite clinical synovitis (swelling)*	
2. With synovitis not better explained by another disease†	
Classification criteria for RA (score-based algorithm: add score of categories A–D; a score ≥6/10 is needed for classification of a patient as having definite RA)‡	
A. Joint involvement§	
1 large joint‖	0
2–10 large joints	1
1–3 small joints#	2
4–10 small joints	3
>10 joints with at least 1 small joint**	5
B. Serology (at least one test is needed for classification)††	
Negative RF and negative ACPA	0
Low-positive RF or low-positive ACPA	2
High-positive RF or high-positive ACPA	3
C. Acute phase reactants (at least 1 test results is needed for classification)‡‡	
Normal CRP and ESR	0
Abnormal CRP or abnormal ESR	1
D. Duration of symptoms§§	
<6 wk	0
≥6 wk	1

*The criteria are aimed at classification of newly presenting patients. In addition, patients with erosive disease typical of RA with a history compatible with prior fulfillment of the 2010 criteria should be classified as having RA. Patients with long-standing disease, including those whose disease is inactive (with or without treatment) and who, based on retrospectively available data, have previously fulfilled the 2010 criteria, should be classified as having RA.

†Differential diagnosis varies among patients with different presentations but may include conditions such as systemic lupus erythematosus, psoriatic arthritis, and gout. If it is unclear about the relevant differential diagnoses to consider, an expert rheumatologist should be consulted.

‡Although patients with a score <6/10 are not classifiable as having RA, their status can be reassessed and the criteria might be fulfilled cumulatively over time.

§Joint involvement refers to any swollen or tender joint on examination, which may be confirmed by imaging evidence of synovitis. Distal interphalangeal joints, first carpometacarpal joints, and first metatarsophalangeal joints are excluded from assessment. Categories of joint distribution are classified according to the location and number of involved joints, with placement into the highest category possible based on the patter of joint involvement.

‖Large joints refer to shoulders, elbows, hips, knees, and ankles.

#Small joints refer to metacarpophalangeal joints, proximal interphalangeal joints, second through fifth metatarsophalangeal joints, thumb interphalangeal joints, and wrists.

**In this category, at least one of the involved joints must be a small joint; the other joints can include any combination of large and additional small joints, as well as other joints not specifically listed elsewhere (e.g., temporomandibular, acromioclavicular, sternoclavicular, etc.).

††Negative refers to IU values that are less than or equal to the ULN for the laboratory and assay; low positive refers to IU values that are higher than the ULN but less than or equal to three times the ULN for the laboratory and assay; high positive refers to IU values that are greater than three times the ULN for the laboratory and assay. When RF is only available as positive or negative, a positive result should be score as low positive for RF.

‡‡Normal/abnormal is determined by local laboratory standards.

§§Duration of symptoms refers to patient self-report of the duration of signs and symptoms of synovitis (e.g., pain, swelling, tenderness) of joints that are clinically involved at the time of assessment, regardless of treatment status.

RF, rheumatoid factor; ACPA, anticitrullinated protein antibody; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate. Redrawn with permission from Aletaha, D., Neogi, T., Silman, A. J., et al. (2010). 2010 rheumatoid arthritis classification criteria. *Arthritis and Rheumatism*, 62(9), 2569–2581.

The serology test can be either RF or ACPA, and the acute phase reactant test can be either

erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP). For serology tests, results are divided into three categories: negative, low positive (above normal but less than three times the upper limit of normal [ULN]), or high positive (greater than three times the ULN). The acute phase reactants are either normal or abnormal. None of these tests alone are sufficient to diagnose RA, but each is a component of diagnosis.

Other classic symptoms experienced by patients with RA include morning stiffness in involved joints persisting for at least 1 hour and subsiding with activity, symmetric joint involvement, and painful, swollen joints. Although RA characteristically affects joint structures, it is a systemic disease with potential extra-articular manifestations. Throughout the disease, the patient also may have generalized symptoms such as weakness, fatigue, mild fever, anorexia, and weight loss. End-organ involvement may occur in patients with high RF titers.

The most common extra-articular manifestation of RA is joint nodules. These occur in 15% to 20% of patients with RA and are most commonly seen in patients with erosive disease. These subcutaneous nodules may develop in any area of the body exposed to pressure. Some of these areas are the olecranon bursa, knuckles, ischial spines, Achilles tendon, extensor surfaces of the forearm, and the bridge of the nose (in patients who wear glasses). These nodules may also form internally on the heart, lungs, and intestinal tract. The nodules are firm and rubbery, occur in clusters, and may be either freely mobile or attached to underlying connective tissue. The treatment of the nodules is confined to the treatment of the underlying disease. These nodules may occur in other connective tissue diseases (e.g., systemic lupus erythematosus), so alone they are not criteria for diagnosing RA.

An ocular manifestation of RA is sicca syndrome; patients have a sensation of grittiness in the eyes, accumulation of dried mucus, and decreased tear production. Scleritis and episcleritis are occasional sequelae of sicca syndrome. Additional extra-articular manifestations of RA include vasculitis, pulmonary fibrosis, and pericarditis.

Initiating Drug Therapy

Physical and occupational therapies are considered mainstays of nonpharmacologic therapy in patients with RA. These therapies help protect the joints and maintain strength, function, and mobility. Reduction of joint stress is an additional goal of therapy. Patients should engage in activity to their fullest possible extent with adequate rest after activity, but they should avoid vigorous exercise and heavy labor during acute exacerbations of the disease. Hydrotherapy and hot and cold packs may be used to relax muscle spasms and facilitate joint movement. Warm showers and paraffin treatments may help relieve morning stiffness.

In 2012, the ACR updated their guidelines for the use of nonbiologic and biologic DMARDs, and in 2013, the EULAR provided updated recommendations for the treatment of RA. Both organizations indicated the importance of starting patients on DMARDs as early in the disease process as possible. Evidence has shown that the earlier in the disease process that DMARDs are started, the greater the chance of reducing disability and disease progression. Ideally, patients should be started on DMARD therapy within 3 months of diagnosis. The use of nonsteroidal anti-inflammatory drugs (NSAIDs) can still be considered for symptom control, but these do not have disease-modifying characteristics.

Goals of Drug Therapy

The goals of drug therapy for RA include reducing pain, stiffness, and swelling; preserving mobility and joint function; and preventing further joint damage. Due to advancements in the treatment of RA, the ACR and EULAR now recommend treating to a goal of remission or if remission is not possible then low disease activity. In 2011, the ACR and EULAR developed a definition for remission, which includes a swollen joint count, tender joint count, CRP level and patient global assessment of ≤1 each, or a simplified Disease Activity Score of ≤3.3. Low disease activity can be assessed in a variety of ways via the Patient Activity Scale (0.28 to 3.7), Clinical Disease Activity Index (greater than 2.8 to 10.0), Disease Activity Score in 28 joints (2.6 to 3.2), or the simplified Disease Activity Index (greater than 3.3 to 11).

Nonsteroidal Anti-inflammatory Drugs

NSAIDs are typically used to help relieve pain and improve symptoms during the diagnostic process. These agents are continued through the initiation of a DMARD to maintain reduced symptoms. This approach allows NSAIDs to exert their anti-inflammatory action while the DMARD takes effect. See the discussion of NSAIDs in Chapter 36 Osteoarthritis and Gout (Table 36.1).

Corticosteroids

Low-dose corticosteroids (prednisone 10 mg or equivalent) are beneficial in patients who are beginning DMARD therapy. Because the therapeutic effect of DMARDs may not be seen until several weeks to months after initiating therapy, corticosteroids may be used to provide almost immediate symptom relief. Corticosteroids are also indicated in elderly patients with recent onset of RA. Last, higher doses of corticosteroids are beneficial in acute flares to regain control of inflammation and pain.

Corticosteroids have been proven to slow the progression of erosions when initiated early in treatment. Most of the trials have examined this benefit in combination with other DMARD therapy, and monotherapy is only recommended if patients have contraindications to other DMARD therapy. The extended-release prednisone has been examined for use in RA patients. The hypothesis is that if the extended-release prednisone is dosed at night, then the medication would be released at the time when proinflammatory cytokines become activated. The studies showed that this formulation resulted in reduced morning stiffness and a reduction in IL-6.

The difficulty in therapy with corticosteroids lies in the fine dosing line that divides therapeutic effects from long-term side effects. Low doses, such as prednisone 5 to 7.5 mg every morning, may be beneficial. The lowest dose possible should be given by gradually decreasing the dose in 1-mg decrements.

Injectable corticosteroids can be used if symptoms are restricted to one or two joints that have not responded to first-line treatment. They may also be of limited benefit for acute flare-ups of RA.

The most common adverse events of corticosteroid therapy include cataracts, glaucoma, mild glucose intolerance, and cutaneous atrophy. Less common adverse events include myopathy, hypothalamic–pituitary–adrenal axis dysfunction, and osteoporosis. Osteoporosis may be avoided by taking a calcium supplement (1,500 mg/d) along with vitamin D (800 mg/d).

Disease-Modifying Antirheumatic Drugs

As stated previously, the early use of DMARDs is advocated because of the high degree of inflammation that is present early in the disease (Table 37.2). Radiographic evidence of joint damage usually is present in the first year of the disease, and functional deterioration due to this damage may be irreversible. Therefore, early initiation of DMARD therapy may be the best course of action to take in meeting the long-range goals of treatment. DMARD therapy should be initiated within 3 months after onset of symptoms. There are several DMARDs to select from; the ones described here are the DMARDs currently recommended by the ACR. Due to lack of data or high adverse events profile, cyclophosphamide, D-penicillamine, cyclosporine, azathioprine, gold compounds, and anakinra are not currently recommended for patients with RA. They can be used in patients who have failed the traditional treatments discussed below.

TABLE 37.2 Overview of Selected Disease-Modifying Antirheumatic Drugs

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Preferred csDMARDs			
methotrexate (Rheumatrex) 7.5 mg/wk in single dose, up to 25 mg/wk	GI effects, leukopenia, oral ulcers, thrombocytopenia, pulmonary toxicity, hepatotoxicity	Pregnancy and 1 mo before conception; caution in alcohol drinkers and liver disease	May take 3–8 wk to achieve clinical benefit; can induce spontaneous abortion and birth defects; monitoring includes CBC, serum creatinine, and liver function tests at 4- to 8-wk intervals
sulfasalazine (Azulfidine) 500–1,000 mg/d in divided doses; may increase up to maximum 3 g/d	GI effects, heartburn, dizziness, headache, rash, neutropenia, thrombocytopenia, orange-yellow color of skin	Contraindicated in intestinal or urinary obstruction Safety in pregnancy not established in RA treatment, although drug has proved safe in patients with inflammatory bowel disease in pregnancy	May take 1–4 mo to achieve clinical effect; causes reversible sterility in men; recommend that men cease therapy 90 d before starting a family; monitoring includes liver enzyme evaluation; CBC is necessary early in therapy but required less with prolonged use.
hydroxychloroquine (Plaquenil) 400–600 mg/d in divided doses	GI effects, rash, CNS effects, ocular effects	Use caution in pregnancy and with lactation.	Six months may be needed for clinical effect. Can trigger exacerbation of psoriasis; prolonged therapy may cause retinal damage. Monitoring should include periodic CBC and eye examination every 3–6 mo to monitor for retinal damage.
leflunomide (Arava) 100 mg PO daily for 3 d; 20 mg daily thereafter	Diarrhea, hair loss, weight loss, rash, infection	Pregnancy	If 20 mg daily is not tolerated, then 10 mg daily may be used. Long half-life; cholestyramine will enhance elimination if agent is to be discontinued.

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Nonpreferred csDMARDs			
D-Penicillamine (Depen, Cuprimine) 125 mg/d as single dose; may increase at monthly intervals to maximum daily dose of 1.5 g	GI effects, rash, itching, renal effects, autoimmune reactions, cytopenia	Not recommended in pregnancy or lactation—causes damage to fetal connective tissue	From 4 to 6 mo may be needed to establish clinical effect of therapy. Monitoring should include CBC with differential and platelets and urinalysis every 2–6 wk.
azathioprine (Imuran) 50–100 mg in single daily dose; can increase after 6–8 wk; 3.5 mg/kg is maximum daily dose	GI effects, bone marrow suppression, infection, hepatotoxicity, alopecia	Renal disease; avoid during pregnancy and lactation	From 6 to 8 and up to 12 wk may be needed to establish clinical effect. Monitoring should include CBC with differential and platelets weekly for the first month, then biweekly for the second and third months, then monthly.
cyclophosphamide (Cytoxan, Neosar) 1 mg/kg/d increased to 2 mg/kg/d after 6 wk	Alopecia, hemorrhagic cystitis, sterility, GI effects, increased susceptibility to infection, thrombocytopenia	Contraindicated for RA during pregnancy and lactation	In renal impairment, decrease dose. Four months may be needed to establish clinical effect. Monitoring includes CBC with differential, platelets, urinalysis for blood repeatedly, ESR, BUN, serum creatinine.
cyclosporine A (Sandimmune, Neoral) 5 mg/kg/d divided into 2 doses	Hypertension, tremor, nephrotoxicity, hepatotoxicity, increased susceptibility to infection, hyperkalemia	Contraindicated for RA during pregnancy and lactation	Approximately 8 wk may be needed to establish clinical effect. Decrease dose by 50% if hypertension or nephrotoxicity results. Monitoring includes CBC with differential, BUN, serum creatinine, serum bilirubin, liver enzymes repeatedly.
Gold compounds *Injectable*: aurothioglucose (Solganal); gold sodium thiomalate (Myochrysine) 10 mg/wk IM, up to a total dose of 1 g; maintenance dose –50 mg/mo *Oral*: auranofin (Ridaura) 3 mg bid	GI effects, rash, itching, stomatitis, vasomotor reactions, bone marrow suppression, nephritis, pneumonitis, exfoliative dermatitis, proteinuria	Uncontrolled diabetes; liver and renal disease, systemic lupus erythematosus, blood dyscrasias; lack of long-term studies in pregnant women, so not recommended during pregnancy or lactation	May take 6–8 wk for injectable form and 3–6 mo for oral form of drug to establish effectiveness. Monitoring includes routine CBC with differential, platelet count; urinalysis to measure protein; renal and liver function tests.
tsDMARD			
tofacitinib (Xeljanz) 5 mg PO twice a day	Bone marrow suppression (lymphopenia, neutropenia, anemia), GI perforations, infections	Coadministration with strong CYP3A4 inducers, known malignancy, history of interstitial lung disease	Not to be used in combination with bDMARDs. Dose adjustments for coadministration with CYP3A4 inhibitors and CYP2C19 inhibitors
Biologic DMARDs			
etanercept (Enbrel) 25 mg SQ twice weekly or 50 mg SQ weekly	Upper respiratory tract infections, pain at the injection site, headache	Concurrent infections or hypersensitivity to medication	Use caution in patients predisposed to infection. Concomitant immunosuppressants can increase risk of serious infection.

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
infliximab (Remicade) 3 mg/kg IV infusion at baseline, 2 wk, 6 wk, then every 8 wk thereafter	Urticaria, infusion reactions, dyspnea, hypotension	Same as above	Same as above
adalimumab (Humira) 40 mg SQ every other week; 40 mg weekly as monotherapy	Redness, swelling, bruising, or pain at the site of injection, headache, upset stomach, diarrhea, infection, rash	Same as above	Same as above
golimumab (Simponi) 50 mg SQ monthly in combination with methotrexate	Injection site reactions, infection, dizziness, antibody formation	Same as above	Same as above
certolizumab pegol (Cimzia) 400 mg SQ at weeks 0, 2, and 4 then 200 mg every other week	Injection site reactions, headache, nausea, infection	Same as above	Same as above
anakinra (Kineret) 100 mg SQ daily	Redness, swelling, bruising, or pain at the site of injection, headache, upset stomach, diarrhea, infection, rash	Sensitivity to *E. coli*–derived proteins; preexisting infection	Routine monitoring of WBCs is recommended; concomitant immunosuppressants can increase risk of serious infection.
abatacept (Orencia) 500–1,000 mg (based on weight) IV at weeks 0, 2, and 4, and then every 4 wk; 125 mg SQ weekly	COPD exacerbations, headache, hypertension, infusion reactions, infections, anaphylaxis	Hypersensitivity to abatacept; use caution in patients with history of infections or COPD.	Concomitant immunosuppressants increase risk of infection. Reserved for patients unresponsive to other therapy
tocilizumab (Actemra) 4–8 mg/kg IV every 4 wk; 162 mg SQ every other week—weekly (weight based)	Increased LDL and transaminase, decreased WBC, infusion-related reactions	Untreated latent TB or hepatitis	Indicated for patients who did not respond to TNF-alpha inhibitor

Due to the development of new DMARDs, a modified nomenclature for the DMARDs has been developed. DMARDs are first divided into synthetic and biologic DMARDs. The synthetic DMARDs are then further divided in conventional synthetic DMARDs (csDMARDs) (methotrexate, leflunomide, sulfasalazine, hydroxychloroquine) and targeted synthetic DMARDs (tsDMARD) (tofacitinib). Biologic DMARDs are also further divided into biologic originator DMARD (boDMARD) and biosimilar DMARD (bsDMARD).

Methotrexate

The most commonly prescribed DMARD is methotrexate (Rheumatrex). The patient best suited for treatment with methotrexate is one who has morning stiffness and synovitis.

Mechanism of Action

Methotrexate, a folic acid antagonist, is thought to affect leukocyte suppression, decreasing the inflammation that results from immunologic by-products. When treatment stops, exacerbation of symptoms may occur as early as 2 weeks after cessation.

Dosage

Methotrexate is available for oral, subcutaneous, intramuscular, or intravenous (IV; reserved for chemotherapy) use. For most patients, a starting dose of 7.5 mg orally once per week is recommended. If a significant decrease in symptoms is not noted, the dose should be increased every few weeks to a maximal dose of 25 to 30 mg weekly. The patient needs to be on the maximal dose for at least 8 weeks before someone can be considered a methotrexate failure. Most patients respond to 12.5 to 15 mg/wk. Injectable methotrexate may be used if there is an inadequate response to oral therapy or if the weekly dose needs to exceed 25 mg.

Time Frame for Response

Approximately 70% to 75% of patients respond favorably to methotrexate therapy, but it may take 3 to 8 weeks before improvement is noted. More than 50% of patients stay on the treatment for more than 5 years. However, if patients have difficulty tolerating side effects, methotrexate should be discontinued or the dosage should be lowered.

Contraindications

Methotrexate is contraindicated in pregnant and breast-feeding patients and those with leukopenia (white blood cell [WBC] count of less than 3,000 cells/mm^3), acquired immunodeficiency syndrome, renal impairment (creatinine clearance less than 30 mL/min), or liver disease (liver enzymes greater than two times the ULN). Methotrexate also has many black box warnings, including the risk of hepatotoxicity, renal impairment, pneumonitis, bone marrow suppression, diarrhea, ulcerative stomatitis, dermatologic

reactions, and opportunistic infections. The ACR also lists acute serious bacterial infections, latent tuberculosis (TB), active fungal infections, active herpes zoster viral infection, platelets less than 50,000 cells/mm^3, treated lymphoproliferative disease within 5 years, and acute or chronic hepatitis B or C as contraindications to methotrexate therapy.

Adverse Events

The most commonly reported adverse events of methotrexate are nausea and abdominal pain. These effects may be minimized by switching to parenteral therapy. Oral ulcers, leukopenia, anemia, and thrombocytopenia are also common. However, these adverse reactions may be minimized by administering 1 mg of folic acid daily. Although methotrexate may inhibit folic acid metabolism, it does not seem to affect the efficacy of the therapy.

The most serious adverse event of therapy is liver toxicity, which occurs more frequently in patients with diabetes, obesity, alcohol use, and existing liver disease. Pneumonitis is another potentially serious side effect of therapy. A baseline chest x-ray may be obtained, and patients should be instructed to report the new onset of a dry cough, dyspnea, or fever. Methotrexate should be immediately discontinued if the patient has pulmonary problems because immutable pulmonary damage may occur.

Baseline laboratory values should be obtained before initiation of therapy and should include a CBC, liver function tests, blood urea nitrogen (BUN), and serum creatinine. During therapy, the CBC should be monitored every 4 weeks, and creatinine, BUN, and liver function tests should be monitored every 3 months. A transient yet marked increase in liver enzymes may be seen, with stabilization occurring with continued treatment or dose reduction. If liver enzymes persist at concentrations of two to three times the ULN, then methotrexate should be discontinued and a liver biopsy obtained.

Methotrexate is classified as pregnancy category X due to the risk of fetal death or severe abnormalities and has implications for both males and females. Therefore, women who wish to conceive should stop taking methotrexate at least one ovulatory cycle before attempting to become pregnant. Men must discontinue methotrexate at least 3 months before trying to conceive. Men and women of childbearing age who are not sterilized should use a reliable form of contraception.

Interactions

Concurrent use with NSAIDs may increase the risk of bone marrow suppression and gastrointestinal (GI) toxicity. The combination should be avoided when taking moderate to high doses of methotrexate. Medications such as penicillins, tetracyclines, probenecid, and sulfonamides that compete with methotrexate for renal tubular secretion will enhance the effects of methotrexate and should be used cautiously. Methotrexate may increase the concentrations of mercaptopurine and theophylline. Concomitant use of cholestyramine decreases the absorption of methotrexate.

Sulfasalazine

Like methotrexate, sulfasalazine (Azulfidine) is an effective DMARD that relieves symptoms relatively quickly. The best candidates for treatment are patients with significant synovitis but no poor prognostic factors.

Mechanism of Action

Sulfasalazine's mechanism of action is not clearly understood but is thought to be due to its conversion to sulfapyridine and 5-acetylsalicylic acid in the gut. The sulfapyridine component is thought to be responsible for the disease-modifying activity. Research has shown the anti-inflammatory features of this conversion, as well as its ability to decrease inflammatory cytokine production.

Dosage

Sulfasalazine is available in oral form in 500-mg tablets. Dosing is started at 1,000 mg/d in two divided doses. The daily divided dose is gradually increased to 2,000 mg over 2 weeks. After 12 weeks of 2,000 mg daily, if the response is still not adequate, then the dose can be increased to 3,000 mg daily. Enteric-coated tablets are recommended for the treatment of RA to reduce the risk of GI-related adverse events.

Time Frame for Response

Patients may start to notice an effect as early as 1 month, but the full effect may take up to 4 months.

Contraindications

Due to its sulfa component, sulfasalazine is contraindicated in patients with a sulfa allergy. Also, once a pregnant woman is at full term, sulfasalazine is classified as a pregnancy category D and should be avoided. Patients with a GI or genitourinary tract obstruction or those with porphyria should not use this medication. Platelet count of less than 50,000 cells/mm^3, liver enzymes greater than two times the ULN, and hepatitis B or C infection resulting in Child-Pugh class B or C hepatic function are contraindications, according to the ACR guidelines.

Adverse Events

The most common adverse events to sulfasalazine are dose dependent and include nausea and diarrhea. Other reported adverse events include dizziness, intestinal or urinary obstruction, oral ulcers, thrombocytopenia, orange-yellow pigmentation of the skin, headache, and depression. Any of these common adverse events may become intolerable and cause discontinuation of the drug. Reversible sterility has been reported in men; therapy should be discontinued 3 months before attempting to father a child.

Agranulocytosis, the gravest adverse event to sulfasalazine, has been reported in fewer than 2% of patients, but it dictates immediate discontinuation. Before initiating sulfasalazine therapy, the practitioner should obtain baseline laboratory test values, including a CBC and liver enzymes. These values should be monitored every 2 weeks for 1 month after initiation of therapy and then monthly for 5 months. If laboratory values remain stable for the first 6 months of therapy, a CBC should be checked every 3 months.

Interactions

The risk of bone marrow suppression will be enhanced if used with other suppressive agents such as azathioprine, methotrexate, or mercaptopurine, and additional monitoring is warranted. Sulfasalazine may increase the effects of oral hypoglycemics and oral anticoagulants; therefore, patients should be monitored closely if on concurrent therapy. Sulfasalazine may decrease the concentration of cyclosporine.

Antimalarials

The antimalarial agents hydroxychloroquine (Plaquenil) and chloroquine are attractive because of their tolerable adverse event profile, with the drugs being discontinued in fewer than 9% of patients. However, because these drugs cannot limit the progression of RA, they are currently used as an adjunct to methotrexate therapy or as single-agent therapy in early, mild RA without bone erosion. Hydroxychloroquine is the preferred agent in this class.

Mechanism of Action

Antimalarials inhibit antigen processing by elevating cellular pH, which changes antigen degeneration. Thus, the presentation of the antigen to T cells is impaired.

Dosage

Hydroxychloroquine and chloroquine are available in oral form and are rapidly and completely absorbed. Dosing is calculated by patient weight, but the typical dosage for hydroxychloroquine is 200 mg twice daily or 400 mg daily.

Time Frame for Response

Therapeutic effects are usually noted within 2 to 6 months of treatment.

Contraindications

Patients with pre-existing retinal field changes should not use antimalarials due to the ocular effects of long-term therapy.

Adverse Events

The most common adverse events associated with antimalarials are nausea, diarrhea, and abdominal discomfort. Less common adverse events include photosensitivity and skin pigmentation changes. A maculopapular, pruritic rash encompassing the entire body may occur and cause extreme discomfort. Although neuromyopathy has been reported rarely, deep tendon reflexes should be monitored regularly for diminished activity.

After absorption, these drugs concentrate in the retina, kidneys, bone marrow, and liver. The concentration of antimalarials in specific organs dictates baseline and ongoing monitoring during therapy. Specifically, patients need a baseline eye examination with a follow-up exam 5 years later and then annually thereafter because of potential retinal accumulation of the drug. A CBC should be performed periodically.

Interactions

Antimalarial agents can decrease the metabolism of beta blockers with some exceptions, including atenolol and nadolol. For patients on beta blockers, consider switching to atenolol prior to initiating antimalarial therapy. Also, cyclosporine and digoxin concentrations may be increased, requiring more frequent monitoring. Antimalarial doses should be separated from magnesium-containing products by 2 to 4 hours due to decreased absorption of the antimalarials.

Leflunomide

Leflunomide (Arava) exerts anti-inflammatory and antiproliferative actions, retarding erosions and joint space narrowing.

Mechanism of Action

Leflunomide is a prodrug that undergoes rapid conversion to its active metabolite. The drug is a competitive inhibitor of dihydrofolate reductase. This inhibition decreases the production of pyrimidines (amino acid building blocks), decreasing T-cell and B-cell proliferation. This action is similar to methotrexate, making this agent a reasonable alternative for patients who cannot tolerate or who have an inadequate response to methotrexate. Since leflunomide inhibits pyrimidine synthesis and methotrexate inhibits purine synthesis, these agents may be used in combination.

Dosage

Since the half-life of the active metabolite is 15 to 18 days, therapy with leflunomide is usually initiated with a 100-mg daily loading dose for 3 days, and then the agent is continued at 20 mg/d if tolerated. If the patient cannot tolerate 20 mg/d, the dose can be lowered to 10 mg/d. The loading dose can be omitted in patients at increased risk for hepatic or hematologic toxicity.

Time Frame for Response

Benefit from leflunomide can be seen as early as 4 weeks but may take up to 3 months.

Contraindications

Like other DMARDs, leflunomide is contraindicated in pregnancy. Since the half-life is so long, a typical washout period for women who wish to conceive is about 2 years. However, agents interrupting the enterohepatic recirculation (e.g., activated charcoal or cholestyramine) can be used to reduce the half-life of the metabolite to about 1 day. The dosing of cholestyramine, as recommended by the manufacturer, is 8 g three times a day for 11 days. To ensure appropriate clearance, plasma concentrations should be less than 0.02 mg/L measured twice at least 14 days apart.

Due to hepatotoxicity, patients with a history of alcoholism or with pre-existing liver disease should not take leflunomide.

Adverse Events

About 5% of patients receiving leflunomide monotherapy have elevated liver enzymes. While this number appears low, there are reports of more than 10 patients dying while on leflunomide therapy; the deaths are thought to be related to the hepatotoxicity of the agent.

More common adverse events include GI symptoms, weight loss, alopecia, and hypertension. Leflunomide also has been associated with bone marrow suppression, including anemia, thrombocytopenia, and agranulocytosis.

A CBC and liver function tests should be taken as a baseline and then monthly for the first 6 months of therapy. If test results remain stable, monitoring can be every 6 to 8 weeks thereafter.

Interactions

Leflunomide is a weak inhibitor of the CYP2C9 enzyme and therefore may increase the levels of agents metabolized through this pathway, including warfarin. Rifampin may increase the concentration of leflunomide's active metabolite. The use of bile acid sequestrants decreases the enterohepatic recycling of leflunomide, decreasing its effectiveness.

Tofacitinib

Tofacitinib is the first tsDMARD available and targets Janus kinase (JAK) activity.

Mechanism of Action

Tofacitinib interferes with JAK1, JAK2, JAK3, and Tyk2 but has higher potency for JAK3. It is a competitive, reversible inhibitor. Tofacitinib prevents the phosphorylation and activation of signal transducers and activators of transcription. This results in decreased signal transduction for cytokines and decreases propagation of the inflammatory response

via decrease leukocyte maturation and activation and cytokine production.

Dosage

The typical dose is 5 mg orally twice daily. However, if used in combination with a strong CYP3A4 inhibitor or concomitant moderate CYP3A4 inhibitor with a potent CYP2C19 inhibitor, the recommended dose is 5 mg by mouth daily. Also, for patients with moderate to severe renal or hepatic impairment, the dose is 5 mg by mouth daily.

Contraindications

There are no absolute contraindications to tofacitinib therapy; however, there are many warnings associated with its use. Due to the risk of bone marrow suppression, tofacitinib should not be initiated if a patient has a lymphocyte count less than 500 cells/mm^3 and absolute neutrophil count of less than 1,000 cells/mm^3. A CBC should be monitored at baseline, 4 to 8 weeks after initiation and then every 3 months thereafter. Tofacitinib may cause hepatotoxicity and patients should be monitored for this. Similar to other DMARDs, tofacitinib may increase the risk of infection including TB, fungal infections, and opportunistic infections. Patients should be screened for latent TB prior to initiating therapy.

Adverse Events

Common adverse effects include headache, diarrhea, hypertension, and upper respiratory infections. Tofacitinib may increase lipid parameters such as total cholesterol, LDL, and HDL, and a lipid panel should be checked 4 to 8 weeks after initiating therapy.

Interactions

Tofacitinib is a major substrate of CYP3A4 and a minor substrate of CYP2C19. Tofacitinib is not recommended to be used with strong CYP3A4 inducers such as rifampin. Due to the risk of infection, tofacitinib should not be used with any biologic DMARDs. Live vaccines should not be administered while a patient is receiving tofacitinib.

Biologic Disease-Modifying Antirheumatic Drugs

Biologic agents are developed from living sources, such as humans, animals, or microorganisms. The introduction of various biologics effective against RA has changed the management of RA. These agents target multiple components involved in the pathogenesis of RA, such as TNF-alpha, T-cell activation, IL-1, and IL-6. Prior to initiating bDMARDs, patients should be screened for latent TB due to the increased reactivation of TB and hepatitis B.

Tumor Necrosis Factor Inhibitors

Etanercept (Enbrel), infliximab (Remicade), adalimumab (Humira), golimumab (Simponi), and certolizumab pegol (Cimzia) are TNF-alpha inhibitors used in RA treatment.

Mechanism of Action

These agents act by binding the circulating TNF-alpha and render it inactive. This then reduces the chemotactic effect of TNF-alpha by reducing IL-6 and CRP, resulting in reduced infiltration of inflammatory cells into joints. Also, when these agents bind to surface TNF-alpha, cell lysis occurs.

Dosage

All five of these agents are injectables. Etanercept is self-administered subcutaneously at 25 mg twice weekly or 50 mg weekly as combination therapy or monotherapy. Infliximab is an IV infusion with a recommended dose of 3 mg/kg at 0, 2, and 6 weeks and then every 8 weeks thereafter. Doses of infliximab have ranged from 3 to 10 mg/kg every 4 to 8 weeks. Infliximab is indicated in conjunction with methotrexate because infliximab antibodies develop when administered as monotherapy. Adalimumab is given at 40 mg every other week as a subcutaneous injection. Adalimumab may be administered concomitantly with methotrexate, glucocorticoids, or NSAIDs. It may also be used as monotherapy; however, the dose may need to be increased to 40 mg weekly. Certolizumab pegol is administered as a subcutaneous injection at a dose of 400 mg at 0, 2, and 4 weeks and then 200 mg every other week thereafter. An alternative maintenance dosing regimen is 400 mg every 4 weeks. Golimumab is only indicated for use in combination with methotrexate, and the recommended dose is 50 mg subcutaneously one time a month.

Time Frame for Response

All of the TNF-alpha inhibitors produce a rapid response, within days to weeks.

Contraindications

Patients should be assessed at baseline for infections or risk factors for infections. There have been reports of TB developing in patients taking infliximab; the theory is that the immunomodulation allows latent TB to flare. This usually occurs within the first 2 to 5 months of therapy. Therefore, all patients must be evaluated for latent TB with a tuberculin skin test or interferon gamma release assay prior to beginning therapy. Other serious infections, including fungal and opportunistic infections, have also occurred with these agents, and careful consideration of the patient's history is important when prescribing them. This class of medications is not recommended for patients with untreated hepatitis B or treated hepatitis B with Child-Pugh score of B or higher. In addition, patients with New York Heart Association class III or IV heart failure should not be initiated on TNF inhibitors.

Adverse Events

Adverse events include injection-site reactions (certolizumab pegol, golimumab, etanercept, adalimumab) or infusion reactions (infliximab). Caution must be used when administering these agents to patients predisposed to infection. Sepsis and fatal infections have occurred in patients receiving TNF-alpha inhibitors. If a patient develops an infection while taking a TNF-alpha inhibitor, the agent should be discontinued until the infection resolves. Other serious but more rare adverse events include demyelinating central nervous system diseases, autoimmune disorders such as lupus-like syndrome, and lymphomas. The risk of lymphoma is increased in children and adolescents, and it is not elucidated if the increased risk is due to the medication or the disease. Due to this risk, these agents are not recommended for the treatment of RA in patients with a treated solid malignancy within the last 5 years or treated lymphoproliferative malignancy.

Interactions

TNF-alpha inhibitors should not be used in combination with other biologic DMARDs due to the increased risk of infection. As a result of immunosuppressive effects, patients should not receive live vaccinations while being treated with a TNF-alpha inhibitor. Also, the response to other vaccines may be diminished while on therapy.

Anakinra

Anakinra (Kineret) is a recombinant form of human IL-1 receptor antagonist but differs by the addition of methionine at one of the N-terminals.

Mechanism of Action

The levels of naturally occurring IL-1 receptor antagonists are not adequate to compete with the elevated amount of IL-1 present in the synovium of RA patients. With limited competition, IL-1 can promote inflammation and degrade cartilage. By exogenously providing this antagonist to RA patients, the joint inflammation process is interrupted.

Dosage

Anakinra is given 100 mg subcutaneously daily. In patients with severe renal dysfunction (creatinine clearance below 30 mL/min), it should be administered every other day.

Time Frame for Response

In patients who responded to anakinra, the effect was seen within 12 weeks.

Contraindications

The primary contraindication to anakinra is sensitivity to *Escherichia coli*–derived proteins. Similar to the other immunomodulators, pre-existing infection or risk of infection may be a contraindication since there is an increased risk of infection in patients taking anakinra. Anakinra should not be administered in combination with TNF-alpha inhibitors due to the increased risk of infection.

Adverse Events

The most common adverse event of anakinra is skin irritation, including erythema, inflammation, and pain at the injection site. This occurs in more than half of patients and usually resolves within a few weeks. Although rare, there is a possibility of hypersensitivity reactions, including anaphylaxis and angioedema. Also, patients are at an increased risk for infection.

Patients also may experience a decrease in WBCs. Routine monitoring is recommended at baseline and then monthly for the first 3 months, and then quarterly for the first year.

Interactions

No known pharmacokinetic drug interactions exist. Pharmacodynamically, agents that suppress the immune system should be used with caution, if at all, due to the increased risk of serious infections. Anakinra should not be used in combination with TNF-alpha inhibitors.

Abatacept

Abatacept (Orencia) is indicated for the treatment of moderate to severe RA as monotherapy or in combination with csDMARDs.

Mechanism of Action

Abatacept is a costimulation modulator that binds to CD80 and CD86 on antigen-presenting cells. This binding blocks the CD28 interaction between the antigen-presenting cell and T cells necessary for T-cell activation. Therefore, abatacept decreases the activation of T cells.

Dosage

Abatacept is given as an IV infusion over 30 minutes and is dosed based on weight (less than 60 kg, 500 mg; 60 to 100 kg, 750 mg; greater than 100 kg, 1,000 mg). It is dosed at weeks 0, 2, and 4 and then every 4 weeks thereafter. It is also available as a subcutaneous injection with can be initiated with or without receiving an IV dose. If a patient receives an IV loading dose (based on weight), the subcutaneous dose is 125 mg within 24 hours of the IV dose followed by 125 mg weekly thereafter. If the patient does not receive an IV loading dose, the dose is 125 mg subcutaneously weekly. If a patient had been receiving the IV formulation and wishes to convert to the subcutaneous formulation, the recommendation is to start the 125 mg subcutaneous weekly at the time of their next scheduled IV dose.

Time Frame for Response

The onset of action for abatacept ranges from 1 to 3 months.

Contraindications

The only absolute contraindication associated with abatacept is hypersensitivity to it or any component of the formulation. Abatacept should be used cautiously in patients with a history of infection or chronic obstructive pulmonary disease (COPD). Patients need to be screened for hepatitis and latent TB prior to initiation due to the risk of reactivation.

Adverse Events

Patients with COPD experienced a higher rate of exacerbations, cough, pneumonia, and dyspnea. Common adverse events include headache, hypertension, and infusion-related reactions. Similarly to other immunomodulators, abatacept is associated with a higher risk of infections. Although rare, abatacept can cause anaphylaxis.

Interactions

Patients should not receive a live vaccine while on abatacept or for up to 3 months after discontinuing the drug. Abatacept should not be used in combination with other bDMARDs due to the increased risk of immunosuppression.

Tocilizumab

Tocilizumab (Actemra) is the first IL-6 receptor inhibitor on the market and is indicated for adult patients with moderate to severe RA after not responding to one or more DMARDs.

Mechanism of Action

Tocilizumab is a humanized anti-IL-6 receptor monoclonal antibody. By inhibiting IL-6 activity, B-cell and T-cell activation is decreased as well as acute phase reactant production

and osteoclast activation.

Dosage

Tocilizumab is available as an IV infusion or a subcutaneous injection. For the IV infusion, tocilizumab is initiated at a dose of 4 mg/kg every 4 weeks with an option to increase to 8 mg/kg if needed based on clinical response. For the subcutaneous formulation, the dose for a patient weighing less than 100 kg is 162 mg every other week with the option to increase to weekly dosing if needed. For patients weighing more than 100 kg, the recommended starting dose is tocilizumab 162 mg subcutaneously every week. For a patient wishing to transition from IV to subcutaneous, they would initiate the subcutaneous dose at the time of their next scheduled IV dose.

Time Frame for Response

It may take up to 3 months for symptomatic improvement with tocilizumab.

Contraindications

Tocilizumab should not be initiated if patients have an absolute neutrophil count of less than 2,000 cells/mm^3, platelets less than 100,000/mm^3, or ALT or AST greater than 1.5 times the ULN. Similar to the other biologic agents, patients should be screened for TB and hepatitis prior to initiation.

Adverse Events

Overall, tocilizumab is well tolerated. There have been laboratory abnormalities associated with tocilizumab that include increased low-density lipoprotein cholesterol, elevated transaminase, and decreased WBCs. Approximately 8% of patients experienced an infusion-related reaction.

Based on laboratory abnormalities, a CBC and liver function tests need to be monitored at baseline and then every 4 to 8 weeks while on therapy. A lipid panel should be checked at baseline, 4 to 8 weeks into therapy, and then every 6 months while being treated with tocilizumab.

Interactions

Avoid using tocilizumab with leflunomide due to concern for increased hematologic toxicity. Patients should not receive live vaccines while on therapy and for at least 3 months after discontinuing treatment. Also, patients may not be able to respond appropriately to inactivated vaccines administered while on therapy. Due to the risk of infection, tocilizumab should not be used with any TNF-alpha inhibitors, anakinra, abatacept, or other immunosuppressants.

Selecting the Most Appropriate Agent

In 2008, the ACR published recommendations regarding the use of nonbiologic and biologic DMARDs for the treatment of RA, and this guideline was updated in 2012. It is important to note that gold and anakinra were not included due to infrequent use and lack of relevant new data. Decisions regarding appropriate therapy are based on disease duration, poor prognostic factors, and disease activity. Disease duration is divided into early (less than 6 months) or established (greater than 6 months). Poor prognostic factors include functional limitation, extra-articular disease, RF positivity, positive ACPA, or bony erosions on radiography. Last, disease activity is divided into low, moderate, or high based on several questionnaire instruments. Treatment algorithms are displayed in Figures 37.1 and 37.2.

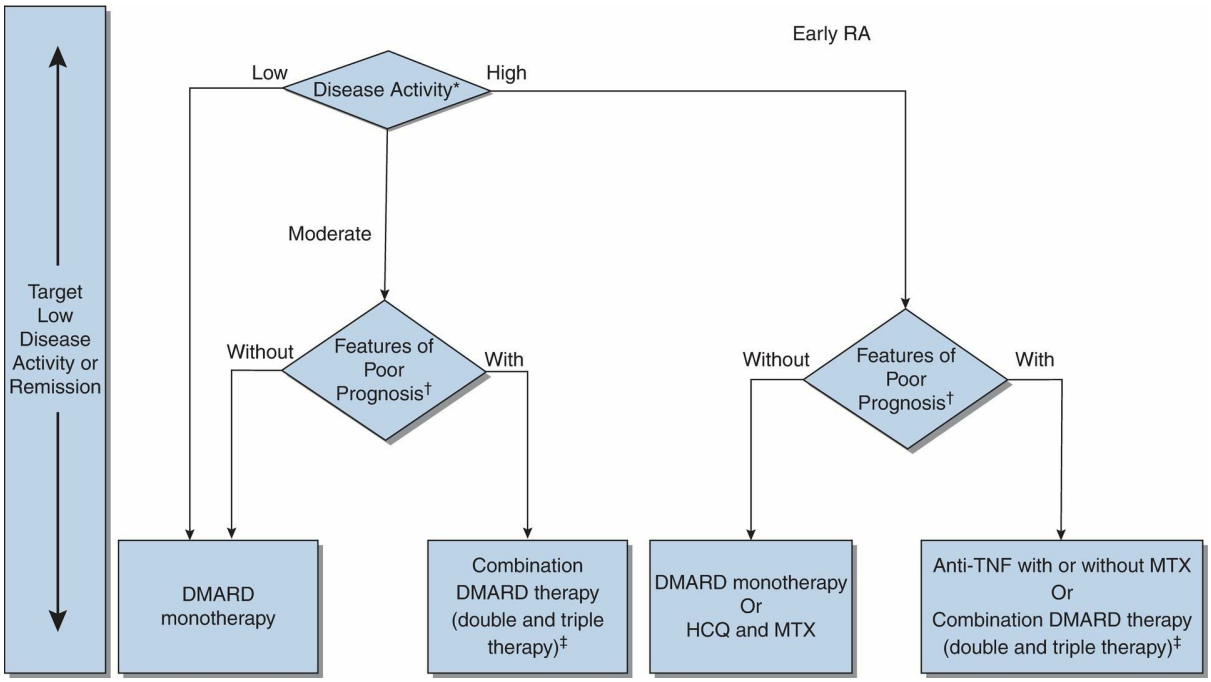

FIGURE 37.1 2012 American College of Rheumatology recommendations update for the treatment of early rheumatoid arthritis (RA) defined as a disease duration less than 6 months. DMARD, disease-modifying antirheumatic drug (includes hydroxychloroquine [HCQ], leflunomide [LEF], methotrexate [MTX], minocycline, and sulfasalazine); anti-TNF, anti–tumor necrosis factor. *Definitions of disease activity are discussed in the full text of the reference and were categorized as low, moderate, or high. †Patients were categorized based on the presence or absence of one or more of the following poor prognostic features: functional limitation (e.g., Health Assessment Questionnaire score or similar valid tools), extra-articular disease (e.g., presence of rheumatoid nodules, RA vasculitis, Felty syndrome), positive rheumatoid factor or anti–cyclic citrullinated peptide antibodies, and bony erosions by radiograph. ‡Combination DMARD therapy with two DMARDs, which is most commonly MTX based, with some exceptions (e.g., MTX + HCQ, MTX + LEF, MTX + sulfasalazine, and sulfasalazine + HCQ) and triple therapy (MTX + HCQ + sulfasalazine). (Reprinted from Singh, J. A., Furst, D. E., Bharat, A., et al. FIGURE 37.2 2012 America College of Rheumatology (ACR) recommendations updated for the treatment of established rheumatoid arthritis (RA), defined as a disease duration ≥6 months or meeting the 1987 ACR classification criteria. Depending on a patient's current medication regimen, the management algorithm may begin at an appropriate rectangle in the figure, rather than only at the top of the figure. Disease-modifying antirheumatic drugs (DMARDs) include hydroxychloroquine (HCQ), leflunomide (LEF), methotrexate (MTX), minocycline, and sulfasalazine (therapies are listed alphabetically; azathioprine and cyclosporine were considered but not included). DMARD monotherapy refers to treatment in most instances with HCQ, LEF, MTX, or sulfasalazine; in few instances, where appropriate, minocycline may also be used. Antitumor necrosis factor (anti-TNF) biologics include adalimumab, certolizumab pegol, etanercept, infliximab, and golimumab. Non-TNF biologics include abatacept, rituximab, or tocilizumab (therapies listed alphabetically). [*]Definitions of disease activity are discussed in the full text of the reference and were categorized as low, moderate, or high. [†]Features of poor prognosis include the presence of one or more of the following: functional limitation (e.g., Health Assessment Questionnaire score or similar valid tools), extra-articular disease (e.g., presence of rheumatoid nodules, RA vasculitis, Felty syndrome), positive rheumatoid factor or anticyclic citrullinated peptide antibodies, and bony erosions by radiograph. [‡]Combination DMARD therapy with two DMARDs, which is most commonly MTX based, with some exceptions (e.g., MTX + HCQ, MTX + LEF, MTX + sulfasalazine, and sulfasalazine + HCQ) and triple therapy (MTX + HCQ + sulfasalazine). [§]Reassess after 3 months and proceed with escalating therapy if moderate or high disease activity in all instances except after treatment with non-TNF biologic (rectangle D), where reassessment is recommended at 6 months due to a longer anticipated time for peak effect. [¶]LEF can be added in patients with low disease activity after 3 to 6 months of minocycline, HCQ, MTX, or sulfasalazine. [#]If after 3 months of intensified DMARD combination therapy or after second DMARD has failed, the option is to add or switch to an anti-TNF biologic. [**]Serious adverse events were defined per the U.S. Food and Drug Administration (FDA); all other adverse events were considered nonserious adverse events. [††]Reassessment after treatment with a non-TNF biologic is recommended at 6 months due to anticipation that a longer time to peak effect is needed for non-TNF compared to anti-TNF biologics. [‡‡]Any adverse event was defined as per the U.S. FDA as any undesirable experience associated with the use of a medical product in a patient. The FDA definition of serious adverse events includes death, life-threatening event, initial or prolonged hospitalization, disability, congenital anomaly, or an adverse event requiring intervention to prevent permanent impairment or damage. (Reprinted from Singh, J. A., Furst, D. E., Bharat, A., et al. (2012). 2012 Update of the 2008 American College of Rheumatology Recommendations for the use of disease-modifying antirheumatic drugs and biologic agents in the treatment of rheumatoid arthritis. *Arthritis Care & Research*, 64(5), 625–639, with permission.)

In 2013, the EULAR published recommendations regarding the management of RA with synthetic and biologic DMARDs (Table 37.3). These guidelines break treatment into three phases based on response to therapy. Similar to the ACR guidelines, the EULAR guidelines do differentiate treatment for patients with or without poor prognostic factors.

TABLE 37.3 EULAR Treatment Recommendations

Phase I	Initial treatment	Methotrexate monotherapy or combination If contraindication to methotrexate: leflunomide or sulfasalazine alone or combination
Phase II	Failure of phase I	With poor prognostic factors: bDMARD Without poor prognostic factors: change csDMARDs
	Failure of second csDMARD regimen	bDMARD
Phase III	Failure of first bDMARD	Replace bDMARD with alternative bDMARD
	Failure of ≥2 bDMARD	Replace bDMARD with tofacitinib

In selecting a DMARD or combining DMARDs, the clinician needs to consider the toxicities of the medications, including the interactions with other prescribed drugs. Some patients may have difficulty adhering to monitoring requirements for some of the more toxic drugs. Other patients may not be able to adhere to a strict dosing schedule. In addition, the time required to achieve benefit can be protracted with certain DMARDs, which may be unacceptable to the patient. Finally, the cost of the various therapies varies widely.

Symptomatic Treatment

NSAIDs and/or corticosteroids are recommended for acute symptoms associated with RA. These agents are particularly helpful while a patient is undergoing diagnostic assessment. NSAIDs do not have disease-modifying abilities, and steroids often have intolerable adverse

effects; therefore, once a definite diagnosis is made, DMARD therapy should be started. NSAIDs and steroids can be continued until the DMARD takes effect.

First-Line Therapy

For patients with early disease, the recommended first-line treatment from the ACR (Figure 37.1) is monotherapy csDMARD for patients with low disease activity regardless of poor prognostic factors or patients with moderate disease activity without poor prognostic factors. For patients with moderate disease activity with poor prognostic factors, combination csDMARD therapy is recommended. This combination can be double or triple therapy and typically will be methotrexate based. For patients with high disease activity without poor prognostic factors, csDMARD monotherapy or combination methotrexate with hydroxychloroquine is recommended. Lastly, for patients with high disease activity and poor prognostic factors, treatment with either combination csDMARD or anti-TNF with or without methotrexate is first line.

The EULAR guidelines state that methotrexate should be a part of the initial treatment strategy for patients with active disease, and if patients have a contraindication to methotrexate, leflunomide or sulfasalazine can be substituted. However, patients with mild or low disease activity may be sufficiently treated with an antimalarial. The recommendation for initial therapy is monotherapy or combination therapy of csDMARDs without explicit advice of when to use monotherapy or combination therapy.

Second-Line Therapy

Based on the ACR recommendations, options for those with established disease or those not responding to primary treatment vary depending on previous treatments, disease activity, and poor prognostic factors. Figure 37.2 outlines the specific recommendations based on previous treatments. For many patients, switching or adding a csDMARD is sufficient for second-line therapy. However, for patients with more advanced, symptomatic disease who have already failed combination csDMARD, advancing to a bDMARD may be beneficial. The initial bDMARD recommended by the ACR are TNF inhibitors, abatacept or rituximab.

For those not responding to first-line treatment appropriately, the EULAR outlines second-line treatment based on the presence of poor prognostic factors. For those patients without poor prognostic factors, changing csDMARD strategy is preferred, and for those with poor prognostic factors, adding a bDMARD is preferred. The recommended first-line bDMARDs are TNF inhibitors, abatacept or tocilizumab.

Third-Line Therapy

For patients who have been treated with a bDMARD and have not yet met treatment goals, recommendations include either switching to another agent within the same class or switching to another bDMARD class. Another option recommended by the EULAR

guidelines is initiating tofacitinib after failure of at least one bDMARD.

Special Populations

Geriatric

Caution should be used when starting elderly patients on NSAIDs due to the increased risk of GI hemorrhage. Further, many elderly patients have decreased renal function, and NSAIDs may contribute to a decline in this function. Several DMARDs and some immunomodulators are renally excreted, and doses should be adjusted in the elderly due to decreased renal function.

Women

Women with RA who plan on having children need to discuss treatment options with their physician and understand the risks of conception. Certain medications, including methotrexate, leflunomide, abatacept, and rituximab, cannot be used during pregnancy because of known teratogenicity. DMARDs with the most data to support their use during pregnancy are antimalarials, sulfasalazine, azathioprine, and cyclosporine. These medications can be used as monotherapy or in combination with corticosteroids or NSAIDs. If corticosteroids are used during pregnancy, the dose should not exceed 15 mg/d because higher doses increase the risk of intrauterine infection and premature delivery. NSAIDs should be avoided after 30 weeks of gestation because of the increased risk of premature closure of the ductus arteriosus in the fetus. TNF-alpha inhibitors are all classified as pregnancy category B, indicating there were no teratogenic effects in animals and limited or no data in humans. There have been case reports of congenital malformations in children exposed to TNF-alpha inhibitors as a fetus. Therefore, TNF-alpha inhibitors need to be used cautiously in pregnant women.

Monitoring Patient Response

Because the drugs used for treating arthritis have many adverse events and because most are used for long-term treatment, monitoring should include baseline studies against which later results can be compared. CBC with differential, urinalysis, creatinine, serum bilirubin, liver enzymes, ESR, BUN, platelet studies, and eye examinations are among the tests performed periodically during therapy.

Patients should follow the treat-to-target approach, which requires more intensive follow-up and monitoring. Patients started on DMARD therapy should be assessed at least every 3 months and as soon as 1 month to have disease activity assessed. If goals are not met at 3 months, therapy should be adapted until the goal or remission or low disease activity is met. Once the goal is met, patients can be reassessed every 3 to 6 months to ensure their goals are sustained.

Patient Education

Patient education depends on the type of agent selected. The patient should know that routine blood work is important to detect adverse events before they become serious and life threatening. Patients taking DMARDs and immunomodulators should report illness immediately, as the risk of serious infections is increased in these patients. Patients need to understand that there is a delay between initiating therapy and experiencing the full clinical effects and that therapy must be continued in order to be effective.

Patient-Oriented Information Sources

Support groups, education of family members, and assistive devices can help with activities of daily living. The ACR has patient information available on their Web site regarding a variety of topics such as medications, research, advocacy, and exercise (www.rheumatology.org/Pratice/clinical/patients/information_for_patients). In addition, the Arthritis Foundation has information directed at patients regarding different aspects of living with arthritis (www.arthritis.org). The National Institutes of Health, in conjunction with the American Society of Health-System Pharmacists and the United States Pharmacopeia, has a drug information Web site with information about thousands of medications (http://www.nlm.nih.gov/medlineplus/druginformation.html).

Nutrition/Lifestyle Changes

Weight loss programs and healthy habits such as adequate rest are key to the success of a treatment program. Patients should consider occupational therapy as needed to help with household chores. The patient should avoid repetitive joint motion and vibrations from electrical appliances or tools to reduce exacerbations. Splinting the affected joint helps relieve pain and prevent deformity. Patients should remove the splint at least once daily and for any exercise activities. Patients should be instructed on strategies to avoid physical and emotional stress, which may precipitate an exacerbation.

Complementary and Alternative Medications

Folk remedies have been used for RA for many years. Although most of these remedies cause no harm, there is little scientific evidence supporting their efficacy. Some of the more commonly used approaches include shark cartilage, chondroitin, herbs, vitamins, acupuncture, magnet therapy, climate therapy, and several diets. Clinicians should be aware of the therapies being considered or used by the patient; joint treatment goals should be established and monitored. Just as in traditional medicine, patients using complementary approaches either alone or as adjunctive therapy require ongoing monitoring for safety and efficacy of the selected approach.

A recent review of the literature suggests that gamma linolenic acid (GLA) may have a moderate effect on reducing pain and joint tenderness. This agent is found in borage seed oil (9% GLA), black currant oil (6% GLA), or evening primrose oil (2% GLA). The dose should be about 540 mg/d of GLA.

Case Study*

J.W., a 46-year-old African American woman, presents to your office with the chief complaint of bilateral stiffness of the shoulders, hands, and wrists in the morning. She reports she is otherwise healthy, takes no medications, and is employed as a systems analyst for a large bank. She recalls having some minor flulike symptoms approximately 3 weeks before her visit. The stiffness makes it difficult for her to work for any extended period. She has also started wearing a wig because she cannot raise her arms in the morning to fix her hair. She has lost 10 pounds over the past 8 months but has not consciously dieted. She finds it increasingly difficult to drive, particularly when making turns and driving in reverse.

Pertinent laboratory results:

ESR 89 mm/hr (0 to 29 mm/hr), ACPA 65 EU/mL (less than 20 EU/mL), SCr 1.0 mg/dL

DIAGNOSIS: Rheumatoid Arthritis with moderate disease activity

1. List specific goals of treatment for J.W.
2. Which drug therapy would you prescribe, and why?
3. What are the parameters for monitoring success of the therapy?
4. Discuss specific patient education based on the prescribed therapy.
5. List one or two adverse reactions for the selected agent that would cause you to change therapy?
6. What would be the choice for second-line therapy?
7. What over-the-counter and/or alternative medications would be appropriate for J.W.?
8. What lifestyle changes should be recommended for J. W.?
9. Describe one or two drug–drug or drug–food interactions for the selected agent.* Answers can be found online.

UNIT 9
Pharmacology for Neurological/ Psychological Disorders

38 Headaches

Kelleen N. Flaherty

Headache is one of the most common complaints presenting in primary care. The pain of a headache can range from mild to severe, can be acute or chronic, and may last hours to days in duration. Severe headache and migraine are estimated to afflict one in seven individuals in the United States based on multiple population-wide studies and have a significant impact on quality of life and health care resource utilization (Burch et al., 2015). While there are three main categories of headaches according to the most recent International Classification of Headache Disorders (ICHD-3; Headache Classification Subcommittee of the International Headache Society [IHS], 2013), the most commonly encountered headaches seen in primary care are the primary and secondary headaches (Box 38.1). A primary headache is one with no identifiable underlying organic disease process; a secondary headache is one for which a specific etiology has been identified. The practitioner must first rule out a secondary headache (or more serious cause of headache pain) and then accurately diagnose the type of primary headache. In some instances, a primary and secondary headache can occur simultaneously. Primary headaches include tension-type headache (TTH), migraine, and cluster headache (CH). This chapter will focus on diagnosing and treating TTH and migraine, the most common forms of primary headache presenting in clinical practice.

BOX 38.1 Primary and Secondary Headaches, International Classification of Headache Disorders (ICHD), Third Edition (Beta)

Primary Headaches

- Migraine
- Tension-type headache (TTH)
- Trigeminal autonomic cephalalgias (TACs) (includes CH, paroxysmal hemicranias, short-lasting unilateral neuralgiform headache attacks, hemicranias continua)
- Other primary headache disorders (primary cough headache, primary exercise headache, primary headache associated with sexual activity, primary thunderclap headache, cold-stimulus headache, external pressure headache, primary stabbing headache, nummular headache, hypnic headache, and new daily-persistent headache [NDPH])

Secondary Headaches

- Headache attributed to trauma or injury to the head and/or neck
- Headache attributed to cranial or cervical vascular disorder
- Headache attributed to nonvascular intracranial disorder
- Headache attributed to a substance or its withdrawal
- Headache attributed to infection
- Headache attributed to disorder of homeostasis
- Headache or facial pain attributed to disorder of cranium, neck, eyes, ears, nose, sinuses, teeth, mouth, or other facial or cranial structure
- Headache attributed to psychiatric disorder

Painful Cranial Neuropathies, Other Facial Pains, and Other Headaches

- Cranial neuralgias and central causes of facial pain
- Other headache, cranial neuralgia, central or primary facial pain

Modified from Headache Classification Committee of the International Headache Society (IHS). (2013). The International Classification of Headache Disorders, 3rd ed. (beta version). *Cephalalgia*, 33 (9), 629–808.

Tension headaches have a dull quality, with pain that radiates bilaterally from the forehead to the occiput in a band-like fashion. The pain often radiates down the neck and sometimes even into the trapezius muscle. The pain is mild to moderate and can last from 30 minutes to several days in severe cases. Tension headaches are not typically present upon awakening, but begin later in the day and progress with time. The pain of these headaches is rarely debilitating, but it can affect a person's ability to function, especially if prolonged or chronic. There are no associated symptoms of nausea, vomiting, photophobia, or phonophobia.

Migraine is a neurologic syndrome causing not only throbbing head pain but also often nausea, appetite change, photophobia, and phonophobia. The pain generally ranges from moderate to severe and can be disabling. The Global Burden of Disease Study in 2010 ranked migraine as the third most prevalent and seventh highest specific cause of disability in the world (ICHD-3, 2013). According to epidemiologic studies, migraine occurs in one in seven individuals in the United States and is two to three times more common in females than males. The National Health Interview Survey (2005–2015) estimated a national prevalence of 13.8%, 18.9% in females and 9% in males, with migraine occurring disproportionately higher in at-risk groups such as the unemployed, the uninsured, or those in lower socioeconomic strata (Burch et al., 2015). The age of onset is from 15 to 35, but peak prevalence is from ages 35 to 45. A family history of migraine has shown to be diagnostic in 60% of cases and is considered to be a significant risk factor. Significant comorbidity has also been demonstrated in population studies, including musculoskeletal complaints, cardiovascular disorders, psychiatric disorders, and epilepsy (Merikangas, 2013). Combined direct and indirect costs for migraine are estimated to be $3.2 billion in the United States, plus $700 million for emergency department visits and $375 million for

in-patient treatment (Merikangas, 2013). Decreased productivity is a significant contribution to the indirect cost burden of migraine. Approximately 53% of migraine visits are to primary care offices, with another 16.7% presenting in emergency departments—adding to the financial burden (Burch et al., 2015). It is estimated that half of the individuals suffering from migraine do not report it or seek help for it, and many who do will discontinue treatment (Merikangas, 2013).

CHs may be chronic or acute and episodic and are far less common than migraine or tension headaches, occurring in less than 1% of the population. They are approximately three times more common in males than in females, and the acute/episodic variety is approximately six times more common than chronic CH (Fischera et al., 2008). The pain is disabling, burning, or boring and centered around one eye and is described by patients as being more severe than childbirth or passing a kidney stone. Attacks are unilateral, generally lasting from 15 to 180 minutes, and may occur one to eight times per day. Associated ipsilateral symptoms may include lacrimation, nasal congestion, rhinorrhea, miosis, ptosis, eyelid edema, or conjunctival injection. Restlessness and agitation may also accompany an attack; individuals often cannot lie down and instead pace the floor (ICHD-3, 2013). Significant disability and comorbidity (including cognitive impairment, anxiety, depression, agoraphobia, and even suicidal tendencies) may be associated with CH (Torkamani et al., 2015). A patient with symptoms suggestive of CH should be referred to a neurologist or headache specialist. Episodic CH occurs in a series of repeated headaches, with periods lasting anywhere from 1 week to 1 year, interrupted by periods of pain-free remission. Chronic CH, on the other hand, lasts at least for 1 year without remission, or without at least one full month of remission (ICHD-3, 2013). While the pathophysiology of CH is incompletely understood, hypothalamic dysfunction is believed to be involved; consequently, circadian rhythms are disrupted. CHs often occur at specific times during sleep–wake cycles, another indication of hypothalamic involvement (Francis et al., 2010).

Causes of Tension Headaches

Tension headaches are highly prevalent in the population, with a lifetime prevalence of 30% to 78% demonstrated in a variety of population studies. Prevalence is approximately twice as high in females as it is in males (Haque et al., 2012; ICHD-3, 2013). The high prevalence of TTH results in a more significant and costly socioeconomic burden than that of migraine (Bezov et al., 2010; ICHD-3, 2013). Chronic TTH has a global prevalence of 0.5% to 4.8%. While stress has been shown to be the most common precipitant of TTH, other precipitants have been identified (ICHD-3, 2013; Yu & Han, 2015). Sleep dysregulation has been shown to have a bidirectional relationship with TTH, with lack of sleep being a precipitant of TTH and TTH being a precipitant of insomnia (Rains et al., 2015). Other precipitants reported include sunlight, fatigue, anxiety, temperature (cold and warm), activity, traveling, and reading. Unlike migraine, food does not appear to be a trigger (Haque et al., 2012). Cigarette smoking has also been correlated with an increased number of days of headache per week.

Although more common in migraine patients, one cause of recurrent tension headaches is the overuse of over-the-counter (OTC) and prescription analgesic medications, leading to medication overuse headache (MOH; ICHD-3, 2013). The headache recurs as each dose of medication wears off, causing the patient to take another analgesic and thus continue the cycle of pain. Treating more than two headaches with an OTC analgesic for either migraine or TTH per week can lead to development of chronic daily headache. Other modifiable risk factors include obesity, caffeine overuse, alcohol consumption, and temporomandibular issues. Nonmodifiable risk factors include female gender, genetics, socioeconomic status, head or neck injury, age, and life events (Cho & Chu, 2015; Yu & Han, 2015).

Pathophysiology of Tension Headaches

While TTH was originally assumed to be psychogenic in nature, evidence now suggests that these headaches have neurobiologic etiologies (ICHD-3, 2013) and may be a consequence of both centrally (chronic) and peripherally (episodic) processed pain. Central pain processing may result in increased tenderness and lower pain thresholds in pericranial and myofascial muscles. There may also be genetic, comorbid (e.g., chronic pain, depression, etc.), vitamin D deficiency, and vascular components to TTH. Other research has implicated nitric oxide (a vasodilator) as a local mediator of TTH. In one study, blocking nitric oxide production led to decreased pericranial muscle hardness and headache pain in patients with chronic TTH (Ashina et al., 1999).

Diagnostic Criteria

The first step in determining the type of headache a patient has is to take a detailed headache history. The history should include the patient's age; the time of day when the attack(s) occur(s); the duration and frequency of attacks; precipitating or relieving factors; the quality, location, and intensity of the pain; use of OTC analgesics; and associated symptoms. The social history and family history are also important. The results of physical and neurologic examinations should be unremarkable in a patient with primary headache, other than revealing possible tenderness of pericranial muscles. Diagnosis is mostly of exclusion: all possible secondary headaches, migraine headache, and CHs are ruled out. Tension headaches may be diagnosed as primary, secondary, or both. The Headache Classification Committee of the International Headache Society characterizes TTH by "frequent episodes of headache, typically bilateral, pressing or tightening in quality and of mild to moderate intensity, lasting minutes to days. The pain does not worsen with routine physical activity and is not associated with nausea, but photophobia or phonophobia may be present (ICHD-3, 2013)."

Diagnostic alarms in the evaluation of a headache patient that require further testing include headache onset after age 50, sudden-onset headache, accelerating headache pattern, headache with fever and stiff neck, and abnormal results on the neurologic examination. With regard to other types of diagnostic testing, the American Headache Society's (AHS) "Choosing Wisely" recommendations counsel against the use of neuroimaging studies in patients with stable headaches that meet criteria for migraine and against the use of CT imaging for headache when MRI is available, except in the emergency setting (Loder et al., 2013). The ICHD-3 diagnostic criteria for frequent episodic tension headache can be seen in Box 38.2.

BOX 38.2 Diagnostic Criteria for Frequent Episodic Tension Headache, International Classification of Headache Disorders (ICHD), Third Edition (Beta)

A. At least 10 episodes of headache occurring on 1 to 14 days per month on average for >3 months (≥12 and <180 days per year) and fulfilling criteria B–D

B. Lasting from 30 minutes to 7 days

C. At least two of the following four characteristics:

1. Bilateral location
2. Pressing or tightening (nonpulsating) quality
3. Mild or moderate intensity

4. Not aggravated by routine physical activity such as walking or climbing stairs

D. Both of the following:

1. No nausea or vomiting
2. No more than one of photophobia or phonophobia

E. Not better accounted for by another ICHD-3 diagnosis

Initiating Drug Therapy for Tension Headaches

Before initiating drug therapy, it is critical to determine the type and frequency of OTC medication use. Patients with tension headaches and headaches in general frequently self-medicate and may be presenting with MOH. Again, treating more than two headaches per week for more than a few consecutive weeks can lead to development of a chronic daily headache pattern. Caffeine and butalbital products are notorious contributors to MOH. The initial treatment of MOH consists of withholding all OTC analgesics for 1 to 2 weeks.

It is also important to help identify headache triggers and to encourage a healthy lifestyle. Often, simple changes, such as eating and sleeping in a consistent pattern, decreasing alcohol and tobacco use, and using good posture, can decrease headache severity and frequency.

Adjuncts to pharmacotherapy include relaxation therapy, biofeedback, self-hypnosis, cognitive therapy, and manual therapy (massage). Data from a large meta-analysis show positive results with the use of biofeedback, particularly when combined with relaxation (Nestoriuc et al., 2008). Patients may also benefit from acupuncture or cervical physical therapy in the case of chronic tension headaches.

Headache sufferers (TTH and migraine) use a substantial amount of complementary and alternative medicine (CAM) for the self-management of headache. The alternative approaches include acupuncture, chiropractic, massage, yoga, homeopathy, and use of dietary supplements such as herbal compounds and vitamins. In one large literature review, some 30% to 70% of CAM users report the therapy to be effective. Most practitioners use CAM as adjunctive therapy to pharmacotherapy, rather than prior to or after treatment with medications. While there have been some studies on the efficacy of CAM, they are methodologically weak. Further, many patients are using CAM therapies concomitantly with conventional treatment and may not report its use to the health care practitioner. Health care practitioners should be vigilant and inquire about CAM use, to anticipate and avoid any potential adverse reactions (Adams et al., 2012).

Goals of Drug Therapy for Tension Headaches

The primary goals of drug therapy should be to reduce the severity and frequency of headaches, thus improving the patient's quality of life and ability to function. The goals for patients with episodic tension headaches are to select appropriate analgesic agents that will have the fewest side effects. Prophylactic therapy should be considered in addition to abortive analgesic agents for patients with more than two significant headaches per week. In a patient with MOH, it is appropriate to start a prophylactic agent and abruptly stop abortive analgesic medications simultaneously (other than barbiturate drugs, which must be tapered). It is important to educate patients about MOH and to limit the use of analgesics to 2 days per week. Again, regular and frequent treatment with analgesics may cause development of chronic headache. It is important that patients do not overuse analgesics, as this is likely to interfere with the efficacy of preventive treatment (ICHD-3, 2013).

Acetaminophen and Aspirin

Acetaminophen at a dose of 1,000 mg can be very effective in treating mild to moderate tension headaches, although given the hepatotoxic qualities of the drug, a U.S. Food and Drug Administration (FDA) advisory committee in 2009 voted to lower the recommended single dose to 650 mg (making 1,000-mg tablets available by prescription only) and to lower the maximum daily limit from its presently recommended 4,000 to 3,250 mg (Schilling et al., 2010). Consequently, in 2011, McNeill Consumer Healthcare lowered the maximum recommended dose of Tylenol and increased the dosing interval for some of their OTC medications (DIH, 2014). Injectable acetaminophen carries a black box warning as of 2013 for potential liver failure, transplant, and death (DIH, 2014). The advantages of acetaminophen are that it is well tolerated and has few drug–drug interactions and side effects. Acetaminophen should be avoided in patients with heavy alcohol consumption, alcoholic liver disease, or chronic liver disease, as the drug is metabolized through the liver. Consumption of three or more alcoholic drinks a day in conjunction with acetaminophen use can have hepatotoxic effects. Chronic use of acetaminophen or use of acetaminophen at high doses can cause liver damage, particularly in older persons; the leading cause of acute liver failure in the United States is acetaminophen overdose (and the leading drug overdose seen in emergency departments is with acetaminophen). Acetaminophen overdose is often accidental; patients need to be cautioned not to exceed 4,000 mg/d and to take care not to take other acetaminophen-containing medications in the same day (Schilling et al., 2010). Prolonged use of acetaminophen and aspirin or nonsteroidal anti-inflammatory drugs (NSAIDs) should be avoided.

Aspirin can also alleviate mild to moderate tension headaches. It inhibits prostaglandin synthesis via nonspecific and irreversible deactivation of both cyclooxygenase 1 (COX-1) and cyclooxygenase 2 (COX-2), reducing the inflammatory response and platelet aggregation. Contraindications to aspirin use include a history of bleeding disorders, asthma, and hypersensitivity to salicylates or NSAIDs. Patients should avoid combining aspirin with other NSAIDs because decreased serum concentrations of NSAIDs result when these drugs are used together. The most common adverse effects associated with aspirin are gastrointestinal in nature, such as nausea, vomiting, or heartburn. Aspirin has also been recommended as first-line treatment for TTH and migraine, regardless of headache severity (Lampl et al., 2012).

Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

NSAIDs work well for moderate tension headaches. They work by selectively inhibiting COX-2, responsible for prostaglandin synthesis, thereby reducing inflammation. These drugs take effect in 30 to 60 minutes, similar to aspirin and acetaminophen. Commonly used NSAIDs for the management of TTH include ibuprofen, naproxen, ketoprofen, diclofenac, and indomethacin.

Common side effects of NSAIDs are abdominal cramps, nausea, indigestion, and even headache. Occasionally, these drugs cause peptic ulcers and GI hemorrhage. Many NSAIDs contain boxed warnings about cardiovascular effects, GI effects, and/or use in patients with renal impairment. COX-2-specific inhibitors are not indicated specifically for headache, but are indicated for acute pain and have shown efficacy in stabbing headache (Ferrante et al., 2010) and migraine (Wentz et al., 2008). Its specificity for COX-2 tends to decrease GI effects, but COX-2 inhibitors also carry black box warnings, particularly for cardiovascular events.

Any given NSAID should be tried in a patient twice before deciding whether it is successful or not. It is not uncommon for a patient to respond poorly to one NSAID and extremely well to another. Route of administration may also be a consideration to improve NSAID response (Barbanti et al., 2014).

Antiemetic Agents

Although patients with tension headaches rarely suffer from nausea, antiemetic agents can augment the pain-relieving properties of analgesics by decreasing gastric emptying, therefore improving analgesic absorption (Barbanti et al., 2014). Commonly used antiemetics are promethazine and prochlorperazine. These medications can be sedating and have numerous other potential side effects, including rare but serious neurologic and bone marrow effects. Promethazine carries a boxed warning for use in children 2 years old and younger and for its injectable formulation. Prochlorperazine carries a boxed warning for use in older patients with dementia-related psychosis who are being treated with antipsychotics (DIH, 2014). Patients should be educated about these possible effects before starting on these medications and should be encouraged to use them sparingly.

Other Abortive Agents

For patients whose headaches do not respond to the above agents, certain combination agents can be considered. Some patients have a good response to OTC agents containing acetaminophen, aspirin, and caffeine (such as Excedrin Extra Strength). However, these agents have a high rate of analgesic MOH when used regularly and should not be used more than 1 to 2 days per week.

Prescription combinations that can be used include butalbital/acetaminophen/caffeine (Fioricet and others) and butalbital/aspirin/caffeine (Fiorinal and others). Butalbital is a barbiturate, which is sedating and potentially habit forming; these medications should not be used in patients with a history of substance abuse. Fiorinal and Fioricet very commonly cause MOH and should not be used for more than 3 days per month. If a patient is taking many butalbital-containing pills per day, they must be slowly tapered to avoid withdrawal symptoms. Patients taking these medications should be closely monitored.

Combination acetaminophen/narcotic products such as Vicodin and Percocet are not recommended; FDA has recommended their removal from the market or an inclusion of a black box warning if the drugs remain on the market (FDA, 2009). Opioid- or butalbital-containing medications should not be prescribed as first-line treatment for recurrent headache disorders (Loder et al., 2013). Table 38.1 gives an overview of selected drugs used to abort TTH.

TABLE 38.1 Overview of Selected Drugs to Abort Tension-Type Headaches

Generic (Brand) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
acetaminophen (Tylenol) 325–650 mg q4h–6h limit dose to 3,250 mg/d	Severe hepatotoxicity on acute overdose, potential liver damage w/ chronic daily dosing, nephrotoxicity, agranulocytosis, rash (including potentially fatal Stevens-Johnson syndrome)	Chronic alcohol use, alcoholic liver disease, impaired liver or renal function, G6PD deficiency	Avoid using w/ alcohol
aspirin 325–650 mg q4h–6h, not to exceed 4,000 mg/d	GI upset (stomach pain, nausea, heartburn, vomiting); GI bleeding and angioedema (uncommon)	Platelet or bleeding disorders, renal dysfunction, erosive gastritis, peptic ulcer disease, asthma, rhinitis, nasal polyps, severe hepatic or renal failure, or sensitivity to salicylates	Avoid using w/ NSAIDs, alcohol, during pregnancy, and in children <16 y with viral infections; discontinue 1–2 wk prior to surgery
NSAIDs			
ibuprofen (Advil) 200–400 mg q4h–6h, not to exceed 1,200 mg/d; under clinical supervision not to exceed ≤2,400 mg/d *Note*: Use lower doses in patients w/ renal or hepatic disease	3%–9%: Dizziness, rash, epigastric pain, heartburn, nausea, tinnitus	**WARNING: NSAIDs are associated with an increased risk of adverse cardiovascular thrombotic events, including MI, stroke, and new onset or worsening of pre-existing hypertension. Use is contraindicated for treatment of perioperative pain in the setting of CABG surgery.** Recent GI bleed, third trimester of pregnancy, renal disease	Use w/ caution if history of CHF, HTN, GI bleeding; monitor for anemia w/ long-term use; older persons are at increased risk for AEs even at low doses; withhold for at least 4–6 half-lives prior to dental or surgical procedures; may increase risk of GI irritation, inflammation, ulceration, bleeding, and perforation
Generic (Brand) Name and Dosage	**Selected Adverse Events**	**Contraindications**	**Special Considerations**
naproxen (Aleve) Initial: 500 mg, then 250 mg q6h–8h not to exceed 1,250 mg/d *Note*: Enteric-coated formulations not recommended for tx of acute migraine	3%–9%: Edema, dizziness, drowsiness, headache, pruritus, skin eruption, ecchymosis, fluid retention, abdominal pain, constipation, nausea, heartburn, hemolysis, tinnitus, dyspnea	Same as above, including **BOXED WARNING**	Same as above
ketoprofen 25–50 mg q6h–8h	>10%: Dyspepsia, abnormal LFTs; 3%–9%: Headache, abdominal pain, constipation, diarrhea, flatulence, nausea, renal dysfunction	Same as above, including **BOXED WARNING**	Same as above
Barbiturates			
butalbital 50 mg, caffeine 40 mg, acetaminophen 325 mg (Fioricet) 1–2 tabs q4h, not to exceed 6 tabs/d *Note*: Do not use butalbital for the management of acute migraine	Drowsiness, light-headedness, dizziness, sedation, shortness of breath, nausea, vomiting, abdominal pain, intoxicated feeling	Hepatic or renal dysfunction, peptic ulcer disease, history of substance abuse, porphyria, pregnancy, concomitant use w/ alcohol or other CNS depressants	Contains acetaminophen; use w/ caution when taking other acetaminophen-containing drugs; do not exceed a total daily dose of 3,250 mg acetaminophen; may be habit forming or subject to abuse; avoid prolonged use or using w/ other sedating medications; not recommended for use in older persons
butalbital 50 mg/caffeine 40 mg/aspirin 325 mg (Fiorinal) 1–2 tabs q4h, not to exceed 6 tabs/d *Note*: Do not use butalbital for management of acute migraine	Same as above	Hemorrhagic diathesis (e.g., hemophilia, hypoprothrombinemia, von Willebrand disease, thrombocytopenias, thrombasthenia and other ill-defined hereditary platelet dysfunctions, severe vitamin K deficiency, and severe liver damage); nasal polyps, angioedema and bronchospastic reactivity to aspirin or other NSAIDs; peptic ulcer or other serious GI lesions; porphyria	Use w/ caution in the debilitated; severe impairment of renal or hepatic function, coagulation disorders, head injuries, elevated intracranial pressure, acute abdominal conditions, hypothyroidism, urethral stricture, Addison's disease, or prostatic hypertrophy; not recommended for use in older persons

Prophylaxis of Tension Headaches

If a patient has more than two tension headaches per week, prophylaxis should be considered. Antidepressant medications are commonly used for headache prophylaxis. In meta-analyses, individuals with chronic headache taking antidepressants are twice as likely to report improvement of symptoms (Dharmshaktu et al., 2012). Abundant evidence exists for the efficacy of amitriptyline, with individuals experiencing relief even at low doses. Its antinociceptive effects are independent from its antidepressant effects (Yu & Han, 2015). There are data supporting the use of venlafaxine and mirtazapine, but data supporting the use of other antidepressants for headache prophylaxis (including migraine) are lacking. Smaller noncontrolled trials or case studies have shown efficacy with other tricyclic antidepressants (TCAs), such as imipramine, doxepin, and protriptyline. While there have been trials conducted on the efficacy of fluoxetine as headache prophylaxis, neither it nor the other selective serotonin reuptake inhibitors (SSRIs) have been shown to be effective as headache prophylaxis despite having a more favorable side effect profile compared with TCAs. Other antidepressants, such as monoamine oxidase inhibitors (MAOIs) and serotonin antagonists, have been studied, but safety issues and side effect profiles make them an inappropriate choice for headache prophylaxis. Antidepressants for which little support exists for the management of headache should only be considered if the headache being treated is comorbid with depression. Alleviation or palliation of one comorbidity, however, will not necessarily resolve the other (Smitherman et al., 2011). Prophylactic medications should be started at low dosages and increased slowly. It can take 4 to 8 weeks before the full effect of these medications is seen. Finding the appropriate prophylactic agent for a patient is a process of trial and error, as medications work differently in different patients.

Amitriptyline, a TCA, is the medication most commonly used to prevent tension headaches and considered to be a first-line, gold standard drug. It can be used in doses much lower than those used for treating depression, ranging from 10 to 75 mg. Common side effects include sedation, constipation, blurred vision, and dry mouth. Amitriptyline should be used with caution in patients with a history of coronary artery disease, urinary retention, glaucoma, and seizures. Usually, only low doses of amitriptyline are needed, making discontinuation because of side effects uncommon. Higher doses of amitriptyline are typically used in headache patients with concomitant depression (Smitherman et al., 2011). Given its anticholinergic properties, amitriptyline is an inappropriate choice for use in older patients.

Second-line drugs that have been determined to be effective include venlafaxine (Effexor, a serotonin/norepinephrine reuptake inhibitor or SNRI) and mirtazapine (Remeron, a tetracyclic antidepressant) at 150 and 30 mg, respectively (Barbanti et al., 2014; Bendston & Jensen, 2011).

These drugs may also concurrently treat depression and anxiety. Common side effects

of venlafaxine include nausea, somnolence, and insomnia, which often diminish after a few weeks. Patients may also experience sexual dysfunction, increased sweating, or nervousness, which may or may not diminish with time. Venlafaxine can also interact with many medications and should be tapered upon discontinuation, as withdrawal symptoms may occur with abrupt discontinuation. Mirtazapine has been used for its analgesic properties in chronic headache and has the added benefit of sometimes controlling nausea (Smith, 2015). An additional caution when considering the use of any antidepressant is that of suicidal ideation, particularly in adolescents. In 2007, the FDA required black box warnings in all antidepressant-prescribing information "…about increased risks of suicidal thinking and behavior, known as suicidality, in young adults ages 18 to 24 during initial treatment (generally the first 1 to 2 months)" (FDA, 2007).

Recently, data have emerged on the use of local anesthetics injected into pericranial myofascial trigger points. Lidocaine and bupivacaine are the most commonly used, with the most commonly injected muscles being the trapezius, sternocleidomastoid, and temporalis. While there aren't many data on this approach, some studies have shown substantial efficacy in headache prophylaxis. Contraindications include pregnancy, infection, open skull defect, or any condition in which injection landmarks become difficult to identify (e.g., obesity). Adverse events are typically mild (associated with injection in general), and severe adverse events are rare (but have been reported, e.g., pneumothorax; Robbins et al., 2014). Table 38.2 lists prophylactic agents for TTH.

TABLE 38.2 Overview of Selected Drugs Used to Prevent Tension-Type Headaches

Generic (Brand) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
amitriptyline (Elavil) Initial: 10–25 mg qhs, usual dose 150 mg qhs; reported dosing ranges 10–400 mg/d (higher doses in patients w/ concomitant depression)	Degree of anticholinergic effects (urinary retention, dry mouth, constipation) are higher in amitriptyline than in other TCAs; drowsiness/sedation (sometimes significant), orthostasis, conduction abnormalities	**WARNING: Antidepressants increase the risk of suicidal thinking and behavior in children, adolescents, and young adults (ages 18–24) with major depressive disorder and other psychiatric disorders.** Not FDA approved for children < age 12	Most widely used; use w/ caution in patients w/ history of CVD (stroke, MI, tachycardia, or conduction abnormalities); use w/ caution in patients w/ BPH, glaucoma, urinary retention, xerostomia, visual problems, constipation, or history of bowel obstruction; use w/ caution in patients with diabetes, seizures, hyperthyroidism (or thyroid supplementation), or hepatic or renal dysfunction; effects may be intensified by use of other CNS drugs or alcohol; use w/ caution in older persons
venlafaxine XR (Effexor XR) 150 mg/d; taper discontinuation to obviate discontinuation syndrome	>10%: Nausea, somnolence, insomnia (often diminish after a few weeks); sexual dysfunction, increased sweating, nervousness (may or may not diminish with time)	**WARNING: Antidepressants increase the risk of suicidal thinking and behavior in children, adolescents, and young adults (18–24 y of age) with major depressive disorder (MDD) and other psychiatric disorders.** Not FDA approved for use in children; monitor for serotonin syndrome, tachycardia, hypertension, and bleeding	Often used because it usually has fewer side effects than amitriptyline; use with caution in older persons
mirtazapine (Remeron) 15–30 mg/d; taper discontinuation to obviate discontinuation syndrome	>10%: Somnolence, increased cholesterol, xerostomia, increased appetite, constipation, weight gain	**WARNING: Antidepressants increase the risk of suicidal thinking and behavior in children, adolescents, and young adults (18–24 y of age) with major depressive disorder (MDD) and other psychiatric disorders.** Not FDA approved for use in children; monitor for serotonin syndrome	Use w/ caution in seizure disorders or in patients predisposed to seizure (e.g., brain damage, alcoholism, concomitant use with drugs that lower seizure threshold), hepatic or renal dysfunction, and in older persons; may actually help with nausea

First-Line Therapy for Tension Headaches

Aspirin and acetaminophen are appropriate first-line agents. They should be used no more than 2 days per week, as with any other analgesic agent, to avoid MOH. Acetaminophen should be used at a maximum single dose of 650 mg and a maximum daily dose of 3,250 mg. If used judiciously, these agents have few adverse effects and are very well tolerated. They work best for mild to moderate headaches. Again, the AHS's "Choosing Wisely" guideline specifically counsels against the use of opioid- or butalbital-containing analgesics as first-line therapy (Loder et al., 2013).

Second-Line Therapy for Tension Headaches

NSAIDs are the next option for treatment of TTH. If one agent fails for two consecutive

headaches, another agent in this class should be tried. NSAIDs seem to work well for more stubborn TTHs. If they provide incomplete relief, an antiemetic agent may be added to augment their effect.

Caffeine-containing analgesics available OTC such as Excedrin Extra Strength can also be an effective treatment. These medications should be used infrequently to obviate MOH and may be alternated with NSAIDs for different headaches.

Third-Line Therapy for Tension Headaches

If the above agents fail, then butalbital-containing compounds (Fioricet or Fiorinal) may be used in patients without specific risk factors for these medications. These agents may also be reserved as backup if the abovementioned agents fail to relieve a more severe TTH. Again, butalbital-containing agents should never be used more than 3 days per month, as they easily trigger MOH. As mentioned earlier, any patient requiring treatment for two or more headaches per week or who has particularly severe TTH should be considered for a prophylactic agent.

Causes of Migraine Headache

The ICHD-3 beta characterizes migraine headaches as a "recurrent headache disorder manifesting in attacks lasting 4 to 72 hours. Typical characteristics of the headache are unilateral location, pulsating quality, moderate or severe intensity, aggravation by routine physical activity and association with nausea and/or photophobia and phonophobia (ICHD-3, 2013)." Why some patients experience migraines while others do not is unknown, but it is clear that there is a genetic component to migraines and that migraines tend to cluster in families (Cho & Chu, 2015). There are many possible migraine triggers, and each patient's triggers are unique. Triggers range from certain foods to too much or too little sleep to medications to hormonal factors and others. In some patients, no obvious triggers are found. Estrogen is thought to play a role in the development of migraines, which explains the predominance of migraines in females. About 25% of migraine attacks occur within 4 days of menses, when estrogen has fallen to a low level. The best way to pinpoint triggers is to have the patient keep a diary of what he or she ate and did in the 12 hours before getting the headache to see if any patterns emerge. A large literature review covering 15 studies evaluating triggers (in males and females, with either spontaneous reporting of triggers or selection from a list) identified a large variety of triggers experienced by individuals reporting them anywhere from 8% of the time to 90% of the time. Some triggers are nonmodifiable (e.g., menstruation, gender, age, etc.), while others are modifiable (e.g., sleep deprivation) (Cho & Chu, 2015; Lipton et al., 2014; Pavlovic et al., 2014). Box 38.3 lists migraine triggers.

BOX 38.3 Factors That May Trigger Migraine Headaches

Psychological factors

Anxiety
Depression
Stress (and relaxation after stress, or the "letdown" hypothesis)
Intense emotion
Crisis; postcrisis letdown

Medications

Vasodilators (e.g., blood pressure medications, medications for erectile dysfunction)
Hormones (contraceptives, hormone replacement therapy)
Caffeine
Vitamins

Dietary factors

Alcohol
Aspartame
Caffeine
Chocolate
Monosodium glutamate
Tyramine-containing foods (e.g., red wine)
"Certain foods" (patient-specific reports)

Environmental/mechanical factors

Head movements
Bright, flashing lights, glare, or sunlight; photophobia
High altitude
Loud noises; phonophobia
Strong odors, perfume
Tobacco smoke (smoking or passive smoking); nicotine
Weather changes (hot or cold)

Lifestyle factors

Dieting, skipping meals or fasting; hunger
Obesity
Strenuous exercise/physical effort
Sleep problems: too much or too little sleep, insomnia, bruxism, snoring, daytime sleepiness
Fatigue
Smoking
Excessive alcohol consumption

Hormonal factors

Ovulation
Menopause
Menses
Pregnancy

Pathophysiology of Migraine Headaches

The pathophysiology of migraine is incompletely understood. Studies have shown an interaction of a large number of factors that result in the phenomenon, including genetics, afferent pain processing, anatomy and physiology of the trigeminal system, modulatory influence on trigeminal pain transmission, and various pain processing phenomena (Goadsby, 2012). While previously believed to be vasculogenic in nature ("a good story ruined by the facts," as Goadsby says), neurogenic mechanisms are now recognized as the underlying cause of migraine pathophysiology, including atypical pain processing, central sensitization, hyperexcitability in the cortex, and inflammation (Schwedt, 2014). Recurring migraine may serve to sensitize the trigeminal system, lowering pain thresholds, and possibly contributing to chronic migraine. A network of primarily unmyelinated nerve fibers largely arising from the ophthalmic branch of the trigeminal nerve surrounds large cranial blood vessels, blood sinuses, the pia, and the dura in close proximity. The trigeminovascular system is an initiator and promoter of tissue inflammation and, when activated, releases neuropeptides such as substance P and calcitonin gene–related peptide that cause vasodilation and inflammation. Stimulation of these vessels and sinuses has been shown to be quite painful. Noradrenergic (from the locus caeruleus) and, more significantly, serotonergic neurons (from the dorsal raphe) regulate this activity; the periaqueductal gray region also contributes to pain modulation. Once triggered, impulses travel out through cranial nerve V and ultimately result in dilated meningeal blood vessels and release of neuroinflammatory and nociceptive compounds (Goadsby, 2012; Schwedt, 2014).

Some 80% of migraineurs report premonitory symptoms (e.g., nausea, bloating, fatigue, stiff neck, etc.) prior to the development of aura. Approximately 30% of migraines are accompanied by a prodromal aura, a focal neurologic phenomenon associated variously with visual, sensory, or motor symptoms, but typically affecting the visual field in a spreading fashion, traveling at approximately 3 mm/min from central to peripheral vision. Aura is not typically associated with pain (Charles, 2013; Goadsby, 2012).

In summary, migraine is a heritable disorder of episodic sensory sensitivity, associated with acute, throbbing pain and enhanced sensitivity to light, motion, sound, and odors. Migraine can be accompanied by nausea and unsteadiness. In different migraineurs, migraines can occur more or less frequently and vary in duration.

Diagnostic Criteria for Migraine Headache

The first step in making a precise diagnosis of migraine is to obtain a thorough headache history. Evaluation of the history should include age at onset; time of day when attacks occur; duration of attacks; precipitating or relieving factors; nature, intensity, and location of headache pain; and any associated symptoms. The patient should also be questioned about any aura symptoms, such as visual symptoms (flashing lights, loss of peripheral vision, diplopia, etc.) or other sensory symptoms (vertigo, tinnitus, paresthesias, or hemiparesis). Having patients keep a migraine diary helps identify triggers and premonitory symptoms. Because a family history is evident in many patients, asking if anyone in the family experiences migraines aids in the diagnosis. Note that some patients may fulfill criteria for both migraine with aura and migraine without aura (ICHD-3, 2013). Specific diagnostic criteria for migraine with aura (classic migraine) and without aura (common migraine) are given in Box 38.4.

BOX 38.4 Diagnostic Criteria for Migraine, International Classification of Headache Disorders (ICHD), Third Edition (Beta)

Migraine without aura

A. At least five attacks fulfilling criteria B–D
B. Headache attacks lasting 4 to 72 hours (untreated or unsuccessfully treated)
C. Headache has at least two of the following four characteristics:
   1. Unilateral location
   2. Pulsating quality
   3. Moderate or severe pain intensity
   4. Aggravation by or causing avoidance of routine physical activity (e.g., walking or climbing stairs)
D. During headache, at least one of the following:
   1. Nausea and/or vomiting
   2. Photophobia and phonophobia
E. Not better accounted for by another ICHD-3 diagnosis

Migraine with aura

A. At least two attacks fulfilling criteria B and C
B. One or more of the following fully reversible aura symptoms:
   1. Visual
   2. Sensory
   3. Speech and/or language

4. Motor
5. Brain stem
6. Retinal

C. At least two of the following four characteristics:
1. At least one aura symptom spreads gradually over ≥5 minutes, and/or two more symptoms occur in succession
2. Each individual aura symptom lasts 5 to 60 minutes
3. At least one aura symptom is unilateral
4. The aura is accompanied, or followed within 60 minutes, by headache

D. Not better accounted for by another ICHD-3 diagnosis, and transient ischemic attack has been excluded

Modified from Headache Classification Subcommittee of the International Headache Society. (2013). The International Classification of Headache Disorders, 3rd ed. (beta version). *Cephalalgia*, 33 (9), 629–808.

Patients most frequently experience migraines in the early morning, but a migraine attack can come at any time of the day. Migraines are more often unilateral than bilateral, with the pain occurring around the eye or the temple. Migraine pain generally peaks 2 to 12 hours into the attack. Common symptoms accompanying migraine include nausea, anxiety, depression, irritability, fatigue, light and noise sensitivity, diarrhea or constipation, and hunger or anorexia. Patients may describe the pain of migraine as pounding, pulsating, or throbbing. A migraine sufferer often seeks refuge in a dark, quiet place.

Initiating Drug Therapy for Migraine Headaches

Practitioners must consider many factors when designing a treatment regimen for patients with migraine, such as the severity of the pain, duration of attack, concomitant disease states, current medication use, and any triggers. Migraine treatment needs to be highly individualized. Table 38.3 gives an overview of selected drugs used for abortive treatment of migraine headaches.

TABLE 38.3 Overview of Selected Drugs for Acute/Abortive Migraine Treatment

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
aspirin 325–900 mg q4h–6h, not to exceed 4,000 mg/d	GI upset (stomach pain, nausea, heartburn, vomiting), GI bleeding and angioedema (uncommon)	Platelet or bleeding disorders, renal dysfunction, erosive gastritis, peptic ulcer disease, asthma, rhinitis, nasal polyps, severe hepatic or renal failure, or sensitivity to salicylates	Avoid using w/ NSAIDs, alcohol; during pregnancy, and in children < 16 y with viral infections; discontinue 1–2 wk prior to surgery
NSAIDs			
See **Table 38.1**.	See **Table 38.1**.	See **Table 38.1**, including: **BOXED WARNING:**	See **Table 38.1**.
OTC caffeine-containing compounds (Excedrin Extra Strength or Excedrin Migraine, acetaminophen 250 mg/aspirin 250 mg/caffeine 65 mg) 1–2 tabs q24h; do not use for longer than 48 h.	Insomnia, agitation	Uncontrolled HTN	Avoid use with other vasoconstrictive agents; use sparingly to obviate MOH
Triptans			
sumatriptan (Imitrex and Alsuma) 25, 50,100 mg PO at headache onset, may repeat dose up to 100 mg in 2 h 6 mg subcutaneous, may repeat dose in 2 h 5 or 20 mg intranasal spray; may repeat dose in 2 h Zembrace SymTouch 3 mg intranasal; may repeat dose in 2 h	PO: 3%–>10%: Malaise/fatigue, jaw pain/tightness/pressure, paresthesia, pressure/tightness/heaviness, warm/cold sensation SC: >10%: Dizziness, warm/hot sensation, pain at injection site, paresthesia; 3%–10%: chest pain/tightness/heaviness/pressure, burning, feeling of heaviness, flushing, pressure sensation, feeling of tightness, drowsiness, neck, throat, and jaw pain/tightness/pressure, mouth/tongue discomfort, weakness, numbness, throat discomfort IN powder: >2%: Abnormal taste, nasal discomfort, rhinorrhea, and rhinitis IN: >10%: Bad taste, nausea, vomiting; 5%–10%: nasal discomfort/disorder	Pregnancy, uncontrolled HTN, ischemic heart disease, stroke, TIA, PVD, severe hepatic impairment, basilar or hemiplegic migraine; use within 24 h of use of ergot derivatives, or within 2 wk of (or concomitant) use of MAOIs; do not use as prophylactic treatment for migraine; not for IV use ZOMIG contraindications are: ischemic coronary artery disease (CAD) or coronary artery vasospasm, including Prinzmetal's angina; or Wolff-Parkinson-White syndrome or arrhythmias associated with other cardiac accessory conduction pathway disorders History of stroke, transient ischemic attack (TIA), or hemiplegic or basilar migraine; peripheral vascular disease; ischemic bowel disease; or uncontrolled hypertension Recent (i.e., within 24 hours) use of ergotamine-containing or ergot-type medication, or another 5-HT1 agonist; or concurrent or recent (within 2 weeks) use of a MAO-A inhibitor Known hypersensitivity to sumatriptan (angioedema and anaphylaxis seen) or severe hepatic impairment	Use w/ caution in history of CAD, HTN, seizure disorder (or low seizure threshold), or hepatic impairment; use caution with concomitant use of other serotonergic drugs (SSRIs, SNRIs, other triptans) or presorotonergic drugs (e.g., tryptophan); use at lowest possible doses ZOMETRA may cause: Myocardial ischemia/infarction, Prinzmetal's angina, arrhythmias; Sensations of chest/throat/neck/jaw pain, tightness, pressure, or heaviness, cerebral hemorrhage, subarachnoid hemorrhage, and stroke, other vasospasm reactions, MOH, serotonin syndrome, increased BP, anaphylaxis, and seizures (use with caution in epilepsy or lowered seizure threshold)
Generic (Trade) Name and Dosage	**Selected Adverse Events**	**Contraindications**	**Special Considerations**
zolmitriptan (Zomig) Tablet: 2.5 mg at onset Orally disintegrating tablet: 2.5 mg at onset Nasal spray: 1 spray (5 mg) at onset	PO: 3%–10%: Chest pain, dizziness, somnolence, pain, nausea, xerostomia, dyspepsia, paresthesia, weakness, warm/cold sensation, neck/throat/jaw pain, diaphoresis	Pregnancy, ischemic heart disease or vasospastic CAD, uncontrolled HTN, symptomatic Wolff-Parkinson-White syndrome or other arrhythmias associated w/ accessory cardiac conduction pathway disorders; do not use within 24 h of (or concomitant with) use of another 5HT, agonist, or use within 2 wk of (or concomitant with) use of MAOIs; do not use with w/ ergot derivatives or sibutramine; do not use for management of basilar or hemiplegic migraine; additional contraindications for IN use: stroke, TIA, PVD	High risk factors for heart disease (HTN, high cholesterol, obesity, diabetes, smoking, strong family history of heart disease, post-menopausal women, and males > 40 y old)
naratriptan (Amerge) 2.5 mg q4h to max of 5 mg/d	1%–10%: Dizziness, drowsiness, malaise/fatigue, nausea, vomiting, paresthesia, pain/pressure in throat or neck	Pregnancy, uncontrolled HTN, ischemic heart disease, PVD, severe hepatic or renal impairment; do not use within 24 h of (or concomitant) use of ergot derivatives or sibutramine (no longer available in the United States); do not use for treatment of basilar or hemiplegic migraine	Use w/ caution in patients w/ risk factors for CAD, smoking, cerebral/subarachnoid hemorrhage, stroke, peripheral vascular ischemia, and history of HTN; not recommended for use in older persons; use lowest possible dose
rizatriptan (Maxalt oral tablet and Maxalt-MLT, orally disintegrating tablet) Tablet: 5–10 mg q2h to max of 30 mg/d (patients taking concomitant propranolol: max of 15 mg/d) Orally disintegrating tablet: 5–10 mg q2h to max of 30 mg (patients taking concomitant propranolol: max of 15 mg/d) *Note:* Patients w/ cardiac risks should be administered first dose in the physician's office under observation	>10%: Dizziness, drowsiness, fatigue (dose dependent); 1%–10%: Increase in BP, chest pain, palpitations, flushing, mild increases in GH, hot flashes, abdominal pain, xerostomia, nausea, dyspnea	Documented ischemic heart disease or Prinzmetal angina or uncontrolled HTN; do not use within 24 h of (or concomitant) use of another 5HT, agonist, or use within 2 wk of (or concomitant) use of MAOIs, or concomitant use w/ ergot derivatives; do not use for treatment of basilar or hemiplegic migraine	Reconsider migraine diagnosis if patient does not respond to first dose; patients w/ symptoms of angina pectoris should be evaluated for CAD or Prinzmetal angina before receiving a second dose; do not administer to patients w/ risk factors for CAD (e.g., HTN, hypercholesterolemia, smoking, obesity, diabetes, strong family history of CAD, menopause, males > 40 y) w/o adequate cardiac workup; use w/ caution in older persons or in patients w/ hepatic or renal impairment (including dialysis); evaluate cardiovascular status periodically; avoid concomitant use of other serotonergic drugs (SSRIs/SNRIs, other triptans) and serotonin precursors (e.g., tryptophan)
almotriptan (Axert) 6.25–12.5 mg q2h to max of 25 mg/d *Note:* Patients taking potent CYP3A4 inhibitors should only take 6.25 mg as a starting dose to a max of 12.5 mg/d	3%–10%: Somnolence, dizziness, nausea	Pregnancy, known or suspected ischemic heart disease, stroke TIA, PVD, uncontrolled HTN; do not use within 24 h of (or concomitant) use of another 5HT, agonist or concomitant use w/ ergot derivatives, MAOIs, or sibutramine; do not use for treatment of basilar or hemiplegic migraine	Do not use for migraine prophylaxis or cluster headache; if patient doesn't respond to first dose, reconsider migraine diagnosis; use w/ caution in patients w/ sulfonamide allergy; do not administer to patients w/ risk factors for CAD (e.g., HTN, hypercholesterolemia, smoking, obesity, diabetes, strong family history of CAD, menopause, males > 40 y) w/o adequate cardiac workup; evaluate cardiovascular status periodically; use w/ caution in patients w/ hepatic or renal impairment; avoid concomitant use of other serotonergic drugs (SSRIs/SNRIs, other triptans)
eletriptan (Relpax) 20–40 mg q2h to max of 80 mg/d	3%–10%: Chest pain/tightness, dizziness, somnolence, headache, nausea, xerostomia, weakness, paresthesia	Pregnancy, ischemic heart disease or signs or symptoms of ischemic heart disease, stroke, TIA, PVD, or uncontrolled HTN; do not use in severe hepatic impairment or with concomitant use within 24 h of an ergot derivative or another 5HT, agonist, or within 72 h of potent CYP3A4 inhibitors or sibutramine; do not use for treatment of basilar or hemiplegic migraine or for migraine prophylaxis	If patient doesn't respond to first dose, reconsider migraine diagnosis; do not administer to patients w/ risk factors for CAD w/o adequate cardiac workup; evaluate cardiovascular status periodically; use w/ caution in patients w/ mild to moderate hepatic impairment; avoid concomitant use of other serotonergic drugs (SSRIs/SNRIs, other triptans) or serotonin precursors (e.g., tryptophan)
frovatriptan (Frova) 2.5 mg q2h to max of 7.5 mg/d	3%–10%: Flushing, dizziness, fatigue, headache, hot or cold sensation, xerostomia, paresthesia, skeletal pain	Ischemic heart disease or signs and symptoms of ischemic heart disease, stroke, TIA, PVD, or uncontrolled HTN; do not use w/ concomitant use within 24 h of an ergot derivative or another 5HT, agonist or w/ sibutramine; do not use for treatment of hemiplegic or basilar migraine	Not intended for migraine prophylaxis or cluster headache; rule out underlying neurologic disease in patients w/ atypical headache or migraine (w/ no prior history of migraine), or inadequate clinical response to first dose; do not administer to patients w/ risk factors for CAD w/o adequate cardiac workup; evaluate cardiovascular status periodically; slow onset, longest half-life of the triptans
Ergot Derivatives			
ergotamine tartrate (Ergomar) 2 mg SL at start of migraine, then 1 tab q30min if needed, to 3 tab/d and 5 tab/wk	Serious vasoconstrictive distress (ischemia, cyanosis, absence of pulse, cold extremities, gangrene, precordial distress and pain, ECG changes and muscle pains), transient tachycardia or bradycardia and hypertension, nausea, vomiting, paresthesias, numbness, weakness, vertigo, localized edema, itching, rare fibrosis (retroperitoneal, pleuropulmonary, and heart valve)	**WARNING: Serious and/or life-threatening peripheral ischemia has been associated with the coadministration of ergotamine tartrate with potent CYP3A4 inhibitors, including protease inhibitors and macrolide antibiotics. Because CYP3A4 inhibition elevates the serum levels of ergotamine tartrate, the risk for vasospasm leading to cerebral ischemia and/or ischemia of the extremities is increased. Hence, concomitant use of these medications is contraindicated.** Pregnancy category X; do not use in patients with PVD, coronary heart disease, or HTN, impaired hepatic or renal function, or sepsis	Withdrawal and MOH may occur with prolonged use
Generic (Trade) Name and Dosage	**Selected Adverse Events**	**Contraindications**	**Special Considerations**
dihydroergotamine (Migranal) IM/SC: 1 mg first sign of headache, repeat hourly to a max dose of 3 mg total, to a max dose of 6 mg/wk IV: 1 mg first sign of headache, repeat hourly to a max dose of 2 mg total, to a max of 6 mg/wk Intranasal: 1 spray (0.5 mg) each nostril, repeat q15min if necessary, to a max of 4 sprays to a max of 6 sprays/d and a max of 8 sprays/wk	3%–10%: Dizziness, somnolence, nausea, taste disturbance, vomiting, application site reaction, pharyngitis Nasal spray >10%: Rhinitis	See **BOXED WARNING** above Pregnancy Category X; do not use in patients with ischemic heart disease (angina pectoris, history of MI, or documented silent ischemia), or in patients w/ clinical symptoms or findings consistent w/ coronary artery vasospasm, including Prinzmetal variant angina; do not use in uncontrolled HTN; do not use with concomitant use of 5HT, agonists, or other ergotamine-containing or ergot-type medications or methysergide within 24 h; do not use for treatment of hemiplegic or basilar migraine, in PAD, sepsis, following vascular surgery, or in severely impaired hepatic or renal function	Use only when a clear diagnosis of migraine headache has been established; not for prolonged use; use with caution in older persons
caffeine/ergotamine (Cafergot) PO: 1 mg ergotamine/100 mg caffeine, 1–2 tabs at onset; may repeat after 1h to max of 6 tabs/d Rectal: 2 mg ergotamine/100 mg caffeine; 1 supp PR; may repeat after 1 h to max 2 supp/d	Nausea, vomiting, irritability, palpitations, paresthesias, MOH, dizziness, tingling of the extremities, rare MI	**WARNING Serious and/or life-threatening peripheral ischemia has been associated with coadministration of Cafergot with potent CYP3A4 inhibitors (e.g., protease inhibitors, macrolide antibiotics). Because CYP3A4 inhibition elevates serum levels of Cafergot, the risk of vasospasm leading to cerebral ischemia and/or ischemia of the extremities is increased. Concomitant use of these medications is contreindicated.** Pregnancy category X; do not use in HTN, PVD, and CAD; do not use with impaired hepatic or renal function or in sepsis	Use w/ caution with concomitant use of less potent CYP3A4 inhibitors; avoid excessive or prolonged use; not indicated for migraine prophylaxis; monitor use in mild to moderate hepatic impairment; MOH may be associated w/ prolonged and unterminated use
Barbiturates—see **Table 38.1**			
Opioids			
butorphanol nasal spray (1 mg) 1 spray in 1 nostril, may repeat in 1 h; can repeat initial dosing sequence q3–4h PRN Adjust for renal and hepatic impairment: 1 mg at onset, 1 mg 60–90 min later, then at intervals of no <6 h	>10%: Somnolence, dizziness, nausea and/or vomiting, nasal congestion, insomnia	History of substance abuse	Use w/ caution in impaired renal, hepatic, or pulmonary function; use w/ caution in older persons; use sparingly—not recommended as a first-line drug
acetaminophen w/ codeine (Tylenol w/ codeine) 1–2 tabs q4h to a max of 12 tabs/d Tylenol w/ codeine 3: 30 mg codeine, 300 mg acetaminophen Tylenol w/ codeine 4: 60 mg codeine, 300 mg acetaminophen	Severe hepatotoxicity on acute overdose, potential liver damage w/ chronic daily dosing, nephrotoxicity, agranulocytosis, rash, drowsiness, constipation	Chronic alcohol use, alcoholic liver disease, or impaired liver or renal function; G6PD deficiency; history of substance abuse; do not use for pregnancy for prolonged use or high doses at term	May be used sparingly in pregnancy; do not exceed 3,250 mg acetaminophen/d (including concomitant use with other acetaminophen-containing products); decrease dose in patients w/ renal impairment; use w/ caution in patients w/ respiratory disorders, CNS depression/coma, head trauma, morbid obesity, prostatic hyperplasia, urinary stricture, thyroid dysfunction, or severe renal or liver insufficiency; may cause CNS depression or hypotension; use w/ caution in patients w/ hypovolemia or cardiovascular disease; abrupt discontinuation after prolonged use may result in withdrawal
Steroids			
dexamethasone Single dose of 4 or 4 mg bid × 2 d then 4 mg daily × 3 d w/tapered discontinuation	Nausea, GI upset, insomnia, mood swings, rare and serious steroid psychosis, peptic ulcer disease, CHF	Pregnancy; systemic fungal infections or acute head injury; avoid concomitant use w/ aldesleukin, BCG, dronedarone, everolimus, natalizumab, nitrinitr, nisoldipine, pazopanib, ranolazine, nimodepin, tolvaptan, and live vaccines	Use as rescue medication only; use w/ caution in thyroid disease, hepatic and renal impairment, CVD, DM, glaucoma, cataracts, myasthenia gravis, GI diseases, and in patients at risk for osteoporosis or seizures; use w/ caution in older persons at the lowest possible dose for a short duration

The most effective treatment for migraines involves both nonpharmacologic and pharmacologic approaches. Nonpharmacologic approaches include various psychological techniques that aid in managing the migraine attack. Relaxation, stress management, and biofeedback are some techniques used to reduce migraine severity and frequency. Progressive muscle relaxation and the use of autogenic phrases are examples of relaxation techniques (see section on tension headaches).

Goals of Drug Therapy

The main goal of pharmacologic therapy is to prevent or relieve the migraine attacks with minimal or no side effects. Short-term goals include decreasing the severity, frequency, and number of migraine days of the headache and relieving nausea, if present. Long-term goals established by the U.S. Headache Consortium include reducing attack frequency and severity, reducing disability, improving quality of life, preventing headache, avoiding headache medication escalation, and educating and enabling patients to manage their disease (Silberstein et al., 2012). Efficacy endpoints in the management of migraine (i.e., in clinical trials) are generally recognized as being pain free (no pain) or headache relief (improvement) response at 2 hours postdose, reduction in 24-hour recurrence rate, and favorable adverse event profile.

Nonsteroidal Anti-Inflammatory Drugs

First-line (level A strength of evidence) abortive agents for mild to moderate migraines are NSAIDs and aspirin. These medications, like all migraine medications, work best when taken early in the attack. The most common side effects are gastrointestinal. The same doses as used for tension headaches are appropriate for migraines (American Academy of Neurology (AAN) guidelines have not changed since 2000) (Marmura et al., 2015). Aspirin may be used in initial dosages of up to 900 mg. Aspirin alone is effective in up to 40% of migraine patients (Silberstein, 2002). Since AAN guidelines have not been updated since 2000, a starting dose of 1,000 mg acetaminophen is still reported as an effective intervention for acute migraine, although recommended doses of acetaminophen in general have been reduced. As with tension headaches, a given NSAID should be used on more than one occasion before deciding whether it is efficacious.

Caffeine-Containing Compounds

OTC caffeine-containing compounds (such as Excedrin Extra Strength or Excedrin Migraine) are also effective for milder migraines, but they can easily cause MOH and should be used no more than 3 days per month or for more than 48 hours at a time. These preparations also contain acetaminophen (250 mg per tablet), so caution is required if acetaminophen or many of the other OTC or prescription acetaminophen-containing preparations are being used, especially concomitantly (Schilling et al., 2010).

5-HT1 Receptor Agonists (Triptans)

Triptans are migraine-specific drugs that work as 5-HT_1 serotonin receptor agonists. These receptors are located on intracranial blood vessels, presynaptically on CNS sensory neurons, and trigeminal terminals. Triptans cause cerebral vasoconstriction and can treat both the pain and nausea of migraine.

Triptans are indicated for acute treatment of migraine with or without aura, and they are used for moderate to severe migraines or for milder migraines that do not respond to NSAIDs, aspirin, or the above combination drugs. Triptans vary in their time to peak concentration, half-lives, adverse event profiles, formulation, and route of administration, which helps guide the selection of a triptan for a particular patient. Given the highly individualized nature of migraine, different medications may be more effective than others in any given patient. If a triptan fails on two separate occasions, another triptan should be tried. Triptans work best when given early in the course of a migraine, but unlike many other agents, they may be effective even when given late in the course of a migraine.

Triptans should not be used more than 9 days per month and should not be used within 24 hours of any other vasoconstricting drug, such as ergotamine. Use of these medications is considered to be a better choice than use of the ergot derivatives, as potency is similar but adverse events are significantly fewer in number (Khoury & Couch, 2010). Triptans should be avoided in patients with basilar, hemiplegic, or retinal migraines; they must also be avoided in patients with coronary artery disease, cerebrovascular disease, or severe peripheral vascular disease. Concomitant use of ergotamines and dihydroergotamine (DHE) is also contraindicated, and, while serotonin syndrome is rare, the possibility for it exists with concomitant use of triptans and SSRIs or SNRIs. No more than one triptan at a time should be used within 24 hours (Pringsheim & Becker, 2014).

The seven triptan drugs are sumatriptan, zolmitriptan, naratriptan, rizatriptan, almotriptan, eletriptan, and frovatriptan. A combination sumatriptan/naproxen formulation is also available. Sumatriptan and zolmitriptan are available as a nasal spray, and sumatriptan is also available in transdermal, subcutaneous, and nasal powder formulations. These are useful for patients with severe nausea who cannot tolerate an oral medication. Rizatriptan is also available as an orally disintegrating tablet. The injectable form of sumatriptan has the fastest onset of action of any of the triptans, but has a short half-life, often giving limited headache relief. Sumatriptan is also associated with more adverse events than the other triptans. Frovatriptan has the longest half-life of the triptans, at 26 hours, making it useful for patients with long-lasting migraines. Use of the triptans in the early, mild stages of migraine (but not during aura) results in greater relief (up to 70% pain free in clinical trials) than does use of the drugs during moderate or severe migraine (up to 30% pain-free in clinical trials), but the patient needs to be able to recognize onset of migraine and distinguish it from TTH. Use of a triptan for more than 9 days per month may result in MOH, during which time preventive therapy will be ineffective (Pringsheim

& Becker, 2014).

Sumatriptan

Sumatriptan (Imitrex) was the first triptan on the market (FDA approved in 1992 and now available as a generic) and still offers the fastest relief of all the triptans presently available. In its subcutaneous form, it offers the highest therapeutic gain of all the triptans in clinical trials. It is safe and well tolerated (available OTC in the United Kingdom) (Antonaci et al., 2010; Johnston & Rapoport, 2010; Tfelt-Hansen, 2007). Sumatriptan is available in tablets (25, 50, and 100 mg), a powder nasal spray (20 mg), a nasal powder (11 mg), a subcutaneous injection (6 mg), and transdermally (6.5 mg). See Table 38.3.

Injectable sumatriptan offers the quickest onset of action (10 minutes), whereas the effects of the tablet take longer (30 to 90 minutes). Sumatriptan is the only triptan with a subcutaneous formulation, making it the fastest-onset triptan available, but it also has the shortest half-life of the triptans, limiting the longer-term relief associated with some of the other triptans with longer half-lives. Injectable sumatriptan is associated with more adverse events than oral sumatriptan (Johnston & Rapoport, 2010). If the headache recurs, the patient can take a second dose of medication, but only after a certain time and without exceeding the maximum dose of 200 mg/d. Patients with migraine with aura cannot take sumatriptan until the headache actually begins because the drug has no effect on relieving aura symptoms. Patients with nausea and vomiting tend to find the nasal formulations easier to take. Pain relief may be dose dependent, but with increased doses come increased adverse events (Johnston & Rapoport, 2010). Adverse events vary by mode of delivery, but most occurred in less than 10% of trial subjects. Concomitant use of sumatriptan with MAOIs is contraindicated (Pringsheim & Becker, 2014).

Zolmitriptan

Zolmitriptan (Zomig; FDA approved in 1997 and now available as a generic) is available in tablet, nasal spray, and orally disintegrating formulations and can be used for migraine with or without aura. The recommended initial dose of zolmitriptan is 2.5 mg. The onset of effect is attained within 45 minutes, resulting in a rapid therapeutic response. Its half-life is 3 hours, longer than that of sumatriptan, and it is extremely potent at serotonin receptors. Zolmitriptan has been shown in clinical trials to be similar in efficacy to sumatriptan (5 vs. 100 mg, respectively), and at a dose of 2.5 mg, it is similar in efficacy to sumatriptan 50 mg, almotriptan 12.5 mg, eletriptan 40 mg, and rizatriptan 10 mg. Therapeutic gain is slightly higher in nasal and orally disintegrating formulations. Efficacy may be dose dependent, with a concomitant increase in adverse events. Dosage should be adjusted down to 1.25 mg in patients with moderate to severe hepatic impairment. Contraindications and adverse effects are similar to the other triptans; MAOIs should also not be used with zolmitriptan, nor should CYP1A2 inhibitors such as cimetidine, fluvoxamine, and ciprofloxacin. See Table 38.3.

Naratriptan

Naratriptan (Amerge; FDA approved in 1998 and now available as a generic) is marketed as an alternative agent for patients who are taking repeated doses of other migraine therapies, specifically those who have recurrent headache or chest tightness when using oral sumatriptan. Naratriptan is available only in 1- and 2.5-mg tablet formulation (see Table 38.3) and reaches peak serum concentrations in 2 to 3 hours. While onset is slow (1 to 2 hours), duration of action is longest of all the triptans; because of its long half-life of 6 hours, headache recurrences are not common. An initial dose of 1 to 2.5 mg should be used; if headache does not resolve, a second dose can be administered within 4 hours, not to exceed a total dose of 5 mg. The safety of treating more than four migraines per month with naratriptan has not been established. Therapeutic gain at 4 hours (as compared with 2 hours) tends to be higher in this triptan. In the original clinical trial, headache relief was experienced by 68% of patients 4 hours postdose and was maintained for 8 to 24 hours. Given its availability only in low dosages, its side effect profile in clinical trials was comparable to placebo, making this triptan a good option for patients experiencing intolerable side effects with other triptans (Johnston & Rapoport, 2010; Pringsheim & Becker, 2014).

Rizatriptan

Rizatriptan (Maxalt; FDA approved in 1998 and now available as a generic) is available in a tablet (5 and 10 mg) and orally disintegrating tablet (Maxalt-MLT; 5 and 10 mg), offering an alternative way to treat a migraine. Onset of action is rapid, particularly with the orally disintegrating tablet. Rizatriptan 10 mg produces faster relief than do sumatriptan 50 mg and naratriptan 2.5 mg and is similar in efficacy to almotriptan 12.5 mg, eletriptan 40 mg, and zolmitriptan 2.5 mg. Effects of rizatriptan can be observed within 30 minutes and last from 14 to 16 hours. In the original clinical trial, 62% of patients taking the 5-mg dose and 71% of patients taking the 10-mg dose experienced pain relief 2 hours postdose. Complete relief was achieved in 33% of patients taking a 5-mg dose and 42% of patients taking the 10-mg dose. The drug is well tolerated, even at 10 tablets per month. A second dose can be taken within 2 hours of the first dose if the headache is not resolving; 30 mg should not be exceeded per 24 hours. Rizatriptan should not be used concomitantly with MAOIs, and if used concomitantly with propranolol, only a 5-mg dose of rizatriptan should be used, to a maximum dosage of 15 mg per 24 hours (DIH, 2014; Pringsheim & Becker, 2014). See Table 38.3.

Almotriptan

Almotriptan (Axert; FDA approved in 2001; no generic available, but a generic has received tentative approval from the FDA) is a rapidly absorbed triptan with a moderately long half-life (3 to 4 hours). Its efficacy is similar to that of the other triptans, but its potential for drug–drug interactions is reduced, given that it is metabolized by three separate metabolic

pathways. It is a well-tolerated drug with few adverse events and is a good choice for triptan-naïve patients or as an alternate drug for patients who need to be switched over from other triptans due to intolerable side effects (Johnston & Rapoport, 2010). Use of almotriptan is contraindicated in patients with renal impairment with concomitant use of a potent CYP3A4 inhibitor. Dose of almotriptan should be adjusted down to 6.25 mg in a single dose, to a maximum dose of 12.5 mg in any patient taking a potent CYP3A4 inhibitor (e.g., ketoconazole, itraconazole, clarithromycin, etc.). See Table 38.3.

Eletriptan

Eletriptan (Relpax; FDA approved in 2002; no generic available but a generic has received tentative FDA approval) is available in 20- and 40-mg tablets. The recommended initial dose is 40 mg at the onset of migraine. If relief is not obtained in 2 hours, the dose may be repeated, to a maximum of 80 mg/d. Onset of action is rapid, and elimination half-life is moderately long (4 hours)—shorter only than naratriptan and frovatriptan. While essentially comparable in efficacy to the other triptans, eletriptan at a dose of 40 mg is the only triptan shown to have greater efficacy than sumatriptan at 100 mg. Both efficacy and adverse events are dose dependent, although trials have reported adverse events to be transient and mild to moderate in nature. Contraindications and adverse effects are similar to those of the other triptans, but eletriptan should also not be used concomitantly within 72 hours of use of potent CYP3A4 inhibitors (e.g., conivaptan, systemic fusidic acid, itraconazole, systemic ketoconazole, posaconazole, and voriconazole; DIH, 2014; Pringsheim & Becker, 2014). See Table 38.3.

Frovatriptan

Frovatriptan (Frova; FDA approved in 2001 and now available as a generic) has a half-life of 26 hours, by far the longest of all the triptans. Hence, its therapeutic gain is better assessed at 4 hours rather than 2; the 40-hour headache response rate for frovatriptan is 66%. Like naratriptan, its onset is somewhat slower (although this is not the case in all patients taking the medication in early migraine), but its effects are more sustained. Frovatriptan is also metabolized both by the kidney and hepatic CYP1A2, reducing the likelihood for drug–drug interactions. It has also been shown to be particularly effective in menstrual-related migraine, not only for acute relief but also as a 2-day "miniprophylaxis." It is available as a 2.5-mg tablet, which is the recommended dose. If a first dose provides some relief but the headache recurs, another dose may be taken no sooner than 2 hours after the preceding dose, to a maximum of 7.5 mg/d. Contraindications and adverse effects are similar to the other triptans (Johnston & Rapoport, 2010). See Table 38.3.

Sumatriptan and Naproxen

Sumatriptan and naproxen (Treximet; FDA approved in 2008; no generic available) is an oral tablet combination medication containing 85 mg sumatriptan and 500 mg naproxen used for treating migraine with or without aura. It is more efficacious than monotherapy

with sumatriptan or naproxen alone (as is combined use of individual sumatriptan and naproxen tablets). Sustained pain relief at 24 hours was also significantly better than monotherapy with either sumatriptan or naproxen in clinical trials. It follows the sumatriptan dosing recommendations (one tablet at migraine onset; if relief is not obtained, a second dose may be taken at least 2 hours later, with a maximum of two tablets in 24 hours), and its adverse events, contraindications, and warnings are the same as those for each of its individual components (including the boxed warning for the naproxen component; Khoury & Couch, 2010). Use of sumatriptan/naproxen is not recommended in patients with a creatinine clearance of less than 30 mL/min, and its use is contraindicated in hepatic impairment (DIH, 2014). See Table 38.3.

Ergot Derivatives

The first migraine-specific drugs to be developed were the ergot derivatives (ergotamine tartrate and DHE, with a variety of trade names). They are generally recognized as safe and effective, but have fallen out of favor because of unpredictable patient responses and greater adverse events as compared with the safer triptans. Ergot derivatives have partial agonist, antagonist, or both types of activity for serotonergic, dopaminergic, and alpha-adrenergic receptors, resulting in constriction of peripheral and cranial vessels. Ergot derivatives are typically used to treat infrequent, long-standing migraines in patients who have had multiple relapses when using triptans, but care should be taken to prescribe the medication infrequently, at recommended doses, and in careful consideration of contraindications (e.g., they are Pregnancy Category X drugs and are absolutely contraindicated in patients with cardiovascular or cerebrovascular disease and in patients taking concomitant medications metabolized by the CYP3A4 pathway, such as protease inhibitors, azole antifungals, and certain macrolide antibiotics). While generally found to be less efficacious than oral sumatriptan in clinical trials, rectal ergotamine was found to have superior efficacy than rectal sumatriptan (73% vs. 63%, respectively; rectal sumatriptan is not available as an approved medication). Ergotamine/caffeine combinations are also available in oral, sublingual, and rectal formulations, although evidence of efficacy for these preparations is inconsistent or conflicting (Bigal & Tepper, 2003; Wilson, 2007).

Ergotamine tartrate (Ergomar; Ergostat has been discontinued) is available in 2-mg sublingual tablets. Ergotamine is not an optimal choice, given its side effect profile (nausea may be sufficient enough for discontinuation). It is associated with more side effects than DHE, and use of the medication more than 10 times per month may cause MOH. DHE (Migranal) is available intramuscularly (1 mg), intravenously (1 mg), subcutaneously (1 mg), and as a nasal spray (0.5 mg). There are no oral formulations. This drug is mainly used to treat severe, refractory migraines; recurring migraines; MOH; or status migrainosus (debilitating migraine attacks lasting longer than 72 hours) and is usually managed by specialists. Cafergot, a combination of caffeine and ergotamine, is available in oral (1 mg ergotamine, 100 mg caffeine) and suppository (2 mg/100 mg) formulations. Cafergot can also increase the incidence of migraines and should be used infrequently (Monteith & Goadsby, 2011; Tfelt-Hansen, 2007; Wilson, 2007). Use of these agents is contraindicated in severe renal impairment (DIH, 2014). See Table 38.3.

Barbiturates

Butalbital-containing compounds such as Fiorinal (butalbital 50 mg/aspirin 325 mg/caffeine 40 mg; tablets and capsules) and Fioricet (butalbital 50 mg/acetaminophen 325 mg/caffeine 40 mg; tablets, capsules, or liquid) are C-III controlled substances and should be used sparingly and only if the migraine-specific agents have repeatedly failed. There are no data to support the efficacy of these medications, and if overused (as infrequently as five times per month), these agents can lead to addiction, MOH, development of chronic daily headache, and withdrawal symptoms. These drugs have been removed from the market in the European Union, Asia, and Latin America due to their associated risks and their lack of efficacy. Fioricet should particularly be used with caution given its acetaminophen content if it is used concomitantly with other acetaminophen-containing drugs (Tepper & Spears, 2009). The "Choosing Wisely" Task Force of the American Headache Society identified overuse of butalbital-containing and opioid medications for the treatment of migraine as a problem (Loder et al., 2013). See Table 38.3 for side effects and contraindications.

Opioids

Opioids have been used as rescue medications for severe migraines that do not respond to the above medications. They are also used in patients who have infrequent migraines and have contraindications to other agents. They are used sparingly for moderate to severe migraines during pregnancy. However, they are in general not recommended for the treatment of migraine and, if used as rescue medications, should be used only a few times per year. Overuse can lead to MOH, status migrainosus, or development of chronic daily headache. These are C-IV medications, and the potential for dependence or abuse should also be taken into account when considering them for use. Examples of these medications include butorphanol (generic nasal spray, 1 mg/spray), tramadol (generic tablet, 100 mg daily; can be titrated to a maximum of 300 mg daily), and acetaminophen plus codeine (Tylenol plus codeine; acetaminophen 300 mg/codeine 30 or 40 mg) for mild to moderate pain. The acetaminophen content per dose is 300 mg, which needs to be considered when used concomitantly with other acetaminophen-containing drugs so that a maximum daily dose of 3,250 mg is not exceeded (Tepper & Spears, 2009; Wilson, 2007). As with the butalbital-containing drugs, use of opioid medications for migraine was the second most identified problem by the "Choosing Wisely" Task Force. Use of opioids is rare (seen most frequently in emergency departments) and has even been described as contributing to disease progression, increased use of health care resources, and comorbidity (Loder et al., 2013; Minen et al., 2014; Tepper, 2012). Opioids are not a good choice for managing migraine pain. See Table 38.3 for side effects and contraindications.

Steroids

If a patient has a severe, persistent migraine or status migrainosus that seems refractory to any abortive medications, a brief course of steroids (typically dexamethasone 6 mg for 5 days or IV 4 to 16 mg) may be used as a rescue medication until the patient is headache free for 24 hours. There are few good data supporting the efficacy of steroid use (AHS level of evidence category C: "possibly effective"), but they have been used with good results (Marmura et al., 2015; Tepper & Spears, 2009; Wilson, 2007). See Table 38.3 for side effects and contraindications.

Antiemetic Agents

The antiemetic agents prochlorperazine, metoclopramide, and droperidol as well as the antipsychotic chlorpromazine are effective adjunctive therapies for patients experiencing an acute migraine with or without nausea and vomiting. Prochlorperazine comes in a suppository form, which is useful for patients unable to tolerate oral medications. Droperidol carries a black box warning for QT prolongation and torsade de pointes. These medications augment the effects of abortive agents and may be taken before or together with these medications.

Prophylactic Drug Therapy for Migraines

Prophylactic medications are used to prevent the occurrence of migraine by reducing the frequency and severity of migraine attacks. Epidemiologic studies have shown that some 38% of migraineurs require some form of preventive therapy, yet only 3% to 13% are receiving prophylactic treatment (Silberstein et al., 2012). A therapeutic trial of a given agent should last for 2 to 3 months before the efficacy of the agent is assessed. The main classes of agents used for migraine prophylaxis are anticonvulsants, beta-blockers, triptans, angiotensin-converting enzyme inhibitors (ACEIs), angiotensin II receptor blockers (ARBs), calcium channel blockers, antidepressants (TCAs and SSRIs/SNRIs), and antihistamines, although strength of evidence for efficacy has been determined for individual medications and not for entire medication classes. A 2012 AAN Quality Standards Subcommittee report identified divalproex sodium, sodium valproate, topiramate, metoprolol, propranolol, and timolol as the agents with the most support for efficacy for migraine prophylaxis (Silberstein et al., 2012). More recently, onabotulinumtoxinA (Botox) has shown efficacy in the management of chronic migraine (Pedraza et al., 2015). The choice of prophylactic agent should be based on the patient's comorbidities and the efficacy and side effect profile of the medication. Table 38.4 gives an overview of selected drugs used to prevent migraines.

TABLE 38.4 Overview of Selected Drugs Used for Migraine Headache Prophylaxis

Generic (Brand) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Beta-Blockers			
propranolol (Inderal) (long acting) Start 80 mg daily; goal 160–240 mg daily; increase dose gradually and taper discontinuation, discontinue after 6 wk if no satisfactory response. *Note*: Adjust dose in hepatic impairment	Common: Drowsiness or fatigue, cold hands and feet, weakness or dizziness, dry mouth, eyes, and skin	**WARNING: Beta-blocker therapy should not be withdrawn abruptly (particularly in patients with CAD), but gradually tapered to avoid acute tachycardia, hypertension, and/or ischemia.** Pregnancy, uncompensated CHF, cardiogenic shock, severe sinus bradycardia or second- or third-degree heart block or with severe asthma or COPD	Useful if there is history of coexisting HTN or CAD; use w/ caution in patients w/ PVD or w/ concomitant beta-blocker use; use w/ caution in patients w/ DM, myasthenia gravis, psychiatric disease, and renal or hepatic dysfunction
timolol Initial: 10 mg bid to a max of 30 mg/d	Anaphylaxis (serious); >3%: fatigue/tiredness, bradycardia; AEs in CAD population more numerous; asthenia or fatigue, heart rate <40 beats/min, cardiac failure—nonfatal, hypotension, claudication, cold hands and feet, nausea or digestive disorders, dizziness	See **BOXED WARNING** above Bronchial asthma or history of bronchial asthma, or severe COPD; sinus bradycardia, second- and third-degree AV block, overt cardiac failure, or cardiogenic shock	Use w/ caution in impaired hepatic or renal function, marked renal failure, muscle weakness, or cerebrovascular insufficiency; use w/ caution w/ concomitant use of catecholamine-depleting drugs, NSAIDs, calcium antagonists, digoxin and either diltiazem or verapamil, quinidine, and clonidine
Tricyclic Antidepressants			
amitriptyline—see **Table 38.1**			
Anticonvulsants			
valproic acid (Depakene, Stavzor) Depakene 250 mg soft gel capsule Stavzor delayed release 125, 250, and 500 mg soft gel capsules initial: 250 mg bid to a max of 1,000 mg/d	≥5%: Headache, asthenia, fever, nausea, vomiting, abdominal pain, diarrhea, anorexia, dyspepsia, constipation, somnolence, tremor, dizziness, diplopia, amblyopia/blurred vision, ataxia, nystagmus, emotional lability, abnormal thinking, amnesia, flu syndrome, infection, bronchitis, rhinitis	**WARNING: May cause teratogenic effects such as neural tube defects (e.g., spina bifida). Hepatic failure resulting in fatalities has occurred in patients; children < age 2 are at considerable risk. Cases of life-threatening pancreatitis, occurring at the start of therapy or following years of use, have been reported in adults and children.** Hepatic disease or significant hepatic dysfunction or with urea cycle disorders	Monitor for hypothermia and thrombocytopenia; monitor psychiatric patients for suicidal ideation; use w/ caution w/ concomitant use of carbapenem, topiramate, aspirin, or lamotrigine; drug interactions are also known for felbamate, rifampin, amitriptyline/nortriptyline, carbamazepine, clonazepam, diazepam, ethosuximide, phenobarbital, phenytoin, tolbutamide, warfarin, and zidovudine; use w/ caution in older persons
divalproex (Depakote) Initial: 250 mg bid, up to 1,000 mg/d	>10%: Nausea, somnolence, dizziness, vomiting; >5%–10%: Asthenia, abdominal pain, dyspepsia, rash	See **BOXED WARNING** above	Same as above

Generic (Brand) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
topiramate (Topamax) Initial: 25 mg qhs for first wk, increased weekly by increments of 25 mg; recommended therapeutic dose 100 mg/d in 2 divided doses *Note*: Taper gradually.	>5%: Paresthesia, anorexia, weight decrease, fatigue, dizziness, somnolence, nervousness, psychomotor slowing, difficulty w/ memory, difficulty w/ concentration/attention, confusion; renal calculi, rare acute-angle glaucoma; >5% in migraine trials: paresthesia, taste perversion	None	Decreases effectiveness of oral contraceptives; monitor for acute myopia, oligohidrosis and hyperthermia, suicidal behavior and ideation, metabolic acidosis, cognitive/neuropsychiatric dysfunction, and hyperammonemia; use caution w/ concomitant administration of valproic acid, oral contraceptives, metformin, lithium, and other carbonic anhydrase inhibitors
Calcium Channel Blockers			
verapamil 40–80 mg tid	>1%: Headache, URI, fatigue, nausea, constipation, dizziness, edema	Severe left ventricular dysfunction, hypotension or cardiogenic shock, sick sinus syndrome, second- or third-degree AV block, atrial flutter or atrial fibrillation and an accessory bypass tract (e.g., Wolff-Parkinson-White, Lown-Ganong-Levine syndromes)	Useful if there is coexisting HTN; monitor LFTs periodically, use w/ caution in patients w/ impaired renal or hepatic function and in patients w/ decreased neuromuscular transmission; use caution w/ concomitant administration of erythromycin, ritonavir, alcohol, aspirin, grapefruit juice, beta-blockers, digitalis, other antihypertensive agents, disopyramide, flecainide, quinidine, lithium, carbamazepine, and rifampin, phenobarbital, cyclosporine, theophylline, inhalation anesthetics, neuromuscular-blocking agents, telithromycin, or clonidine

The current recommendations for starting prophylactic therapy are recurring migraines that affect the patient's functioning and quality of life despite acute symptomatic treatments, intolerance or failure of multiple acute treatments, overuse of acute medications, MOH, special circumstances such as hemiplegic migraines, and more than two headaches per week (Pringsheim et al., 2010; Silberstein, 2002).

Medications should be started at low doses and titrated slowly until the desired effects occur. Dosages may need to be lowered if side effects occur. A full therapeutic trial takes at least 2 months. It may take months until an effective agent is found.

Anticonvulsants

Valproic acid (Depakene) and divalproex sodium (Depakote) can reduce the frequency, severity, and duration of migraines. Use of these drugs is contraindicated in patients with liver disease. Side effects such as tremor, weight gain, nausea, and hair loss may limit their use as agents for prophylaxis. Numerous drug interactions can result when valproic acid or divalproex sodium is administered with other anticonvulsants. Increased effects or toxicity of valproic acid are seen with the administration of CNS depressants and aspirin. Valproic acid is contraindicated in pregnancy because it is toxic to the fetus (in 2013, FDA changed the pregnancy category for valproate from "D" to "X").

Topiramate (Topamax) has been shown to be effective in migraine prophylaxis and is particularly effective for patients who have chronic daily headache or who have failed to respond to many other prophylactic treatments. Topiramate was also shown in trials to be at least as or more effective as other migraine prophylactic therapies such as propranolol, valproate, and amitriptyline. A retrospective claims analysis of oral migraine prevention medications revealed that topiramate was the most commonly prescribed migraine prevention medication and the preventive agent for which there was the greatest amount of patient adherence (Hepp et al., 2015). Topiramate has many potential side effects that limit its use, such as concentration and memory impairment, significant somnolence, mood disturbance, and tremor. It should be used with caution in patients with renal or hepatic impairment.

Beta-blockers

Beta-blockers are often considered first-line agents for prophylactic treatment of migraine, with many studies showing a 50% reduction or more in occurrence of migraine. Propranolol (Inderal), metoprolol (Lopressor), and timolol are evidence class A medications, while atenolol (Tenormin) and nadolol (Corgard) are evidence class B medications. They have all been used for migraine, with similar efficacy. Nebivolol (Bystolic) and pindolol are evidence class C ("possibly effective"), and bisoprolol (Zebeta) is evidence class U (inadequate information) (Loder et al., 2012; Marmura et al., 2015). Only propranolol and timolol have been approved by the FDA for migraine prophylaxis. Beta-blockers are contraindicated in patients with uncompensated congestive heart failure, bradycardia, second- or third-degree atrioventricular block, and asthma. Side effects include fatigue, vivid dreams, depression, impotence, bradycardia, and hypotension. Many pathways of the cytochrome P450 enzyme system metabolize beta-blockers. Beta-blockers have numerous drug interactions, so careful consideration of polypharmacy is necessary prior to prescribing them.

Tricyclic Antidepressants

TCAs can also be used as first-line agents for migraine prophylaxis. The agents most commonly used include imipramine (Tofranil), nortriptyline (Pamelor), and amitriptyline (Elavil), although only amitriptyline is recommended by the 2012 AAN/AHS guidelines (Loder et al., 2012). Patients usually need only low doses for prophylaxis, lower than those generally used to treat depression. Patients should avoid use if they are currently taking an MAOI, have glaucoma, or are pregnant. Anticholinergic side effects commonly occur and include sedation, constipation, blurred vision, hypotension, and slowed conduction in the atrioventricular node. TCAs also have many potential drug interactions; prescribers should consult a reference before administering them.

Calcium Channel Blockers

Verapamil (Calan) is the calcium channel blocker most commonly used in migraine prophylaxis; however, it provides only a slight benefit in reducing the frequency of attacks (AAN category U: not recommended; Loder et al., 2012). It is often considered a second- or third-line agent for use when other agents are ineffective or contraindicated. The mechanism of action is believed to be the inhibition of serotonin release, which may not be achieved until after 8 weeks of therapy. Its use is contraindicated in patients with bradycardia, heart block, ventricular tachycardia, or atrial fibrillation. Side effects include constipation, fluid retention, bradycardia, and hypotension. Numerous drug interactions are associated with calcium channel blockers; prescribers must consult a reference before administering.

Other Prophylactic Agents

MAOIs can also be used for migraine prophylaxis, but because they have multiple serious side effects, their use should be managed by a neurologist. Gabapentin (Neurontin) has recently been established to be effective in the treatment of chronic daily headache at dosages of 1,800 to 2,400 mg/d. ACEIs and angiotensin receptor blockers are also being studied as potential prophylactic agents. SSRIs, such as venlafaxine and fluoxetine, have been used with some success, although are classified by the 2012 AAN/AHS guidelines as ineffective. They are particularly useful in patients also suffering from anxiety or depression.

Selecting the Most Appropriate Agent

It is important to initiate therapy at the first sign of a migraine. The 2015 updated AAN/AHS guidelines have been revised according to level of evidence criteria. The following section discusses the recommended therapy for migraines (Table 38.5).

TABLE 38.5 Recommended Order for Treatment of Migraine Headaches

Order	Agents	Comments
First line	NSAIDs (oral) or aspirin	With moderate to severe migraines, can use antiemetic as needed
Second line	Triptans	*First tier* • sumatriptan 50–100 mg • almotriptan 12.5 mg • rizatriptan 10 mg • eletriptan 40 mg • zolmitriptan 2.5 mg *Slower effect/better tolerability* • naratriptan 2.5 mg • frovatriptan 2.5 mg
Third line	Triptans plus an NSAID	Can use antiemetic as needed
	Infrequent headache: • ergotamine 1–2 mg • dihydroergotamine 2 mg nasal spray	*For headache recurrence*: • ergotamine 2 mg, most effective rectally/usually w/ caffeine • naratriptan 2.5 mg • almotriptan 12.5 mg • eletriptan 40 mg

Data from Goadsby, P. J., & Sprenger, T. (2010). Current practice and future directions in the prevention and acute management of migraine. *Lancet Neurology*, 9 (3), 285–298.

First-Line Therapy

NSAIDs and aspirin are appropriate first-line therapy for mild to moderate migraine. They are inexpensive and generally well tolerated. Triptans are first-line therapy for moderate to severe migraine with or without an antiemetic. NSAIDs may be tried for more severe migraines, but they are often unsuccessful.

Second-Line Therapy

OTC caffeine-containing compounds are appropriate treatment options for mild to

moderate migraines that have not responded to the above agents. They can also be used as rescue medications if NSAIDs and aspirin fail to relieve a given attack. For more severe migraines, an ergot derivative along with an antiemetic can be used as second-line therapy if multiple triptans have failed in past treatment efforts.

Third-Line Therapy

If the above agents are ineffective in treating mild to moderate migraines, triptans should be tried. For severe migraines that have not responded to triptans or ergot derivatives and antiemetics, butalbital-containing compounds or opioids may be considered.

Cluster Headaches

Patients suspected of having CHs should be promptly referred to a neurologist to exclude potentially serious differential diagnoses. There is clinical evidence for the efficacy of several medications for the acute treatment of CH. Subcutaneous sumatriptan 6 to 12 mg (the only drug FDA approved for CH), intranasal sumatriptan 6 to 12 mg, zolmitriptan nasal spray 5 to 10 mg, and 100% inhaled oxygen 10 to 15 L/min are recommended for the management of acute attacks. Subcutaneous octreotide (Sandostatin), a somatostatin receptor agonist, has also been shown to be efficacious at 100 mcg, as has olanzapine 2.5 to 10 mg and intranasal lidocaine 10% solution (Pomeroy & Marmura, 2013). For individuals with repeated CH, preventive medications should be considered. There are data supporting the use of a variety of medications, including verapamil, lithium, melatonin, topiramate, gabapentin, valproic acid, DHE, leuprolide, intranasal capsaicin, and baclofen. Preventive therapies may take some time and possible upward titration to become effective (Pomeroy & Marmura, 2013).

Special Population Considerations

Pediatric

The most common headache type seen in children is migraine. Migraines may present differently in children than in adults. Prevalence is higher in boys prior to puberty, but higher in girls thereafter. Epidemiologic studies have shown that prevalence increases with age, hitting a peak in adolescence. Average age of onset is 7 in boys and 11 in girls, and the incidence of migraine with aura peaks before migraine without aura. The pain is throbbing and pulsating but tends to be bifrontal or bitemporal. Children may have severe nausea and vomiting along with the pain. The headache usually persists for 1 to 3 hours but may last for longer than a day. A particular challenge with pediatric patients is distinguishing migraine from a host of other possible disorders (e.g., epilepsy or vascular or metabolic disorders), further complicated by interpreting the complaint from the child or his or her parents. Cheese, chocolate, and citrus fruits are common triggers of migraine in children. Nonpharmacologic approaches to migraine management, such as developing good sleeping habits and routines, are important. Biofeedback and relaxation therapy are the most commonly used behavioral approaches and have shown some efficacy in reducing frequency and severity of headaches. Clinical trial data for the pharmacologic management of pediatric migraine are limited. Pediatric migraines are usually best managed by simple analgesics such as acetaminophen and ibuprofen, with an antiemetic added if necessary. Patients and their caregivers, however, need to be cautioned not to use the medication too frequently; use of OTC analgesics more than five times per week can lead to MOH or development of chronic daily headache. Triptans are not indicated for use in children, although safety and efficacy of the nasal formulations of sumatriptan and zolmitriptan and oral formulations of rizatriptan and almotriptan have been demonstrated in clinical trials in patients ages 12 to 17. Topiramate is presently the only FDA-approved medication for children over the age of 12, but other agents have some limited efficacy. Amitriptyline is a popular drug of choice for prevention of pediatric migraine; nortriptyline is also used, as well as other antiepileptics besides topiramate such as valproic acid, levetiracetam, zonisamide, and gabapentin. Cyproheptadine has also been used, as have the antihypertensives propranolol and verapamil. Children are obviously treated with lower doses. Prophylactic medications may require tapering up or down, and, while most of these agents are well tolerated, patients should be monitored for adverse effects. Many of the pediatric formulations are available as suspensions (Kacperski, 2015).

Tension headaches do occur in children. Recurrent tension headaches should prompt a search for underlying stressors at home or at school. A vision examination should also be performed. Tension headaches are usually best managed by simple analgesics, taking care not to overuse the medication.

Geriatric

New-onset migraines do not often occur in the older population. Changes in renal and hepatic function often occur with advancing age, so if an older patient is experiencing migraines, adjustment of drug dosages is recommended.

A new headache pattern in an older patient should make the practitioner suspicious of organic disease or a medication side effect. Many of the medications used to treat migraine are contraindicated for use in older populations (naratriptan is not recommended for use in older persons, and rizatriptan should be used with caution) or need to be used at a lower dose. Comorbidities and polypharmacy need to be considered carefully prior to choosing pharmacologic management.

Women

As noted earlier, migraines occur more often in women than in men: likely an estrogen-related phenomenon. Pregnancy is a primary concern if drug therapy is to be initiated, even though migraines can diminish during the second and third trimesters. Practitioners should consider drug therapy for pregnant women using the risk-versus-benefit approach. The agents selected should be those that are safe to use during pregnancy. Triptans and ergot derivatives are *strongly contraindicated* in pregnancy. Acetaminophen is the safest analgesic to use during pregnancy, but it is usually minimally effective. For more severe migraines, ibuprofen may be used in the first and second trimester only. Tylenol with codeine may be used sparingly throughout the pregnancy. Valproic acid is category X and is contraindicated in pregnancy for migraine prophylaxis.

Menstrual migraines are a common problem that may be particularly responsive to triptans. Frovatriptan, in particular, has been used with success as "miniprophylaxis" for menstrual-related migraine (Johnston & Rapoport, 2010). Women may also be particularly vulnerable to migraine during perimenopause and menopause, when estrogen levels dramatically decline. In one cross-sectional analysis, women using hormone replacement therapy were found to be 40% more likely to have migraines than those who were not taking hormone replacement (Misakian, 2003). If a woman wishes to stay on hormone replacement therapy despite migraines, she can be given a reduced dose and can be switched to pure estradiol or synthetic ethinyl estradiol. Using continuous dosing instead of interrupted dosing may also reduce migraine frequency.

Monitoring Patient Response

Careful monitoring of therapy is important. The practitioner should document the frequency, intensity, and duration of migraines before starting any new therapy and should evaluate the patient periodically after implementing any drug or lifestyle change to assess its effectiveness. Prescribers should monitor how frequently patients are taking abortive therapies to ensure they are not using them excessively. Patients should return to the office after a few attempts with a therapy to assess its effectiveness, and practitioners should switch to another agent if the therapy is unsuccessful. Practitioners also need to evaluate prophylactic therapies for patient compliance and effectiveness. They should note in the chart side effects to therapy and treatment failures to avoid repeating ineffective therapies. Patients should also be queried directly about the use of dietary supplements, as they may not volunteer the information (i.e., not considering it to be a “drug”).

Patient Education

Drug Information

Practitioners need to educate patients about their headaches and what they should realistically expect from treatment. The prescriber should attempt to identify headache triggers (i.e., diet, medication, or environmental factors) by encouraging patients to keep diaries and to pay close attention to when migraines start and should encourage the patient to avoid or minimize these triggers.

Practitioners also must educate patients about their drug therapy. They should tell patients how frequently they can take an abortive therapy, what the maximum daily dose is, and what side effects to expect from the medication. If the patient will be using a nasal spray or injectable medication, the prescriber should demonstrate proper administration technique. Also, prescribers need to encourage patients to take their prophylactic therapies as scheduled, emphasizing that taking prophylactic therapies on an as-needed basis will not improve the condition. If switching to a new therapy, the prescriber should remind the patient to stop using the old therapy and not to use the two therapies simultaneously (unless this is intended). Patients must be strongly cautioned about drug–drug interactions, the dangers of concomitant use with some medications, and the use of any medications or dietary supplements they may not report. Acetaminophen overdose is common; patients must ensure that they are not taking a combined dose of acetaminophen from two or more medications that exceeds a maximum daily dose of 3,250 mg.

Nutrition

Foods that can trigger headaches include aspartame, caffeine, chocolate, monosodium glutamate, and red wine and other alcohol. The patient should be aware of any foods that trigger his or her headaches (a migraine diary is helpful for this) and should avoid them. Some medications should be taken with food, and taking some (oral) medications on a full stomach may slow absorption of the drug.

Complementary and Alternative Medicine

Some patients use feverfew to prevent migraines. The active ingredients in feverfew are the sesquiterpene lactones, which have an anti-inflammatory effect that blocks the transcription of inflammatory proteins and inhibits the release of serotonin. A minimum of 0.2% is the recommended dosage. Side effects include nausea, flatulence, diarrhea, and indigestion. Withdrawal symptoms when stopping long-term use can include muscle stiffness, anxiety, and rebound migraines. It also has anticoagulant properties, so prothrombin time and INR levels should be checked periodically, and it should be stopped 2 weeks before surgical procedures.

Another dietary supplement used for migraine prophylaxis is butterbur. This contains petasin and isopetasin, which have vasodilatory properties and inhibit leukotriene synthesis, reducing inflammation. A dose of 50 mg twice daily has been shown to reduce migraines (Grossman & Schmidramsl, 2001). There should be at least 7.5 mg petasin in the preparation. Side effects include abdominal pain, distended abdomen, and reduced urinary output.

Magnesium, high-dose riboflavin (vitamin B_2), and coenzyme Q10 have also been shown to reduce migraines (Goadsby & Sprenger, 2010).

Case Study*

J.J., age 24, presents to your practice for the first time. She reports constant headaches. She smokes a pack of cigarettes a day but is in good health otherwise. She states that the headaches usually occur in the morning and last a few hours. The pain, localized to an area near her right temple, has a throbbing quality. The headache often results in nausea and vomiting and sensitivity to bright lights. She has tried to treat the headaches with acetaminophen, ibuprofen, and naproxen unsuccessfully. The headaches are causing her to miss work, and she is afraid she will lose her job.

Diagnosis: Migraine Headaches without Aura

1. List specific goals of therapy for J.J.
2. What drug therapy would you prescribe? Why?
3. What are the parameters for monitoring success of the therapy?
4. Discuss specific patient education based on the prescribed therapy.
5. List one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What would be the choice for the second-line therapy?
7. What OTC and/or alternative medicines might be appropriate for this patient?
8. What dietary and lifestyle changes might you recommend?
9. Describe one or two drug–drug or drug–food interactions for the selected agent.*

39 Seizure Disorders

Quinn A. Czosnowski ■ Craig B. Whitman ■ Laura Aykroyd

Epilepsy is a common neurologic condition affecting an estimated 2.2 million people in the United States and is the nation's fourth most common neurologic disorder. Every year, approximately 150,000 new cases are diagnosed with the highest rate occurring in children and older adults. Epilepsy is a complex neurologic disorder best defined as recurrent seizure activity. A single seizure does not constitute epilepsy unless a brain abnormality is identified, which may result in future seizure episodes. It is a multifaceted disease with various physical manifestations, prognoses, outcomes, and responses to treatment. Frequent seizures can lead to neuronal damage, which may lead to changes in memory and other cognitive functions. Therefore, it is important for the practitioner to be aware of the various etiologies and to screen patients appropriately with accurate and reliable diagnostic testing. With appropriate diagnosis and treatment, more than 90% of people with epilepsy lead normal, healthy, and productive lives.

Causes

Seizures can occur at any age, with etiology varying by age. The most common cause of epilepsy is idiopathic, accounting for about 65% of all cases. Other causes of epilepsy include vascular abnormalities (11%), congenital malformations (8%), and trauma (5%). Seizures from degeneration, infection, and neoplasm are considerably less prevalent. In newborns and infants, perinatal injuries, metabolic defects, congenital malformations, and infection are more likely causes of epilepsy, but still less frequent than the idiopathic diagnoses.

Some cases of epilepsy are hereditary or congenital (present at birth), and some are acquired (e.g., serious head injury, a central nervous system [CNS] infection, stroke, or dementia). However, not all people with these disorders develop epilepsy. This suggests that there is a certain threshold that plays a role in the development of epilepsy and may be based on individual biochemistry. Why a person may have a seizure at one time rather than another relates to cause. This further suggests that there may be immediate triggers that can provoke an attack in a predisposed person (e.g., sudden seizure activity in people who are playing video games, working with a calculator, or listening to a particular piece of music). These sensory triggers are uncommon and are often referred to as *reflex epilepsy*.

Predisposing factors that may cause epilepsy more often are sleep deprivation, hyperventilation, fever from underlying illness, hormonal changes occurring during menses, and drug or alcohol ingestion. All of these may lower the seizure threshold and provoke seizures in people who are predisposed.

Several acute metabolic, infectious, medication-related, and other disorders (e.g., alcohol or drug withdrawal, viral meningitis, or hypoglycemia from an overdose of insulin) are associated with seizures. However, upon recovery from these disorders, a person is not necessarily predisposed to future seizures. These are known as *secondary* or *acute* seizures rather than epilepsy.

Pathophysiology

To understand the pathophysiologic process of an epileptic seizure, it is necessary to understand normal neuronal conduction. Normal cellular transmission between nerve cells is dependent on a normal distribution of positively or negatively charged ions between the inside and the outside of the cell. In normal human physiology, there is a resting membrane potential (70 μV) that leaves the inside of the cell negatively charged with respect to the outside of the cell. A stimulus is needed to produce a cellular discharge, and once stimulated, an action potential is generated. After the generation of the action potential, there is a brief period during which the nerve cell membrane is hyperpolarized, which makes it more difficult for a second action potential to be generated until the normal resting membrane ionic gradient is restored.

Communication between neurons occurs through highly specialized structures called *synapses*. There are hundreds of synapses on each neuron. In these synapses, neurotransmitters are released from vesicles in the neurons where they are stored and then diffuse across the synaptic region to contact specific receptors. Once stimulated, the receptors can open or close a specific ion channel. There are two types of ion channels—excitatory and inhibitory. The channels consist of a number of different protein substances. The main inhibitory neurotransmitter in the CNS is gamma-aminobutyric acid (GABA). There are several excitatory neurotransmitters as well, including glutamate and aspartate. These chemicals can activate several different receptors that, depending on their action, can excite or inhibit a group of nerve cells.

To produce an actual seizure, a large group of nerve cells (neurons) must fire abnormally and together. It is thought that this firing occurs within certain highly organized areas of the brain that tend to support seizure activity. This is known as an *epileptic focus*. When epileptic discharges (focus) occur, normal inhibitory circuits (GABA-ergic) begin to fire, which tends to limit the size of the focus. The implication is that a seizure may result from impairment of the inhibitory brain nerve cells or conditions in which there is abnormal excitation. The epileptic focus that is produced may lead to a focal seizure only in the involved area of the brain, or the discharge may travel through other pathways to become more generalized and involve the entire brain. Clinical manifestations of a seizure can be classified by type of seizure, but the manifestations depend on the balance between abnormal, excitatory, and inhibitory neuronal firing, the location of the epileptic focus, and the patterns and degree of spread of the epileptic focus.

Classification of Seizures

The International Classification of Epileptic Seizures (ICES) categorizes seizures in two major groups: partial seizures and generalized seizures. The terminology used by the ICES, however, is not always the same as that used by many clinicians. For instance, many practitioners call the ICES "absence" seizure a *petit mal*, and the designation "tonic–clonic" is often referred to as a *grand mal* seizure. A complex partial seizure is often referred to as a *psychomotor* or *temporal lobe* seizure, and a simple partial seizure has been called *focal* or *jacksonian*.

Furthermore, classifying epileptic seizures by seizure type is difficult because seizures often appear within a cluster of other signs and symptoms. To help classify seizure type, physicians may look for precipitating factors, age of onset, severity, chronicity, diurnal or circadian cycling, anatomic location of seizure focus, and physical manifestations to help define the patient's treatment and prognosis.

Partial (Focal, Local) Seizures

Partial seizures begin in a localized area of the brain, although there may be generalization to involve both hemispheres. Simple partial (focal) seizures typically result in no alteration of consciousness, and the first clinical and electroencephalogram (EEG) change indicates an initial activation of nerve cells in a limited part of one cerebral hemisphere.

The patient's symptoms are determined by the anatomic location of the seizure focus. There may be motor, sensory, autonomic, or psychic symptoms. These may evolve into complex partial or secondary generalized tonic–clonic seizures. An EEG recorded during this time may show some low-voltage fast activity, rhythmic spikes, and slow-wave activity.

Complex partial seizures (psychomotor) are associated with impaired consciousness and with some form of automatic behavior (automatisms). This type of seizure can evolve from a simple partial seizure and can generate into a secondarily generalized tonic–clonic seizure. The EEG may show a unilateral or bilateral, low-voltage, fast activity with rhythmic spikes and slow waves. Complex partial seizures may be preceded by an aura.

Generalized (Convulsive or Nonconvulsive) Seizures

Generalized seizures involve both hemispheres of the brain from the onset, and they result in early loss of consciousness. Generalized seizures may involve only loss of consciousness (similar to absence seizures), or they may result in generalized tonic–clonic, clonic, or myoclonic seizures.

Absence seizures (petit mal) usually have a sudden onset, are brief (often lasting less than 10 seconds), and interrupt ongoing activities. The patient exhibits a blank stare and is usually unresponsive when spoken to, although at times the patient may be able to relate what was said to him or her during the initial phase of the seizure. There may be some mild

clonic or tonic jerking, but it is not prolonged. There is abrupt onset and discontinuation. There is no postictal confusion, which may be characteristic of other seizure types, and there are no other associated symptoms. The EEG shows a very rhythmic, 3 cycles/s spike-wave discharge during the event. There is often confusion as to the diagnosis of absence seizures versus complex partial seizures. Absence seizures are usually restricted to childhood and are provoked by hyperventilation.

A subtype of absence seizure is the *atypical absence seizure*, in which the alteration of consciousness may not be complete. A child experiencing this type of seizure may continue with some activities. There may be an associated loss of muscle tone of the face and neck muscles, and there may be mild clonic twitching of the eyelids and mouth. The onset and discontinuation of this type of seizure is gradual.

Tonic–clonic seizures (grand mal) are associated with abrupt loss of consciousness. There may be some vague, ill-defined warning signs but no true aura. The patient experiences a sudden, sharp, bilaterally symmetric contraction of muscles and may cry, fall, or do both. The patient's head may be extended and appear cyanotic. There may be associated tongue biting and incontinence. Depressed consciousness that can be prolonged (several hours) characterizes the postictal period, during which the patient exhibits bilaterally symmetric clonic jerking of the extremities, increased salivation and frothing at the mouth, and deep respiration and relaxation of muscles. After the postictal period, the patient usually reports waking with muscle stiffness and headache. The EEG typically shows generalized high-voltage, spike-wave activity.

Clonic seizures consist of rapidly repetitive bilateral jerking of the extremities and facial muscles with loss of consciousness. The postictal phase is usually short.

Atonic seizures (drop attacks or astatic seizures) are characterized by a sudden loss of muscle tone, which may be only fragmentary. This type of seizure may be brief and not associated with loss of consciousness. It can occur in a repetitive, rhythmic, and successive manner and may be seen in patients with more diffuse neurologic insult and psychomotor retardation. Atonic seizures are frequently associated with Lennox–Gastaut syndrome, a pediatric epilepsy associated with multiple seizure types, mental retardation, and abnormal EEG findings.

Myoclonic seizures are sudden, brief, shock-like muscular contractions. They may be generalized or they may be confined to the face and trunk muscles, to one or more of the extremities, or to individual muscle groups. Myoclonic seizures can occur regularly in a repetitive manner, or they can be sporadic. These seizures may accompany other neurologic conditions, such as metabolic or toxic states, as well as epilepsy.

Tonic seizures consist of brief, generalized tonic contractions with associated head extension, possible stiffening of the back, and stiffening of all four extremities. These seizures can be associated with autonomic symptoms, a rapid heart rate, and cessation of breathing followed by cyanosis. This type of seizure is also seen in Lennox-Gastaut syndrome and may be precipitated during slow-wave sleep.

Status Epilepticus

Status epilepticus (SE) is a life-threatening emergency that requires immediate identification and treatment. The standard definition is seizure activity persisting for more than 30 minutes or two or more sequential seizures without recovery between them. Clinical practice and recent guidelines define SE as continuous clinical and/or electrographic seizure activity persisting for more than 5 minutes or recurrent seizure activity without recovery between seizures. Thirty-day mortality of convulsive SE is estimated as 19% to 27% and as high as 65% in nonconvulsive status. Significant morbidity is also associated with SE with the poorest functional outcomes in patients with refractory seizures. Precipitating factors include drug noncompliance and sudden withdrawal from antiepileptic drugs (AEDs), CNS infection, withdrawal from alcohol or sedative drugs, metabolic disturbances, sleep deprivation, stroke, trauma, or encephalitis.

Diagnostic Criteria

The accurate diagnosis of a seizure helps the health care provider decide whether to initiate or withhold drug treatment and which medications to prescribe. A well-conducted history and physical and neurologic examinations may allow a diagnosis of epilepsy to be made without further diagnostic or laboratory testing. The initial assessment should include associated factors (e.g., age, medical history, precipitating events), symptoms during the seizure (e.g., aura, behavior, motor symptoms, loss of consciousness), and symptoms following a seizure (e.g., postictal state). Unfortunately, many of the manifestations of epilepsy are subtle, making diagnosis and classification difficult. In fact, no single test, clinical finding, or symptom is reliable by itself to discriminate between epilepsy and nonepileptic events.

One of the most useful and standard tests for assisting in the diagnosis of epilepsy is the EEG. The EEG is a brain wave tracing showing voltage fluctuations versus time that is recorded from scalp electrodes placed in specific locations on the head (i.e., montages). An EEG is recommended as part of the neurodiagnostic evaluation of children and adults presenting with an apparent unprovoked first seizure.

Neurologic imaging studies also help in the diagnosis of epilepsy. Computed tomography (CT) scanning of the brain is used to detect masses or lesions, bleeding, or stroke-like conditions. Magnetic resonance imaging (MRI), although helpful in diagnosing lesions, bleeding, and stroke-like states, also helps find more subtle brain abnormalities, including medial temporal sclerosis. Current guidelines recommend the use of CT or MRI as part of the initial neurodiagnostic evaluation of adults presenting with an apparent unprovoked first seizure. MRI is the preferred imaging study for use in children. Other less frequently used tests include cerebral arteriography and positron emission tomography (PET). Cerebral arteriography may detect vascular malformation, aneurysms, and significant vascular disease. PET helps particularly in diagnosing partial epilepsy. PET scans measure regional cerebral blood flow and metabolism both during and between seizures. However, PET scanning is expensive, and some insurance carriers do not approve the test for reimbursement.

Initiating Drug Therapy

The selection of the ideal AED depends on several factors, including seizure type and the age and sex of the patient. Treatment with AEDs starts after the diagnosis is confirmed and the patient has experienced two or more seizures. If a patient has one or more risk factors for recurrent seizures (EEG abnormalities, structural lesions, partial seizures, or a family history), then pharmacotherapy can be initiated.

Many epilepsy specialists advocate monotherapy as the first principle of management. If monotherapy fails, replacement by a second AED is recommended. Monotherapy has several advantages, including increased compliance. The most frequent cause of failure to control seizure activity is the patient's lack of adherence to drug therapy. Management of toxicity is easier with monotherapy because adverse events often can be correlated with serum drug levels. Some epilepsy specialists report that up to 75% of their patients have had complete seizure control on monotherapy.

Usually, when monotherapy with several drugs has failed, polytherapy may be tried. In contrast to monotherapy, polytherapy may increase the risk of chronic toxicity in the patient. Whenever two or more drugs are used simultaneously, decisions regarding therapy become more complex, and there is an increased risk of adverse events and drug interactions.

The particular drug selected depends on the seizure type and toxicity. Table 39.1 and Figure 39.1 outline the recommended treatment order and algorithm of treatment.

TABLE 39.1 Recommended Order of Treatment for Epileptic Seizures

	Partial (Both Simple and Complex) Seizures	Generalized Tonic–Clonic Seizures	Absence Seizures	Atypical Absence, Myoclonic, and Atonic Seizures
First-line therapy	carbamazepine, phenytoin, fosphenytoin, valproic acid, lamotrigine, lacosamide, topiramate, oxcarbazepine	carbamazepine, lacosamide phenytoin, valproic acid, fosphenytoin	ethosuximide, valproic acid, lamotrigine	valproic acid
Second-line therapy (alternative therapy)	eslicarbazepine, ezogabine, felbamate, gabapentin, levetiracetam, perampanel, phenobarbital, pregabalin, primidone, tiagabine, vigabatrin	felbamate, gabapentin, lamotrigine, levetiracetam, phenobarbital, primidone, ethotoin, mephobarbital, mephenytoin, vigabatrin	clonazepam, parmethadione, trimethadione, methsuximide, phensuximide	Clonazepam, levetiracetam

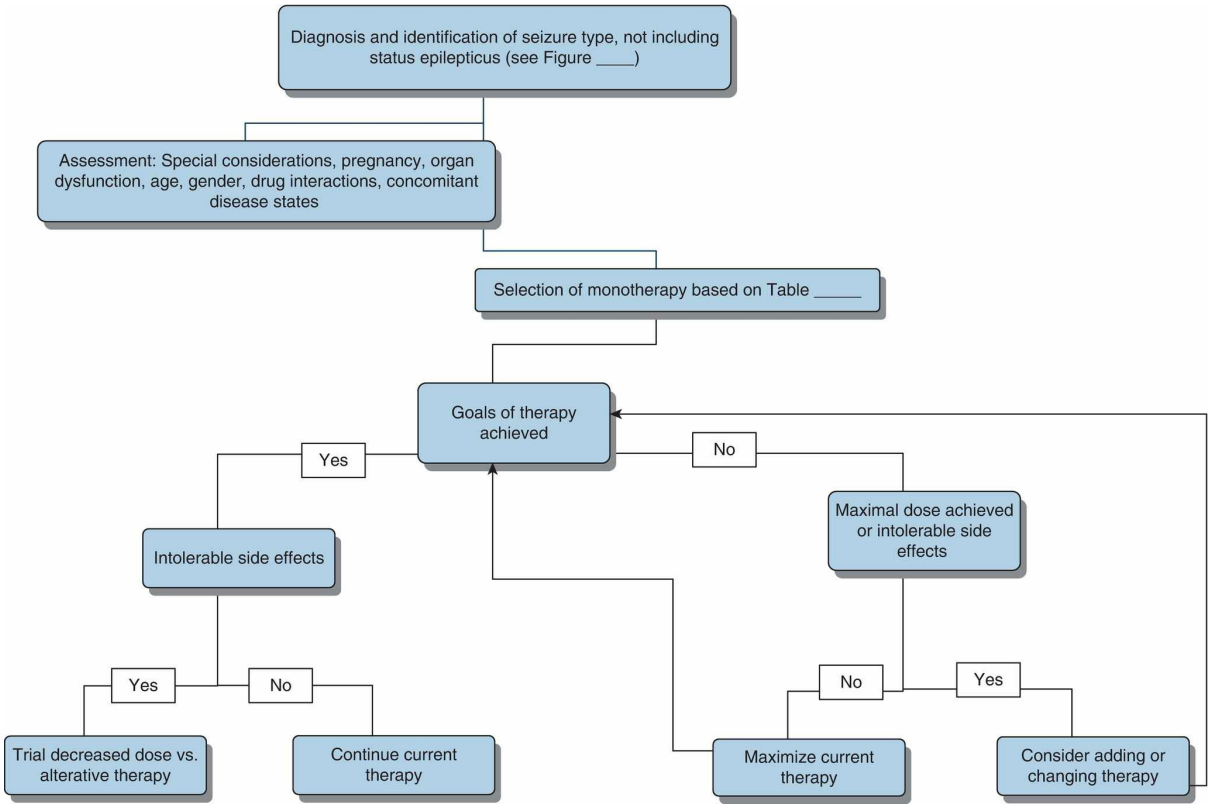

FIGURE 39.1 Treatment algorithm for epilepsy.

Surgical Treatment of Epilepsy

The surgical treatment of epilepsy has become an important therapeutic modality. Candidates for surgery may include patients who have failed multiple medical therapies, with refractory SE or who experience intolerable drug side effects. Various surgical procedures can be performed, including anterior temporal lobectomy, amygdalohippocampectomy, extratemporal focus removal, lesionectomy, corpus callosotomy, and hemispherectomy. Outcomes are generally good with approximately 70% of patients seizure free after a temporal lobectomy.

Goals of Drug Therapy

The drug treatment of patients with epilepsy is designed to reduce the number of seizures. A realistic goal for most patients is to completely control seizures, ideally achieved with monotherapy. In addition to controlling seizures, another goal should be improving the patient's quality of life by allowing a return to normal activities of daily living without restriction (except driving; see Patient Education).

Hydantoins (Phenytoin and Fosphenytoin)

Indications/Uses

One of the oldest and most effective AEDs is phenytoin (Dilantin). Fosphenytoin (Cerebyx), a prodrug, was approved 40 years later and is used for the same indications as its parent compound, phenytoin. Hydantoins are effective in treating a wide range of seizure types, including generalized tonic–clonic as well as simple or partial seizure activity. In either case, they can be used as first-line agents for monotherapy. Phenytoin is one of the most commonly used anticonvulsants for generalized tonic–clonic (grand mal) seizure activity and for simple and complex partial seizures. It can also be used to prevent early posttraumatic seizures occurring within 7 days after a traumatic brain injury.

Mechanism of Action

Phenytoin blocks posttetanic potentiation by stabilizing neuronal membranes. It decreases seizure activity by increasing the efflux or decreasing the influx of sodium ions across cell membranes in the motor cortex during generation of nerve impulses. It also regulates neuronal excitability by inhibiting calcium conduction through altering calcium uptake in presynaptic terminals and preventing cyclic nucleotide accumulation and cerebellar stimulation. Phenytoin is the active moiety of fosphenytoin, after administration fosphenytoin is converted to phenytoin by plasma esterases.

Dosage

Phenytoin is available in multiple dosage forms, including chewable tablets, extended-release capsules, suspension, and intravenous (IV). Regardless of dosage form, a loading dose of phenytoin is typically given to achieve a therapeutic level as quickly as possible. The loading dose is 15 to 20 mg/kg/d in both adults and children. The maximum infusion rate for IV administration of phenytoin is 50 mg/min to avoid cardiovascular collapse or 25 mg/min in patients with preexisting cardiac disease. If given orally, it is divided into three doses given every 2 to 4 hours to increase tolerability with a max of 400 mg per dose secondary to absorption. Following a loading dose, the normal maintenance dose is 4 to 6 mg/kg/d in adults and 5 to 12 mg/kg/d in children based on age. Absorption is also impaired when administered in patients on continuous enteral nutrition; therefore, it is recommended to hold enteral nutrition feeds 1 to 2 hours before and after each phenytoin dose given per feeding tube.

The dose, concentration in solutions, and infusion rates for fosphenytoin are expressed as phenytoin sodium equivalents. Fosphenytoin should always be prescribed in phenytoin sodium equivalents: 75 mg of fosphenytoin sodium = 50 mg of phenytoin sodium (see Table 39.2). Fosphenytoin is given as a loading dose of 15 to 20 phenytoin equivalents/kg followed by a maintenance dose of 4 to 6 phenytoin equivalents/kg/d. Advantages include

the ability to give it as an intramuscular injection in those without IV access and at a maximum infusion rate of 150 phenytoin equivalents/min.

TABLE 39.2 Overview of Antiepileptic Drugs

Generic (Trade) Name	Significant Metabolic/ Transporter Interactions	Selected Adverse Events	Contraindications	Special Considerations
phenytoin (Dilantin) Loading dose: 15–20 mg/kg IV. If PO, give in divided doses q2–4h to decrease GI adverse events SE: 20 mg/kg IV loading dose Maintenance dose: 300 mg/d or 5–6 mg/kg/d in three divided doses or qd–bid using an extended-release form of the drug	Strong inducer: CYP2B6, CYP2C19, CYP3A4 Major substrate: CYP2C19, CYP2C9	Nystagmus, ataxia, cognitive impairment, lethargy, gingival hyperplasia, increase in body hair, coarsening of facial features, acne, folate deficiency, skin rash	Heart block; sinus bradycardia Pregnancy Category D	Avoid IM and SQ administration due to pain, erratic absorption, and risk of local tissue damage An in-line 0.22–5 mcg filter is recommended for IVPB solutions. Therapeutic ranges: Neonates: 8–15 mcg/mL total phenytoin; 1–2 mg/mL free phenytoin Children and adults: Total concentration: 10–20 mcg/mL Free: 1–2.5 mcg/mL
fosphenytoin (Cerebyx) See dosing recommendation above; order in phenytoin equivalents (PE)	See phenytoin	See phenytoin	See phenytoin	See phenytoin
carbamazepine (Tegretol) 6–12 y: 20–30 mg/kg/d in 2–4 divided doses per day; usual dose is 400–800 mg/d, maximum 1 g/d 12 y–adult: usual dose 800–1,200 mg/d in 3–4 divided doses	Strong inducer: CYP1A2, CYP2B6, CYPC19, CYP3A4 Major substrate: CYP3A4 (causes autoinduction starting between days 3 and 5 of therapy and maximal effects within 4 wks)	Hematologic abnormalities, drowsiness, fatigue, ataxia, SIADH, rash (Stevens-Johnson syndrome), GI upset, confusion, nystagmus, and seizures	Hypersensitivity to tricyclic antidepressants, bone marrow suppression, recent use of an MAO inhibitor (≤14 d) Pregnancy Category D	Oral suspension should not be administered simultaneously with other liquid medicinal agents or diluents. To avoid GI upset, take with food or water and divide doses. The appearance of a rash does not automatically rule out using carbamazepine. Therapeutic ranges: 6–12 mcg/mL; 4–8 mg/mL if used in combination with other AEDs; toxic >15 mcg/mL
oxcarbazepine (Trileptal) Initial dose: 300 mg bid; increased by 600 mg/d at weekly intervals Children 4–16 y: 8–10 mg/kg in 2 divided doses/d, not to exceed 600 mg/d		Dizziness, diplopia, ataxia, headache, weakness, rash, hyponatremia	Pregnancy Category C	Commonly leads to hyponatremia; elderly at higher risk
eslicarbazepine (Aptiom) Initial dose: 400 mg daily; increased to 800 mg/d after 1 wk. Max dose 1,200 mg/d Dose adjustment for CrCl <50 mL/min	Moderate inducer of CYP3A4 Moderate inhibitor of CYP2C19 Substrate of UGT2B4	Dizziness, somnolence, diplopia, fatigue, nausea, ataxia, cognitive dysfunction, vomiting, abnormal vision, abdominal pain, tremor, dysgeusia, abnormal gait, and hyponatremia (decrease > 10 mEq/L)	History or presence of second- or third-degree AV block Oxcarbazepine use Pregnancy Category C	
valproic acid (Depakote, Depakene) Children and adults: 30–60 mg/kg/d in 2–3 divided doses SE: 20–40 mg/kg loading dose Dose adjustment: Reduce dose in hepatic impairment and avoid in severe impairment.	Weak inducer: CYP2A6 Weak inhibitor: CYP2A6 Minor substrate: CYP, 2A6, 2B6, 2C18, 2C9, 2E1	Lethargy, GI upset, weight gain, alopecia, hepatitis	Hepatic dysfunction; hepatic failure resulting in death has occurred, and children <2 y are at considerable risk. Pregnancy Category X for migraine prophylaxis/D for other indications	Therapeutic range: total concentration 50–100 mcg/mL; toxic > 200 mcg/mL Free: 4–15 mcg/mL Seizure control may improve at levels > 100 mcg/mL Toxicity may occur at levels of 100–150 mcg/mL Take with food or milk; do not administer with carbonated drinks.
ethosuximide (Zarontin) Children 3–6 y: 15–40 mg/kg/d in 2 divided doses Children > 6 y and adults: 20–40 mg/kg/d in 2 divided doses	Major substrate: CYP3A4	Nausea, GI upset, hiccups, headache	Pregnancy Category C	Seldom-used drug for absence seizures in children Therapeutic range: 40–100 mg/L
phenobarbital Infants: 5–8 mg/kg/d in 1–2 divided doses Children 1–5 y: 6–8 mg/kg/d in 1–2 divided doses Children 5–12 y: 4–6 mg/kg/d in 1–2 divided doses Children >12 y–adults: 1–3 mg/kg/d in 2–3 divided doses or 50–100 mg bid–tid SE: 20 mg/kg loading dose; may give additional 5–10 mg/kg after 10 min	Strong inducer: CYP1A2, CYP2A6, CYP2B6, CYP2C8, CYP2C9, and CYP3A4 and P-glycoprotein Major substrate: CYP2C19	Sedation, ataxia, cognitive impairment, hyperactivity, rash, problems with sleep, megaloblastic anemia (responds to folic acid)	Use caution in patients with hypovolemic shock, congestive heart failure, hepatic impairment, respiratory dysfunction or depression, previous addiction to the sedative/hypnotic group, chronic or acute pain, renal dysfunction, and the elderly. (Because of its long half-life and addiction potential, phenobarbital is not recommended as a sedative in the elderly.) Pregnancy Category D	Avoid rapid IV administration (>50 mg/min). Do not add IV form to acidic solutions. Tolerance, or psychological and physical dependence, may occur with prolonged use. Abrupt withdrawal in patients with epilepsy may precipitate status epilepticus. Therapeutic ranges: Infants and children: 15–30 mcg/mL Adults: 20–40 mg/mL Toxic range: >40 mcg/mL
primidone (Mysoline) Children < 8 y: 10–25 mg/kg/d tid–qid Children > 8 y–adults: Start at 100–125 mg qhs for 3 d; then, increase to 100–125 mg bid for 3 d; then, increase to up to 250 mg tid	Strong inducer: CYP1A2, CYP2A6, CYP2B6, CYP2C8, CYP2C9, and CYP3A4 and P-glycoprotein	Same as phenobarbital	Porphyria Use caution in renal or hepatic impairment or pulmonary insufficiency. Pregnancy Category D	Folic acid as a supplement to avoid folic acid deficiency and megaloblastic anemia: Adults: 5–12 mcg/mL Children <5 y: 7–10 mcg/mL Toxic level: >15 mcg/mL Be consistent with protein intake during primidone therapy. (Low-protein diets increase the duration of action.) Avoid foods high in vitamin C because of displacement of drug from binding sites.
ezogabine (Potiga) 100 mg TID; increase at weekly intervals by no more than 150 mg/d. Max dose 1,200 mg daily—no benefit demonstrated above 900 mg Dose reduction in elderly, CrCl <50 mL/min, or hepatic impairment	Inhibits: OAT3, P-glycoprotein	Loss of visual acuity—black box warning, skin discoloration (bluish, gray-blue, brown), confusion, hallucinations, urinary retention, QT prolongation, drowsiness, impaired coordination, gait disturbances	Pregnancy Category C	If no substantial benefit after adequate titration, then DC and consider other therapies Black box warning—ability to cause retinal abnormalities and loss of visual acuity ~1/3 of patients at 4 y Baseline eye exams and then every 6 mos QT prolongation—credible meds.org

Generic (Trade) Name	Significant Metabolic/ Transporter Interactions	Selected Adverse Events	Contraindications	Special Considerations
gabapentin (Neurontin) 900–1,800 mg/d in 3 divided doses Children >12 y: 300 mg on day 1 at bedtime; 300 mg bid on day 2; 300 mg tid on day 3 Dose adjustment; renal failure (CrCl < 60 mL/min)		Ataxia, fatigue, dizziness, somnolence, weight gain, GI upset	Pregnancy Category C	Dosage adjustments for patients with renal impairment: CrCl >60 mL/min: 1,200 mg/d CrCl 30–60 mL/min: 600 mg/d CrCl 15–30 mL/min: 300 mg/d CrCl <15 mL/min: 150 mg/d
tiagabine (Gabitril) Children 12–18 y: 4 mg qd for 1 wk; may increase to 8 mg daily in 2 divided doses for 1 wk; then may increase by 4–8 mg weekly to response or up to 32 mg in 2–4 divided doses/d Adults: 4 mg qd for 1 wk; may increase by 4–8 mg/wk to response or up to 56 mg in 2–4 divided doses/d	Major substrate: CYP3A4	Dizziness, somnolence, asthenia, confusion, GI upset, anorexia, fatigue, impaired concentration, speech or language problems, confusion	Pregnancy Category C	Should be taken with food
lamotrigine (Lamictal) Children 2–12 y with concomitant AEDs without valproic acid therapy: 5–15 mg/kg/d, max. 400 mg/d in 2 divided doses Adults: 100–400 mg/d in 1–2 doses/d Dose adjustment: Children 2–12 y with concomitant valproic acid therapy: 1–5 mg/kg/d; max. 200 mg/d in 2 divided doses Adults with concomitant valproic acid therapy: 50–200 mg/d in 2 divided doses	Inhibits OCT2	Dizziness, headache, rash, ataxia, tremor, GI upset, diplopia, Stevens-Johnson syndrome (rare)	Use with caution with lactation, hepatic or cardiac dysfunction, and in children. Pregnancy Category C	Take without regard to meals; drug may cause GI upset. Immediately report development of a rash. Gradually decrease dosage (taper) over 2 wk when discontinuing drug therapy. If doses held for >5 half-lives, consider restarting using initial dosing recommendations
perampanel (Fycompa) Initial dose: 2 mg/d at bedtime; increase by 2 mg every 7 d. Maximum dose 12 mg/d If on enzyme-inducing AEDs: Initial dose 4 mg/d at bedtime Dose reduction in mild to moderate hepatic impairment Avoid if CrCl < 30 mL/min	Major substrate: CYP3A4	Perampanel carries a black box warning due to its potential to cause serious life-threatening neuropsychiatric events (aggression, anger, homicidal thoughts, and hostility). Common side effects include dizziness, somnolence, headache, fatigue, gait/balance disturbances, and falls	Pregnancy Category C	Watch for neuropsychiatric symptoms with initiation and titration.
levetiracetam (Keppra) 500 mg twice daily; max 3,000 mg SE: loading dose of 1,000–3,000 mg		Somnolence, asthenia, fatigue, dizziness, ataxia, anorexia, cognitive difficulties, tremor, dizziness, ataxia, headache, fatigue, GI upset, renal calculi	Hypersensitivity to sulfonamides; hypersensitivity to topiramate or any of its components Pregnancy Category C	Limited drug interactions Concentrations only helpful to assess compliance to therapeutic regimen; no therapeutic range Maintain adequate fluid intake.
lacosamide (Vimpat) Initial dose monotherapy: 100 mg twice daily, increased by 100 mg/d at weekly intervals Initial dose adjunctive therapy: 50 mg twice daily; increased by 100 mg/d at weekly intervals Maximum dose of 300 mg/d in patient with CrCl < 30 mL/min or mild/moderate hepatic impairment	Substrate: CYP3A4, CYP2C9, CYP2C19	Common adverse events seen include dizziness, fatigue, somnolence, blurred vision, diplopia, nausea, and tremor. Increases in PR interval, second- and third-degree AV block, syncope, atrial fibrillation, and atrial flutter may occur, especially in patients with a history of cardiovascular disease.	History of/current second- or third-degree AV block Pregnancy Category C	Use caution in patients with cardiac history. Consider ECG monitoring at baseline and when at steady state in patients with significant cardiac history.
topiramate (Topamax) Adults: initial: 50 mg/d; titrate by 50 mg/d at 1-wk intervals to a target dose of 200 mg bid Dose adjustment: CrCl <70 mL/min: administer 50% of dose and titrate more slowly.		Cognitive difficulties, tremor, dizziness, ataxia, headache, fatigue, GI upset, renal calculi	Hypersensitivity to topiramate or any of its components Pregnancy Category D	Maintain adequate fluid intake.
zonisamide (Zonegran) Initial dose: 100 mg daily, titrated by 100 mg every 2 wk for a maintenance dose of 400–600 mg/d Not recommended in CrCl < 50 mL/min	Major substrate of CYP3A4	Fatigue, dizziness, ataxia, and anorexia Psychiatric symptoms, psychomotor slowing, fatigue, and somnolence more common with doses > 300 mg/d	Sulfonamide allergy	
rufinamide (Banzel) Adults: initial dose 400–800 mg/d divided in two doses. Titrated by 400–800 mg/d every other day until max dose of 3,200 mg/d If on concurrent valproate, start at 400 mg/d. Children: 10 mg/kg/d in two divided doses; titrate by 10 mg/kg/d every other day until 45 mg/kg/d or 3,200 mg reached. Consider supplemental doses following hemodialysis.		Common: QT shortening, somnolence, fatigue, coordination abnormalities, dizziness, gait disturbances, ataxia, nausea, vomiting, status epilepticus, and rash. Less common but clinically important adverse events include multiorgan hypersensitivity reactions, DRESS, SJS, and leukopenia.	Familial short QT syndrome, history or presence of short QT due to risk of sudden cardiac death Hypersensitivity to triazole derivatives Pregnancy Category C	Must be taken with food

Phenytoin is unique because it is metabolized in a nonlinear manner, exhibiting Michaelis-Menten enzyme kinetics. The enzymes that metabolize phenytoin are saturable, meaning that as the amount of drug approaches this saturation point, small incremental increases in a dose can result in disproportionately high serum levels. Further, as the concentrations reach closer to the saturation point, the half-life of phenytoin increases. This must be considered when adjusting phenytoin doses.

The therapeutic serum concentration of phenytoin is 10 to 20 mcg/mL in a person with a normal albumin level, while the therapeutic level of free, unbound phenytoin is 1 to 2.5 mcg/mL. In clinical scenarios in which protein binding is impaired, such as hypoalbuminemia, or concurrent medication therapy competes for protein-binding sites, the free fraction and pharmacologically active component are increased. Equations have been developed to help prescribers estimate free fraction in states of hypoalbuminemia, renal failure, and critical illness.

Contraindications

There are no absolute contraindications for phenytoin other than allergy (Table 39.2). It carries a black box warning for severe cardiovascular events (hypotension and arrhythmias) with rapid IV administration.

Adverse Events

Phenytoin exhibits adverse effects specific to dosage form and serum concentration in addition to other adverse effects. Common adverse events across dosage forms and concentrations include gingival hyperplasia, hirsutism, coarsening of facial features, rash, ataxia, altered coordination, nystagmus, confusion, peripheral neuropathy, vitamin D deficiency and osteopenia, hepatitis, megaloblastic anemia, thrombocytopenia, and mild sensory polyneuropathy. Serious but less common adverse events include blood dyscrasias (anemia, neutropenia, leukopenia, thrombocytopenia), hepatitis, Stevens-Johnson syndrome (SJS), drug reaction with eosinophilia and systemic syndromes (DRESS), and systemic lupus erythematosus (SLE). The IV forms of phenytoin and fosphenytoin carry boxed warnings for cardiovascular events with rapid infusion including hypotension, bradycardia, cardiac arrhythmias, cardiovascular collapse (especially with rapid IV use), venous irritation, thrombophlebitis, and possibly death. The IV formulations of phenytoin are also associated with local tissue necrosis following extravasation. Concentration-specific adverse effects of phenytoin are listed in Table 39.3.

TABLE 39.3 Relationship between Total Serum Concentration of Phenytoin and Adverse Events

Serum Concentration	Adverse Events
>20 mcg/mL	Far lateral nystagmus
>30 mcg/mL	45 degrees lateral gaze nystagmus and ataxia
>40 mcg/mL	Decreased mentation and lethargy
>100 mcg/mL	Lethal

Interactions

Phenytoin is a cytochrome P450 CYP2C9 and CYP2C19 enzyme substrate and a CYP1A2, CYP2C9, CYP2D6, and CYP3A3/CYP3A4 enzyme inducer. In addition to enzyme interactions, because of the high protein binding exhibited by phenytoin, it may be displaced by other highly protein-bound drugs, such as valproic acid and salicylic acid. Drug interactions occur frequently with phenytoin and can have a significant impact on therapeutic outcomes. Box 39.1 contains a list of non-AEDs that interact with phenytoin, and Table 39.2 lists AEDs that may interact with phenytoin.

BOX 39.1 Nonantiepileptic Drugs That Interact with Phenytoin

Non-AEDs Affecting Phenytoin Levels

Decreases Phenytoin Levels

Alcohol (long-term use)

Antacids, folic acid, rifampin, tube feedings

Increases Free Phenytoin Levels

Aspirin, diazoxide, tolbutamide

Increases Total Phenytoin Levels

Alcohol (shortly after intake), amiodarone, chloramphenicol, chlordiazepoxide, chlorpheniramine, cimetidine, disulfiram, fluconazole, fluoxetine, imipramine, isoniazid, metronidazole, omeprazole, propoxyphene, sulfonamides, ticlopidine, trazodone

Carbamazepine

Indications/Uses

Carbamazepine is indicated for the treatment of partial and generalized tonic–clonic seizures. It is a first-line drug choice for monotherapy in simple or complex partial seizures with secondary generalization.

Mechanism of Action

Carbamazepine's mechanism of action is not completely understood. It is believed to alter synaptic transmission by limiting the influx of sodium ions across cell membrane channels. Other potential mechanisms of action include depressing activity in the nucleus ventralis of the thalamus or decreasing summation of temporal stimulation.

Dosage

Carbamazepine is available as an immediate-release tablet, extended-release tablet, and oral suspension. The usual starting dosage of carbamazepine is 200 mg twice daily as tablets or 100 mg four times daily as a suspension. Doses should be increased weekly by increments of no more than 200 mg. The usual maintenance dose is 800 to 1,200 mg divided into 2 to 4 doses, depending on the dosage form chosen. The therapeutic plasma concentration is 4 to 12 mg/L. Carbamazepine undergoes autoinduction, which begins 3 to 5 days into therapy and is complete after 21 to 28 days of therapy. This results in a variable drug half-life and time to steady. Patients' serum concentrations will often vary significantly from week 1 of therapy to week 4 of therapy despite remaining on the same dosage of carbamazepine. As a result, frequent monitoring may be required following initiation or changes in dosing. Practitioners should be wary of decreasing a dose for a slightly elevated level during the first month of therapy due to a high likelihood that the serum concentration will decrease as a result of autoinduction. However, if a serum level is low during the first month of therapy, it is highly likely that the patient's level will drop further and a dosage increase is warranted.

Contraindications

Contraindications to carbamazepine include hypersensitivity to carbamazepine or tricyclic antidepressants, bone marrow suppression, recent use of a monoamine oxidase (MAO) inhibitor (≤14 days), and concurrent use of nefazodone, delavirdine, or other nonnucleoside reverse transcriptase inhibitors.

Carbamazepine has black box warnings due to the risk of serious dermatologic reactions in patients with the HLA-B*1502 allele. Asian patients should be screened for the variant HLA-B*1502 allele prior to initiating therapy because this variant is associated with a significantly increased risk of SJS and toxic epidermal necrosis. It also has a black box

warning for aplastic anemia and agranulocytosis. Baseline CBC should be checked with periodic monitoring. Those patients demonstrating decreased WBC or platelets should be monitored more closely for the development of significant bone marrow suppression.

Adverse Events

Common adverse events associated with carbamazepine include pruritus, rash, constipation, nausea, vomiting, ataxia, dizziness, somnolence, blurred vision, urinary retention, xerostomia, and hyponatremia. Serious but less common adverse events include blood dyscrasias, syndrome of inappropriate diuretic hormone secretion (SIADH), cardiac conduction abnormalities, SJS, and DRESS (see Table 39.2). Carbamazepine is not effective in the treatment of myoclonic seizures and may in fact exacerbate seizures in these patients. Concentration-related adverse effects include dizziness, ataxia, drowsiness, nausea, vomiting, tremors, agitation, nystagmus, urinary retention, arrhythmias, coma, seizures, respiratory depression, and cardiac conduction disturbances.

Interactions

Carbamazepine is a significant inducer of numerous CYP450 enzymes, including CYP1A2, CYP2B6, CYP2C9, CYP2C19, and CYP3A4. Caution should be used when administering other medications metabolized via these pathways. It is also a major substrate of CYP3A4. Since it induces CYP3A4 and is metabolized by CYP3A4, it can induce its own metabolism resulting in decreased serum concentrations over time. This effect is complete after approximately 3 to 4 weeks of therapy. Table 39.2 and Box 39.2 list drug interactions among carbamazepine, AEDs, and other drugs.

BOX 39.2 Nonantiepileptic Drugs That Interact with Carbamazepine

Non-AEDs Affected by Carbamazepine

Decreased Levels due to Carbamazepine

Benzodiazepines, corticosteroids, cyclosporine, doxycycline, folic acid, haloperidol, oral contraceptives, theophylline, warfarin

Non-AEDs Affecting Carbamazepine Levels

Increases Carbamazepine Level

Cimetidine, danazol, diltiazem, erythromycin, fluoxetine, imipramine, isoniazid, propoxyphene, verapamil, nicotinamide

Decreases Carbamazepine Level

Alcohol (long-term use), folic acid

Oxcarbazepine

Indications/Uses

Oxcarbazepine (Trileptal) is indicated for monotherapy or as adjunctive therapy in treating partial seizures in adults or in children ages 4 to 16 and as adjunctive therapy for partial seizures in children younger than age 2.

Mechanism of Action

Oxcarbazepine's pharmacologic effect is exerted through oxcarbazepine and the 10-monohydroxy metabolite (MHD) of oxcarbazepine. The exact mechanism by which oxcarbazepine and MHD work is unknown. However, studies indicate that the drug blocks sodium channels, resulting in stabilization of hyperexcited neural membranes and inhibition of repetitive neuronal firing. Increased potassium conductance and modulation of high-voltage activated calcium channels may contribute to the anticonvulsant effect.

Dosage

The typical starting dosage is 300 mg twice daily, increasing by 600 mg/d at weekly intervals. The target maintenance dosage is 600 to 2,400 mg/d. There are no therapeutic levels established for this agent.

Contraindications

Oxcarbazepine is contraindicated in patients with a hypersensitivity to the drug or any of its components. Oxcarbazepine should be avoided in patients who have had a hypersensitivity reaction to carbamazepine because there is a cross-reactivity of about 30% and in patients at risk for hyponatremia (2.5% of patients).

Adverse Events

Common adverse events include dizziness, somnolence, diplopia, fatigue, nausea, ataxia, vomiting, abnormal vision, abdominal pain, tremor, dyspepsia, and abnormal gait (see Table 39.2). Clinically significant hyponatremia (less than 125 mmol/L) has been reported. Elderly are at an increased risk. Oxcarbazepine has been linked to fatal dermatologic reactions, including SJS, and patients with toxic epidermal necrolysis (TEN) should be monitored for signs and symptoms.

Interactions

Oxcarbazepine is a weak inducer CYP3A4. This leads to potential interactions with numerous AEDs, including valproic acid, lamotrigine, carbamazepine, phenytoin, and phenobarbital. Strong inducers of CYP enzymes (carbamazepine, phenytoin, and

phenobarbital) have been shown to decrease plasma levels of the metabolite MHD (29% to 40%). Oxcarbazepine also interacts with non-AEDs metabolized by CYP3A4, including dihydropyridine calcium antagonists and oral contraceptives, leading to decreased plasma concentrations.

Eslicarbazepine

Indications/Uses

Eslicarbazepine is a newer agent approved as an adjunctive therapy for partial-onset seizures in adults 18 years and older.

Mechanism of Action

Eslicarbazepine acetate is primarily converted to the major active metabolite eslicarbazepine along with minor active metabolites of R-licarbazepine and oxcarbazepine. The exact mechanism for eslicarbazepine is unknown but it is thought to block voltage-gated sodium channels resulting in stabilization of hyperexcited neural membranes and inhibition of repetitive neuronal firing.

Dosage

The recommended initial starting dose is 400 mg once daily, which can be increased after 1 week to the recommended maintenance dose of 800 mg once daily. The maximum dose is 1,200 mg once daily. Patients with CrCl < 50 mL/min should receive an initial dose of 200 mg once daily, and titration should occur no more frequently than every 2 weeks by no more than 200 mg with a max dose of 600 mg once daily. There are no published data for use in hemodialysis or severe hepatic impairment.

Contraindications

Contraindications to eslicarbazepine include a history of hypersensitivity to oxcarbazepine or carbamazepine or the presence or history of second- or third-degree AV block.

Adverse Events

Common adverse events include dizziness, somnolence, diplopia, fatigue, nausea, ataxia, cognitive dysfunction, vomiting, abnormal vision, abdominal pain, tremor, dyspepsia, abnormal gait, and hyponatremia (decrease > 10 mmol/L). Severe but less common adverse effects including SJS/TEN, DRESS, severe hyponatremia (less than 125 mmol/L), dose-dependent decreases in serum T3 and T4, and increased liver transaminases and bilirubin have been reported.

Interactions

Eslicarbazepine is a substrate of UGT2B4 as well as a moderate inhibitor of 2C19 and a moderate inducer of CYP3A4. Eslicarbazepine may increase the concentrations of a number of medications that are substrates of CYP2C19; of particular importance is phenytoin. Due to its ability to induce CYP3A4, concomitant use with CYP3A4 substrates

should be avoided if possible due to a decrease in their serum concentrations. Eslicarbazepine concentrations may be increased by carbamazepine and decreased by carbamazepine, phenytoin, phenobarbital, and primidone.

Valproic Acid and Derivatives (Divalproex)

Indications/Uses

Valproic acid and its derivatives (divalproex) are approved as monotherapy and adjunctive therapy in complex partial and complex absence seizures and as adjunctive therapy in patients with multiple seizure types, including absence seizures. It is considered first-line therapy for generalized tonic–clonic, simple partial, complex partial, and absence seizures. It has also been used in the treatment of partial myoclonic seizures, atonic seizures, infantile spasms, and SE.

Mechanism of Action

The exact mechanism is not completely understood but is believed to work by affecting GABA. It has been postulated to affect GABA in numerous ways, including increasing GABA availability, enhancing the action of GABA, and mimicking its action at postsynaptic sites.

Dosage

There are three specific forms of valproic acid available in the United States. While the dosage forms and dosing intervals vary, the total daily starting dose is the same (see Table 39.2). The recommended initial dose is 15 mg/kg/d increasing at 1-week intervals by 5 to 10 mg/kg/d. The dose is titrated to a desired therapeutic effect or toxicity, whichever occurs first. Doses above 60 mg/kg/d are not recommended. The therapeutic range is 50 to 100 mg/L with some patients requiring levels higher than 100 mg/L to achieve seizure control.

Contraindications

Valproic acid is contraindicated in patients with significant hepatic disease and in those with urea cycle disorders.

It carries several black box warnings including the potential for hepatic failure leading to death in all patients as well as an increased risk of hepatotoxicity in patients with known mitochondrial disorders due to mutations in mitochondrial DNA polymerase gamma (POLG). There is a warning for major congenital malformations, in particular spina bifida. It should not be given to women of childbearing age or during pregnancy unless other medications have failed to control their seizures. The last black box warning is for severe life-threatening pancreatitis that can occur at any time during therapy.

Adverse Events

Common adverse events include fatigue, tremor, GI upset, alopecia, behavioral changes, and weight gain. Severe adverse effects include thrombocytopenia, pancreatitis,

hyperammonemia/encephalopathy, and hepatotoxicity, which may occur at various times in therapy. Severe hepatotoxicity has been reported, especially in children age 2 and younger who are also taking other anticonvulsants. Patients taking valproic acid should be monitored for symptoms of hepatotoxicity, including malaise, weakness, facial edema, anorexia, jaundice, and vomiting. Other adverse events include a change in the menstrual cycle, ataxia, drowsiness, impaired judgment, headache, erythema multiforme, prolonged bleeding time, transient increased liver enzymes, tremor, nystagmus, SIADH, and fever. Levels above 100 mg/L are associated with increased adverse effects.

Valproic acid is teratogenic and produces spina bifida in 1% to 2% of pregnancies. It is a Pregnancy Category X drug for migraine prophylaxis and a category D drug for all other indications and should be avoided if possible during pregnancy.

Interactions

Minor interactions may occur with drugs that affect the CYP2C19, CYP2C9, CYP2D6, and CYP3A3/4 enzyme systems. Valproic acid may increase free phenytoin levels through displacement from protein-binding sites. Carbamazepine, lamotrigine, and possibly clonazepam reduce serum concentrations of valproic acid, while aspirin may increase valproic acid levels. Increased effects and possibly toxicity have been associated with the concomitant use of diazepam, CNS depressants, and alcohol.

Concurrent administration with carbapenems (e.g., meropenem) will cause a rapid decline in valproate plasma concentrations, producing an average drop of 66% within 24 hours.

Ethosuximide

Indications/Uses

Ethosuximide (Zarontin) is one of the drugs of choice for absence seizures. It should always be used in combination with another agent. It also is used for managing akinetic epilepsy and myoclonic seizures.

Mechanism of Action

The exact mechanism of ethosuximide is not completely understood, but it suppresses the paroxysmal spike-and-wave pattern in absence seizures and depresses nerve transmission in the motor cortex.

Dosage

The usual adult dosage is 500 mg daily adjusted by 250 mg every 4 to 7 days. The average daily maintenance dose is 20 to 30 mg/kg/d. The initial dose for children ages 3 to 6 is 250 mg daily with the same titration schedule and usual maintenance dose as adults. Doses greater than 1.5 g/d are not recommended. Serum concentrations should be monitored periodically with a therapeutic range of 40 to 100 mg/L (see Table 39.2).

Contraindications

Allergy is the only absolute contraindication to taking ethosuximide.

Adverse Events

Common adverse events are GI upset and fatigue. Ethosuximide has been associated with blood dyscrasias, CNS depression, SLE, and cutaneous reactions.

Interactions

Ethosuximide is a major substrate of CYP3A4 and, therefore, serum concentrations are affected by inducers and inhibitors of CYP3A4.

Barbiturates

Barbiturates have a relatively broad spectrum of antiepileptic activity and can be used as alternative monotherapy in generalized tonic–clonic seizures as well as in simple or complex partial seizures with or without secondary generalization. Barbiturates are usually sedating and have long-term cognitive, memory, and behavioral effects, and drug dependence may develop. Therefore, it is usually best to try exhausting other alternatives before initiating barbiturate therapy.

Phenobarbital

Indications/Uses

Phenobarbital is the most commonly used barbiturate-based anticonvulsant. In addition to the indications listed previously, phenobarbital is used for myoclonic epilepsies, SE, and neonatal and febrile seizures in children.

Mechanism of Action

Phenobarbital works by binding to the barbiturate-binding site at the GABA receptor complex, leading to enhanced GABA activity. It interferes with the transmission of impulses from the thalamus to the cerebral cortex, resulting in an imbalance in central inhibitory and facilitatory mechanisms.

Dosage

In SE, phenobarbital is commonly given as a 15 to 20 mg/kg loading dose to more rapidly achieve therapeutic levels. The loading dose should be given no faster than 1 mg/kg/min with a maximum infusion of 30 mg/min for infants and children and 60 mg/min for adults. The recommended adult maintenance dose is 2 to 3 mg/kg/d or 60 to 250 mg/d. The recommended maintenance dose in children is highly variable based on age and ranges from 1 to 5 mg/kg/d. Serum concentrations should be monitored periodically with the usual therapeutic range being 15 to 40 mg/L.

Contraindications

The drug should be administered cautiously to patients with severe liver disease because of increased side effects. It is also contraindicated in patients with porphyria and respiratory disease with dyspnea or obstruction and those with a history of sedative or hypnotic addiction.

Adverse Events

The principal adverse events—drowsiness and fatigue—make phenobarbital difficult to use

(see Table 39.2). It also may cause ataxia and blurred vision, nausea, vomiting, constipation, and, over a long period, cognitive impairment and behavioral disturbances. Other major adverse events include cardiac arrhythmias, bradycardia, dizziness, light-headedness, CNS excitation or depression, and gangrene with inadvertent intra-arterial injection. To a lesser extent, hypotension, hallucinations, hypothermia, SJS, rash, agranulocytosis, megaloblastic anemia, thrombocytopenia, laryngospasm, respiratory depression, and apnea (especially with rapid IV use) also may occur.

If an overdosage or toxicity occurs, the expected signs and symptoms include unsteady gait, slurred speech, confusion, jaundice, hypothermia, hypotension, respiratory depression, and coma. Patients may require an IV vasopressor to treat hypotension. Repeated doses of activated charcoal significantly reduce the half-life of phenobarbital; the usual dose is 0.1 to 1 g/kg every 4 to 6 hours for 3 to 4 days unless the patient has no bowel movement, causing the charcoal to remain in the GI tract. Urinary alkalinization with IV sodium bicarbonate helps promote elimination. Patients in stage 4 coma due to high serum barbiturate levels may require charcoal hemoperfusion.

Interactions

Phenobarbital is a strong inducer of CYP1A2, CYP2B6, CYP2A6, CYP2C8, CYP2C9, and CYP3A4 and P-glycoprotein. It is also a major substrate of CYP2C19. As a result, it interacts with a number of other AEDs. Other drug interactions include increased toxicity of propoxyphene (Darvon), benzodiazepines, CNS depressants, and methylphenidate (Box 39.3).

BOX 39.3 Nonantiepileptic Drugs That Interact with Phenobarbital

Non-AEDs Affected by Phenobarbital

Decreases Phenobarbital Level

Beta-blockers, chloramphenicol, chlorpromazine, cimetidine, corticosteroids, cyclosporine, desipramine, doxycycline, folic acid, griseofulvin, haloperidol, meperidine, methadone, nortriptyline, oral contraceptives, quinidine, theophylline, warfarin

Non-AEDs Affecting Phenobarbital Levels

Increases Phenobarbital Levels

Chloramphenicol, propoxyphene, quinine

Decreases Phenobarbital Levels

Chlorpromazine, folic acid, prochlorperazine

Increased Toxicity

Benzodiazepines, CNS depressants, methylphenidate

Primidone

Indications/Uses

Primidone (Mysoline) is structurally related to the barbiturates. It is metabolized to phenobarbital and to phenylethylmalonamide (PEMA). PEMA may enhance the activity of phenobarbital. Primidone is used in the management of grand mal, complex partial, and focal seizures.

Mechanism of Action

Its mechanism of action is similar to phenobarbital and is thought to decrease neuronal excitability and raise the seizure threshold.

Dosage

The adult dose of primidone is 125 mg/d increased by increments of 125 mg every 3 days. The usual dose is 750 to 1,500 mg/d in 3 or 4 divided doses with a maximum recommended dose of 2,000 mg/d. The usual serum level for primidone is 5 to 12 mg/L; however, serum phenobarbital levels are typically used for monitoring purposes (see Table 39.2).

Contraindications

See the contraindications for phenobarbital.

Adverse Events

Primidone has an adverse event profile similar to phenobarbital. Dose-related adverse events include fatigue, cognitive impairment, and ataxia. Other adverse events include nausea, vomiting, hematologic abnormalities, and an SLE-like syndrome. A skin rash may develop, and over time, further cognitive impairment and behavioral changes may develop. Patients who have GI upset while taking primidone may take the medication with food.

Interactions

Drug interactions with primidone are similar to those with phenobarbital.

Ezogabine

Indications/Uses

Ezogabine is a newer agent approved as an adjunctive therapy for partial-onset seizures in adults 18 years and older who have responded poorly to other therapies and in whom the benefits may outweigh the risks of decreased visual acuity.

Mechanism of Action

Ezogabine binds to and stabilizes the KCNQ voltage-gated potassium channel in the open position enhancing the M-current and regulating neuronal excitability. It may also have some effect on augmentation of GABA-mediated currents.

Dosage

The initial dose is 100 mg three times daily and should be titrated no more frequently than every week by increments of less than 150 mg/d. The maximum daily dose is 1,200 mg although increased adverse effects and a lack of additional benefit were seen with daily doses exceeding 900 mg/d. If no substantial benefit is seen after reaching target dose, then consider discontinuation and an alternative therapy.

An initial starting dose of 50 mg three times daily should be considered in the elderly, patients with a CrCl < 50 mL/min, and moderate or severe hepatic impairment. In addition, the maximum daily dose varies for the elderly (750 mg), patients with a CrCl < 50 mL/min (600 mg), and patients with moderate hepatic impairment (750 mg) and severe hepatic impairment (600 mg).

Contraindications

Hypersensitivity to pregabalin or any component of the formulation is a contraindication. Ezogabine has a black box warning for its ability to cause retinal abnormalities, which can cause loss of visual acuity.

Adverse Events

Ezogabine use is associated with development of retinal pigment abnormalities in approximately one third of patients after 4 years of therapy. Patients prescribed ezogabine should receive eye exams, which include testing of visual acuity and dilated fundus photography prior to starting therapy and then every 6 months thereafter. Therapy should be discontinued if vision or retinal pigmentary changes are identified unless there are no suitable alternatives. Due to the risk of vision loss, patients who fail to respond to ezogabine after appropriate dosage titration should have therapy discontinued.

Skin discoloration (bluish, gray-blue, or brown) occurs in approximately 10% of

patients on prolonged therapy (greater than 2 years). Alternate therapies should be considered if this develops. Neuropsychiatric symptoms (confusion, hallucinations, and psychosis) may occur at any time but typically within the first 8 weeks of therapy and resolve with discontinuation of therapy. Other unique adverse events include urinary retention requiring catheterization, which is typically seen in the first 6 months, and QT prolongation of approximately 8 msec on ECG. More common side effects include dizziness, drowsiness, fatigue, impaired coordination and concentration, gait disturbances, blurred vision, and tremor.

Interactions

Ezogabine inhibits OAT3 and P-glycoprotein and does not have any effects of CYP450 enzymes. Ezogabine may decrease the lamotrigine AUC by approximately 18%. Carbamazepine and phenytoin have been shown to decrease the ezogabine AUC by 31% and approximately 34%, respectively. In addition to enzymatic drug interaction, concomitant treatment with medications that are likely to prolong QT should be avoided. A list of medications with potential to prolong QT intervals can be found at crediblemeds.org. It may also cause a false elevation in serum and urine bilirubin measurements.

Gabapentin

Indications/Uses

Gabapentin (Neurontin) is a safe and well-tolerated anticonvulsant with uncomplicated pharmacokinetics. However, it is uncommonly used in the treatment of epilepsy. It can be used as adjunct therapy in the treatment of complex partial seizures and possibly generalized tonic–clonic seizures. There are insufficient data to support its use as monotherapy.

Mechanism of Action

Gabapentin is structurally related to GABA, but it is not thought to influence synthesis or uptake of GABA. Gabapentin-binding sites have been found throughout the brain in relation to presynaptic voltage-gated calcium channels. It is thought that gabapentin may reduce release excitatory neurotransmitters through its activity at these channels, but the precise mechanism of action in epilepsy is unknown.

Dosage

The mean dosage in adults is approximately 1,800 mg/d, with a maximum of 3,600 mg/d. The therapeutic range is not well defined. It may be given once or twice daily, and its half-life is 5 to 7 hours.

Contraindications

Gabapentin is contraindicated in patients who are hypersensitive to the drug or to any of its components.

Adverse Events

Principal adverse effects are fatigue, dizziness, and blurred vision. In addition, neuropsychiatric events including emotional lability, hostility, and hyperkinesia have been reported in children (see Table 39.2). Many of the CNS-like symptoms resolve in a few weeks. The CNS effects are more pronounced with rapid dosage increases or in the setting of renal dysfunction. There have also been reports of modest weight gain. Serious adverse events including DRESS and SJS have been reported with its use.

Interactions

Gabapentin does not have any major drug interactions (antacids decrease its bioavailability), and serum level monitoring is not required.

Pregabalin

Indications/Uses

Pregabalin (Lyrica) is approved as adjunctive therapy for partial-onset seizures in adult patients.

Mechanism of Action

Pregabalin binds to the voltage-gated calcium channels in the brain, inhibiting excitatory neurotransmitter release.

Dosage

Pregabalin is typically started at a dose of 150 mg daily in two or three divided doses and should be titrated based on efficacy and side effects to a maximum dose of 600 mg/d. It requires dosage adjustment in patients with impaired renal function to avoid accumulation and increased adverse effects.

Contraindications

Hypersensitivity to pregabalin or any component of the formulation is a contraindication. Caution should be used in patients with a history of angioedema, heart failure, hypertension, or diabetes due to the risks of weight gain and edema.

Adverse Events

Peripheral edema and weight gain are common adverse effects. Other common adverse events include dizziness, somnolence, ataxia, and blurred vision.

Interactions

Pregabalin may enhance the sedative effects of other CNS depressants and may enhance the fluid-retaining effects of thiazolidinediones.

Lamotrigine

Indications/Uses

Lamotrigine (Lamictal) seems to be efficacious for generalized tonic–clonic, absence (especially atypical), and complex partial seizures. It also may be effective in Lennox-Gastaut syndrome (not approved for use in children younger than age 2).

Mechanism of Action

Although its mechanism of action is not completely clear, lamotrigine stabilizes neuronal membranes by acting on excitatory amino acid release and inhibiting voltage-sensitive sodium channels.

Dosage

The starting dosage for lamotrigine is 25 mg daily, with a slow titration every 2 weeks to a maintenance dose of 300 to 400 mg/d. The titration may even be slower, such as 25 mg every other day, in patients taking valproic acid. This slower titration should help lower the risk for rash.

Contraindications

Lamotrigine is contraindicated in patients with a hypersensitivity to lamotrigine or any of its components.

Adverse Events

Overall, lamotrigine is well tolerated and does not appear to have any long-term cognitive side effects. The principal adverse events include nausea, fatigue, dizziness, diplopia, and ataxia (see Table 39.2). In approximately 5% to 10% of patients (most often in children), a rash may develop. If a rash develops, the drug should be discontinued immediately. SJS and TEN have been reported with the majority of cases occurring in the first 8 weeks of therapy. The risk may be increased by coadministration with valproic acid, higher than recommended starting doses, and rapid dose increases. However, isolated cases have been reported with prolonged therapy or without these risk factors. Other adverse events include angioedema, nystagmus, and hematuria.

Interactions

The combined use of lamotrigine and carbamazepine may result in increased serum concentrations of carbamazepine and carbamazepine 10/11 epoxide. Valproic acid inhibits lamotrigine metabolism, whereas carbamazepine and phenytoin induce its metabolism. These enzyme interactions may result in significant changes in the half-life of lamotrigine.

When used with valproic acid, the half-life is extended to 48 hours (from 24 hours when used alone), and with carbamazepine or phenytoin, it is reduced to 12 hours. Phenobarbital and primidone tend to decrease lamotrigine levels by approximately 40%. Although acetaminophen (Tylenol) may decrease lamotrigine levels, caution must be used when giving lamotrigine concomitantly with a folate inhibitor because it is an inhibitor of dihydrofolate reductase.

Levetiracetam

Indications/Uses

Levetiracetam (Keppra) has shown efficacy in the adjunctive treatment of adults with partial-onset, myoclonic, or primary generalized tonic–clonic seizures. While it does not have an FDA approval for use as monotherapy, it is approved in Europe for use as monotherapy in the treatment of partial-onset seizures.

Mechanism of Action

The mechanism of action of levetiracetam is not known, but it is theorized to inhibit voltage-dependent N-type calcium channels, facilitate GABA-ergic inhibitory transmission, reduce delayed potassium currents, and bind to synaptic proteins that modulate neurotransmitter release.

Dosage

Levetiracetam is started at a dosage of 500 mg twice daily with immediate-release formulations (1,000 mg daily with extended release) and titrated up to 3,000 mg/d. Dosages of greater than 3,000 mg/d have been used in clinical trials with good tolerability but without evidence of additional benefit. When switching to oral therapy, dose and frequency remain the same.

Contraindications

Levetiracetam is contraindicated in patients with a hypersensitivity to levetiracetam or any of its components.

Adverse Events

The primary adverse events associated with levetiracetam therapy include somnolence, asthenia, headache, and infection. Most of these occur within the first 4 weeks of therapy, with no dose–toxicity relationship seen. Another common adverse event is changes in behavior, including aggression, neurosis, and psychosis, which may require a dose reduction. Serious but rare adverse events include anemia, neutropenia, eosinophilia, and SJS/TEN.

Interactions

Since levetiracetam does not undergo significant metabolism, there are no clinically relevant enzymatic drug interactions with this agent.

Lacosamide

Indications/Uses

Lacosamide is approved for monotherapy and adjunctive therapy of partial-onset seizures.

Mechanism of Action

Lacosamide stabilizes neuronal membranes and enhances the slow inactivation of sodium channels.

Dosage

The initial dose of lacosamide when used as monotherapy is 100 mg twice daily and as adjunctive therapy is 50 mg twice daily. The dose may be increased at weekly intervals by 100 mg/d to a maintenance dose of 200 to 400 mg/d. An initial loading dose of 200 to 400 mg has been used in some patient with SE. When switching to oral therapy, dose and frequency remain the same. In patients with creatinine clearance of less than 30 mL/min or mild to moderate hepatic impairment, the dose should not exceed 300 mg/d. Lacosamide should be avoided in patients with severe liver disease.

Contraindications

There are no contraindications to lacosamide according to the manufacturer.

Adverse Events

Common adverse events seen with lacosamide include dizziness, fatigue, somnolence, blurred vision, diplopia, nausea, and tremor. Less commonly, increases in PR interval, second- and third-degree AV block, syncope, atrial fibrillation, and atrial flutter may occur, especially in patients with a history of cardiovascular disease.

Interactions

Phenytoin, carbamazepine, and phenobarbital may decrease the serum concentration of lacosamide.

Tiagabine

Indications/Uses

Tiagabine (Gabitril) is used as adjunctive therapy in adults and children older than age 12 with partial seizures.

Mechanism of Action

Its mechanism of action is not known; however, in vitro experiments show that it enhances GABA activity.

Dosage

The starting dosage of tiagabine is 4 mg daily and is titrated 4 to 8 mg weekly to response or up to 56 mg daily in 2 to 4 divided doses. The maintenance dose typically ranges from 32 to 56 mg/d.

Contraindications

Avoid using tiagabine in patients with hypersensitivity to any components of the formulation. Caution should be used in patients with hepatic impairment.

Adverse Events

Adverse events of tiagabine include dizziness, headache, somnolence, CNS depression, memory disturbance, ataxia, confusion, tremors, weakness, and myalgia (see Table 39.2). Rarely, severe dermatologic reactions such as SJS may occur.

Interactions

Tiagabine is a CYP2D6 and CYP3A3/4 enzyme substrate and is cleared more rapidly when given with other hepatic enzyme–inducing AEDs (i.e., carbamazepine, phenytoin, primidone, and phenobarbital).

Perampanel

Indications/Uses

Perampanel (Fycompa) is used as adjunctive therapy for partial-onset seizures without secondary generalized seizures in patients greater than 12 years of age.

Mechanism of Action

The exact mechanism of perampanel's antiseizure activity is unknown, but it is a noncompetitive antagonist of the AMPA glutamate receptor on postsynaptic neurons.

Dosage

The recommended initial starting dose in patients not on enzyme-inducing AEDs is 2 mg once daily at bedtime, which can be increased in 2-mg increments every 7 days to a maximum recommended dose of 8 to 12 mg daily. Patients on enzyme-inducing AEDs should start on an initial dose of 4 mg with the same titration of 2 mg weekly with a maximum dose of 8 to 12 mg daily. Elderly patients should have their dose titrated no more frequently than every 2 weeks.

Use is not recommended in patients with a CrCl < 30 mL/min or on hemodialysis. Patients with mild to moderate hepatic impairment should be started on no more than 2 mg once daily and titrated no more frequently than every 2 weeks. The maximum dose is 6 mg once daily in Child-Pugh Class A impairment and 4 mg once daily in Class B impairment. Use should be avoided in Class C impairment due to lack of data.

Contraindications

Avoid use in patients with hypersensitivity to perampanel or any component of the formulation. Perampanel carries a black box warning due to its potential to cause serious life-threatening neuropsychiatric events (aggression, anger, homicidal thoughts, and hostility).

Adverse Events

Common side effects include dizziness, somnolence, headache, fatigue, gait/balance disturbances, and falls. Neuropsychiatric events (aggression, anger, homicidal thoughts, and hostility) are more common with initiation of therapy and following dosage titrations. Therapy should be adjusted or discontinued if this develops.

Interactions

Perampanel is a minor substrate of CYP1A2 and 2B6 and a major substrate of CYP3A4. In addition, it is a weak inducer of 3A4. Strong inducers of CYP3A4 should be avoided due to

their potential to decrease perampanel concentrations. The use of other AEDs, which are enzyme inducers (carbamazepine, oxcarbazepine, phenytoin, etc.), may decrease perampanel concentrations and starting doses should be increased as a result. Concomitant use of CNS depressants may increase the risk of sedation.

Topiramate

Indications/Uses

Topiramate (Topamax) is used as monotherapy or adjunctive therapy for partial-onset seizures and primary generalized tonic–clonic seizures. It is also used as adjunctive therapy for seizures associated with Lennox-Gastaut syndrome.

Mechanism of Action

It is thought to decrease seizure frequency by blocking sodium channels in neurons, by enhancing GABA activity, and by blocking glutamate activity.

Dosage

The dosage starts at 25 to 50 mg twice a day and is increased to 200 to 400 mg/d in weekly increases of 25 to 50 mg/d. In patients with a creatinine clearance of below 70 mL/min, the dosage should be lowered by 50%.

Contraindications

Caution must be used in patients with hepatic or renal impairment, during pregnancy, and in breast-feeding mothers.

Adverse Events

Prominent adverse events are fatigue, dizziness, ataxia, somnolence, psychomotor slowing, nervousness, memory difficulties, speech problems, nausea, paresthesias, tremor, nystagmus, and upper respiratory infections (see Table 39.2). These may occur more frequently in patients taking more than 600 mg/d of topiramate or when titration occurs too rapidly (3 to 4 weeks to maintenance dose). Other adverse events include chest pain, edema, confusion, depression, difficulty concentrating, hot flashes, dyspepsia, abdominal pain, anorexia, xerostomia, gingivitis, myalgia, back pain, leg pain, rigors, nephrolithiasis, and epistaxis.

Therapy should never be withdrawn abruptly. Proper hydration is essential to decrease the risk of kidney stones.

Interactions

Topiramate is a CYP2C19 enzyme substrate inhibitor; thus, concurrent administration with phenytoin can decrease topiramate concentrations by as much as 48%, administration with carbamazepine reduces them by 40%, and administration with valproic acid reduces them by 14%. Digoxin (Lanoxin) and norethindrone (Aygestin) blood levels are decreased when given with topiramate, and concomitant administration with other CNS depressants

increases topiramate's sedative effects. If used with carbonic anhydrase inhibitors, the risk of nephrolithiasis increases.

Zonisamide

Indications/Uses

Zonisamide is a broad-spectrum, sulfonamide-derivative AED approved as adjunctive therapy in partial-onset seizures in adults.

Mechanism of Action

Zonisamide appears to block sodium channels and select calcium channels.

Dosage

The dosage of zonisamide is 100 mg once daily, giving it a distinct compliance advantage over other agents requiring more frequent dosing. The titration to the daily maintenance dose of 400 to 600 mg is slow, at a rate of 100 mg daily every 2 weeks. There are no guidelines for dose adjustment in patients with renal or hepatic impairment, though it is not recommended for use in patients with creatinine clearance of less than 50 mL/min.

Contraindications

Use should be avoided in patients with a history of hypersensitivity to sulfonamide agents or any components of the zonisamide formulation.

Adverse Events

Potentially fatal reactions such as SJS, TEN, and agranulocytosis have been reported. Other important adverse events include fatigue, dizziness, ataxia, and anorexia. In children, there have been reports of high fever secondary to hyperhidrosis; zonisamide is not approved for use in children.

Interactions

Zonisamide is a major substrate of CYP3A4. Concentrations may be decreased when using inducers, such as phenytoin, phenobarbital, and rifampin. Serum levels may be increased when used concomitantly with protease inhibitors, azole antifungals, and macrolide antibiotics.

Felbamate

Indications/Uses

Felbamate can be used as either monotherapy or adjunctive therapy in the treatment of partial seizures. It is also used as adjunctive therapy in the treatment of partial and generalized seizures associated with Lennox-Gastaut syndrome in children. Due to an increased risk of life-threatening adverse effects, the American Academy of Neurology has published a practice advisory directing use.

Mechanism of Action

The mechanism of action is unknown but is believed to have weak inhibitory effects on GABA and benzodiazepine receptor binding.

Dosage

The initial dose of felbamate is 1,200 mg/d in divided doses three or four times a day. The dose may be titrated in 600-mg increments every 2 weeks to 2,400 mg/d based on response and to 3,600 mg/d if clinically indicated. Prior to prescribing felbamate, an "informed consent" form needs to be signed by the patient and physician.

Contraindications

Avoid use in patients with hypersensitivity to felbamate or any component of the formulation or with a known sensitivity to other carbamates. It has black box warnings for an approximately 100-fold increased risk of aplastic anemia in addition to an increased risk of acute hepatic failure. As a result, its use should be avoided in patients with a history of blood dyscrasias or hepatic dysfunction.

Adverse Events

Common adverse effects of felbamate include somnolence, headache, dizziness, ataxia, skin rash, nausea, vomiting, anorexia, and miosis. Rarely, felbamate has been associated with cases of hepatic failure and therefore should not be used in patients with a history of liver disease. An increased risk of developing aplastic anemia is present as well, and routine hematologic monitoring should be performed to detect evidence of bone marrow suppression.

Interactions

Felbamate is a major substrate for CYP3A4 and may be affected by concomitant use of drugs such as phenytoin. In addition, felbamate may increase concentrations of valproic acid and phenobarbital and may decrease the effectiveness of oral contraceptives.

Vigabatrin

Indications/Uses

Vigabatrin (Sabril) is an AED approved for the treatment of infantile spasms and refractory complex partial seizures not controlled with usual treatments. It is only available in the United States through a restricted distribution program called the SHARE program. Only prescribers and pharmacies registered with the program are able to prescribe and distribute the drug.

Mechanism of Action

Vigabatrin irreversibly inhibits GABA transaminase, increasing the levels of GABA in the brain.

Dosage

The adult dose of vigabatrin is 500 mg as an oral tablet twice daily. The dose should be titrated by increments of 500 mg weekly based on the patient's response and adverse effects. The recommended maintenance dose is 1,500 mg twice daily. Upon discontinuation, the drug should be tapered by 1,000 mg weekly. The dose for the treatment of infantile spasms is 50 mg/kg/d divided twice daily titrated by increments of 25 to 50 mg/kg/d every 3 days. The maximum dose for infants is 150 mg/d. Dose adjustments are necessary in renal impairment.

Contraindications

Hypersensitivity to vigabatrin or any component of the formulation contraindicates its use. Vigabatrin has a black box warning for its ability to cause permanent bilateral concentric visual field constriction.

Adverse Events

Common adverse effects of vigabatrin include somnolence, headache, dizziness, irritability, insomnia, weight gain, and diarrhea. Vigabatrin can cause permanent vision loss in patients receiving the drug. Patients who do not show substantial benefit within a short time after initiation (2 to 4 weeks for infantile spasms, less than 3 months for adults) should have the drug discontinued to avoid this adverse effect. Vision loss increases with larger doses and cumulative exposure and can affect more than 30% of patients. Vision should be assessed at baseline, at 4 weeks, and every 3 months thereafter.

Interactions

Vigabatrin may increase the sedative effects of other drugs and alcohol.

Rufinamide

Indications/Uses

Rufinamide (Banzel) is indicated for adjunctive treatment of seizures associated with Lennox-Gastaut syndrome in patients 1 year of age or older

Mechanism of Action

Rufinamide is a triazole derivative whose precise mechanism is unknown. In vitro data suggest it prolongs the inactive state of sodium channels and limits repetitive firing of sodium-dependent action potentials.

Dosage

The starting dose in patients less than 17 years old is 10 mg/kg/d divided into twice-daily doses. The dose should be increased by 10 mg/kg/d every other day until a maximum of 45 mg/kg/d or 3,200 mg, whichever is lower, is reached. Patients on concomitant valproate should start on doses less than 10 mg/kg/d in divided doses.

The starting dose in patients 17 years or older is 400 to 800 mg daily divided into twice daily doses. The dose should be increased by 400 to 800 mg every other day to a maximum dose of 3,200 mg/d. Patients on concomitant valproate should start at 400 mg daily in divided doses.

The extent of absorption is decreased with increasing doses. It should be taken with food as food significantly increases absorption. While no dosage adjustments are provided by the manufacturer, approximately 30% of a dose is removed by a 4-hour run of hemodialysis. A supplemental dose may need to be considered based on clinical response.

Contraindications

Patients with familial short QT syndrome and presence or history of short QT syndrome should not take rufinamide due to a potential for increased risk of sudden cardiac death. It's use is contraindicated in patients with hypersentivity to triazole derivatives or any component of the formulation.

Adverse Events

Common adverse events in clinical trials included QT shortening, somnolence, fatigue, coordination abnormalities, dizziness, gait disturbances, ataxia, nausea, vomiting, SE, and rash. Less common but clinically important adverse events include multiorgan hypersensitivity reactions, DRESS, SJS, and leukopenia.

Interactions

Rufinamide undergoes extensive hydrolysis via carboxylesterases with no appreciable CYP-mediated metabolism. It is a weak inhibitor of CYP2E1 and a weak inducer of CYP3A4. Despite no appreciable CYP-mediated metabolism, carbamazepine, phenytoin, phenobarbital, and primidone may decrease levels of rufinamide. Rufinamide may decrease levels of carbamazepine and estrogen or progestin-based contraceptives. Rufinamide concentrations are significantly increased with concomitant administration of valproic acid. If given together, initiate at lower doses and consider slower dosage titration. Levels of phenytoin and phenobarbital may be increased with coadministration. Food significantly increases the extent of absorption, and patients should be instructed to take it with a meal.

Benzodiazepines

The benzodiazepine antianxiety agents are discussed in depth in Chapter 41.

Clobazam

Indications/Uses

Clobazam (Onfi) is indicated for adjunctive treatment of seizures associated with Lennox-Gastaut syndrome in patients 2 years of age or older.

Mechanism of Action

Clobazam is thought to act as an agonist at the $GABA_A$ receptor to enhance GABA action, thereby depressing nerve transmission in the motor cortex area.

Dosage

Initial clobazam doses are determined by patient weight. Patients weighing 30 kg or less should start on 5 mg daily, while patients weighing more than 30 kg should start on 10 mg/d. Doses greater than 5 mg daily should be given in divided doses twice daily. Dose increases should occur no more frequently than every 7 days and by no more than 100% of the previous dose. Maximum doses per package labeling are 20 mg/d for patients weighing 30 kg or less and 40 mg/d in patients weighing more than 30 kg. Dose decreases should occur slowly and no more frequently than weekly to avoid withdrawal symptoms.

Contraindications

Contraindications include hypersensitivity to clonazepam, any of its components, or other benzodiazepines.

Adverse Events

Constipation, somnolence, sedation, pyrexia, lethargy, and drooling occurred at least 10% more frequently than placebo in clinical trials. Physical and psychological dependence are possible with all benzodiazepines.

Interactions

Clobazam is primarily metabolized by CYP3A4 but also 2C19 and 2B6 to its active metabolite N-desmethyl, which is metabolized by 2C19. Strong 2C19 inducers (e.g., theophylline) may decrease clobazam activity, while strong (e.g., fluconazole) to moderate (e.g., omeprazole) 2C19 inhibitors may increase clobazam activity. Alcohol may increase clobazam concentrations by as much as 50%.

Clobazam is a weak inducer of CYP3A4 and may reduce the effectiveness of some hormonal contraceptives. Nonhormonal forms of contraception should be considered when using clobazam. In addition, clobazam inhibits CYP2D6 in vivo and drugs metabolized by this pathway may require dosage adjustment. Concomitant use of CNS depressants may increase the risk of sedation.

Clonazepam

Indications/Uses

Clonazepam (Klonopin) is effective as an adjunctive drug in some patients with myoclonic, atonic, and generalized tonic–clonic seizures. It also is used for prophylaxis of absence, petit mal, variant (Lennox-Gastaut), akinetic, and myoclonic seizures.

Mechanism of Action

Clonazepam is thought to act at the GABA receptor to enhance GABA action, thereby depressing nerve transmission in the motor cortex area.

Dosage

Clonazepam is given in three divided doses with an initial daily starting dose of up to 1.5 mg in adults and 0.1 to 0.2 mg/kg/d in children. The dose may be increased by 0.5 to 1 mg every 3 day until seizures are controlled or adverse effects are evident (maximum, 20 mg/d). Tolerance to this drug is common.

Contraindications

Contraindications include hypersensitivity to clonazepam, any of its components, or other benzodiazepines, severe liver disease, and acute narrow-angle glaucoma. Caution must be used in patients with chronic respiratory disease or impaired renal function and in patients who are mentally challenged (may have more frequent drug-induced behavioral symptoms).

Adverse Events

Fatigue, sedation, and behavioral changes (e.g., aggressiveness and confusion) are the principal adverse reactions. Tachycardia, chest pain, headache, constipation, nausea, and decreased salivation are other adverse reactions.

Interactions

Medications that induce CYP3A4 enzyme substrates, such as phenytoin and barbiturates, may increase clonazepam clearance. Concomitant use of CNS depressants may increase the risk of sedation.

Lorazepam

Indications/Uses

Lorazepam (Ativan) is used intravenously to treat SE and has an unlabeled use for partial complex seizures.

Mechanism of Action

The drug is believed to depress all levels of the CNS, including the limbic system and reticular formation, probably through the increased action of GABA. Before IV use, the injection must be diluted with an equal volume of compatible diluent. If it is injected intra-arterially, arteriospasm and gangrene may occur. The injectable form contains benzyl alcohol 2%, polyethylene glycol, and propylene glycol, which may be toxic in high doses.

Dosage

In the treatment of SE, lorazepam may be given as a 4-mg slow IV bolus (maximum rate of 2 mg/min). Doses may be repeated every 10 to 15 minutes until seizures stop.

Contraindications

Lorazepam is contraindicated in patients with a hypersensitivity to lorazepam or to any of its components. There is also a risk of cross-sensitivity with other benzodiazepines. It should not be used in comatose patients; patients with preexisting CNS depression, narrow-angle glaucoma, severe, uncontrolled pain, and severe hypertension; and pregnant women. Caution must be used in patients with renal or hepatic impairment, organic brain syndrome, myasthenia gravis, or Parkinson disease.

Adverse Events

Common adverse reactions include tachycardia, chest pain, drowsiness, confusion, ataxia, amnesia, slurred speech, paradoxical excitement, headache, and depression. Light-headedness, rash, decreased libido, xerostomia, bradycardia, cardiovascular collapse, syncope, constipation, nausea, vomiting, decreased salivation, phlebitis, and blurred vision also may occur. Menstrual irregularities, increased salivation, blood dyscrasias, and physical and psychological dependence occur with prolonged use.

Interactions

Lorazepam has a decreased effect with oral contraceptives (combination products), cigarette smoking, and levodopa. Its effects are increased with morphine or other narcotic analgesics. An increased risk of toxicity occurs with the concomitant use of alcohol, CNS depressants, MAO inhibitors, loxapine (Loxitane), and tricyclic antidepressants.

Diazepam

Diazepam is used to treat SE and as an adjunct in convulsive disorders. Its mechanism of action is the same as that of lorazepam.

Dosage

Diazepam may be given intravenously 5 to 10 mg every 5 to 10 minutes 5 or less mg/min to treat SE (maximum dose of 30 mg). It may also be given as a rectal gel out of hospital as a 10-mg, one-time dose and may be repeated once if necessary.

Contraindications

Diazepam should not be used by patients with severe or acute liver disease. Contraindications include hypersensitivity to diazepam or to any of its components. Other contraindications are similar to those for lorazepam. Caution should be used in patients taking other CNS depressants, patients with low albumin levels or hepatic dysfunction, and elderly patients and infants. Because of its long-acting metabolite and the risk for falls in the elderly population, diazepam is not considered a drug of choice.

Adverse Events

Adverse drug effects resemble those of lorazepam.

Interactions

Diazepam is a CYP1A2 and CYP2C9 enzyme substrate. It is also a minor enzyme substrate for CYP3A3/4, and diazepam and desmethyldiazepam are CYP2C19 enzyme substrates. Enzyme inducers may increase the metabolism of diazepam, resulting in decreased efficacy. Increased toxicity, sedation, and respiratory depression may result when diazepam is given with CNS depressants (e.g., alcohol, barbiturates, and opioids). Cimetidine (Tagamet) may decrease the metabolism of diazepam. Valproic acid may displace diazepam from binding sites, which may result in an increase in sedative effects. Selective serotonin reuptake inhibitors (e.g., fluoxetine [Prozac], sertraline [Zoloft], paroxetine [Paxil]) greatly increase diazepam levels by altering its clearance.

Selecting the Most Appropriate Agent

There are several excellent AEDs from which to choose for various seizure types. The goal of monotherapy is to promote patient compliance, minimize side effects and toxicity, and reduce cost. In general, first-line monotherapy drugs are tried before using second-line monotherapy drugs, and first-line drugs may be first combined before trying the various second-line, adjunctive agents. Whether the second-line, adjunctive agents will be effective in monotherapy is still to be determined. The choice of an AED is determined by ease of use (i.e., dosing regimen), pharmacokinetics, interactions, need for monitoring, and toxicity (which could be dose related, idiosyncratic, chronic, or teratogenic). Ultimately, the optimal treatment for a given patient can be established by a process of trial and error and by knowledge of prior AEDs used.

First-Line Therapy

Selecting the appropriate therapy for each patient is difficult, but there is a science to choosing the best treatment:

- Select the appropriate drug and dose for the type and severity of the seizure being treated.
- Consider the patient's characteristics. For example, does the patient have hepatic or renal insufficiency, liver disease, hypoalbuminemia, burns, pregnancy, or malnutrition? What concomitant medications does the patient take? How old is the patient? Does the patient comply with the medication regimen? What adverse events are associated with the medication?
- Determine the patient's socioeconomic status.

If the initial AED fails, the practitioner should taper this drug's dosage while starting another first-line AED, if available. A list of commonly used first-line drugs for different seizure types can be found in Table 39.1.

Second-Line Therapy

Before switching to a second-line agent, the practitioner must optimize treatment with the selected first-line drug (unless the patient experiences intolerable adverse effects) and exhaust all possible first-line drug therapy choices. The practitioner at this point may, based on the patient's past medical history, initiate combination therapy with two or more first-line drugs or a first-line drug and a second-line drug. Table 39.1 contains a list of second-line drugs.

Third-Line Therapy

If all medications fail and the patient experiences intractable seizures, surgery may be a third-line treatment option. Before recommending surgery, the practitioner should make

sure drug treatment errors such as inappropriate drug selection, drug interactions, or inappropriate dosage are not contributing.

Special Population Considerations

Status Epilepticus

Guidelines recommend achieving definitive control of SE within 60 minutes of onset. All patients with an epileptic cause will need emergent, abortive therapy, as well as an antiepileptic medication to maintain or achieve seizure control. The goal of treatment is to stop clinical and electrographic seizure as quickly as possible using a combination of benzodiazepines and AEDS (see Figure 39.2). Concurrently, acute supportive care measures including airway management, IV access, hemodynamic support, and identification of the underlying cause must be provided.

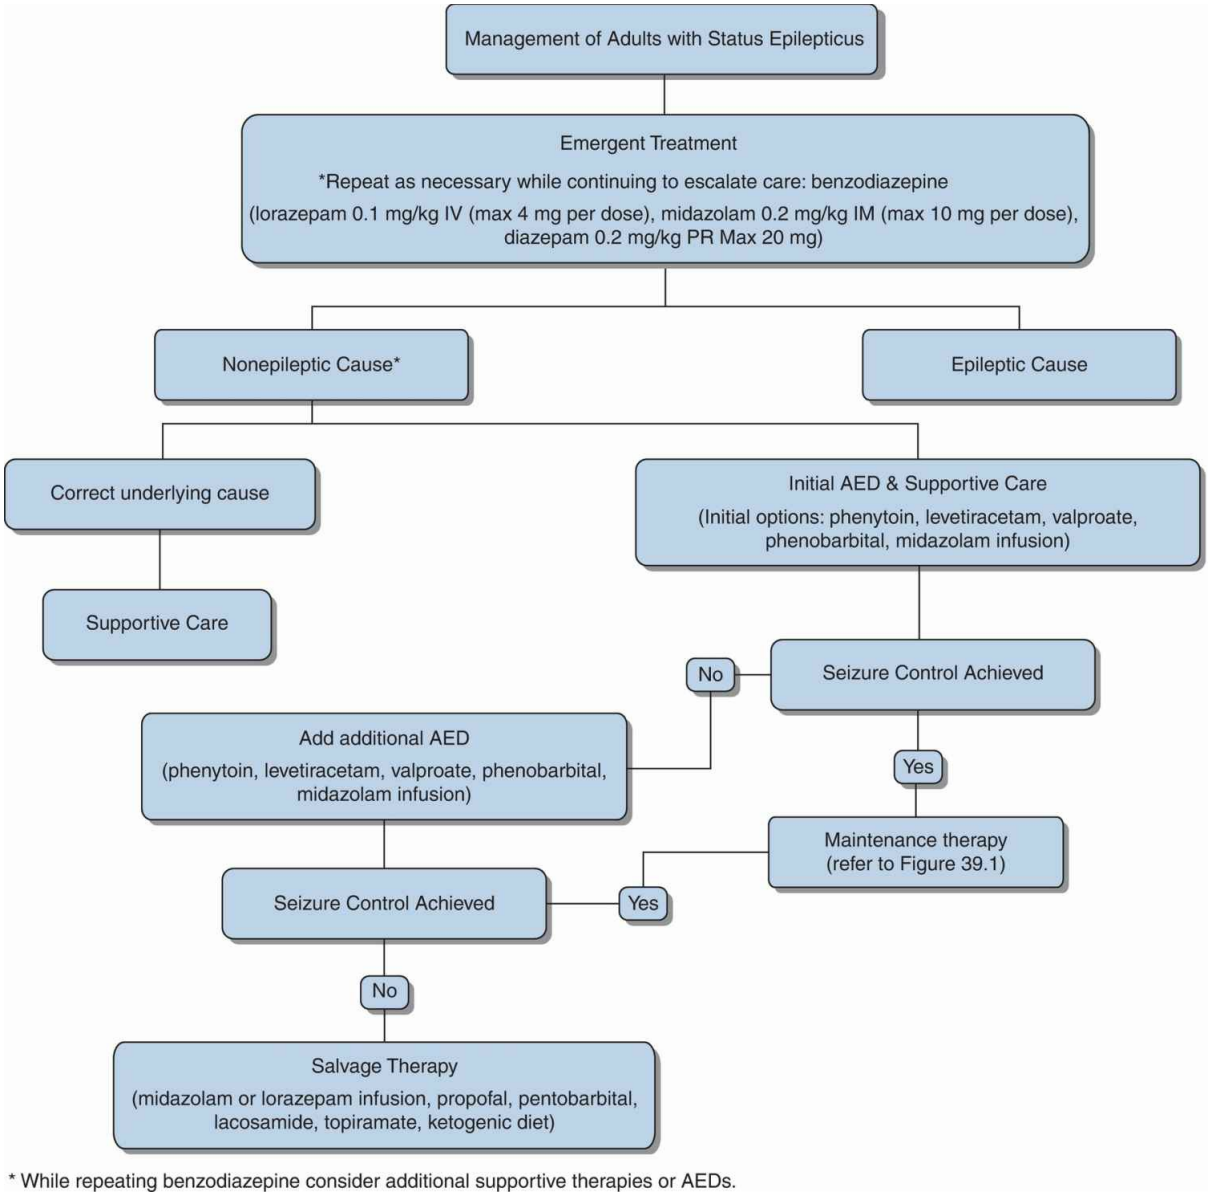

FIGURE 39.2 Treatment algorithm for status epilepticus.

Benzodiazepines are the first-line treatment option to emergently abort seizure activity. IV administration is preferred; however, if unable to obtain IV access, IM, rectal (PR), or intranasal options can be utilized. First-line therapy, lorazepam 0.1 mg/kg IV up to 4 mg per dose, doses can be repeated as needed based on clinical response. All benzodiazepines can cause respiratory depression; therefore, careful monitoring is required especially with escalating or repeated doses. Midazolam is the preferred IM agent; 0.2 mg/kg up to a maximum of 10 mg can be given to adults. Diazepam PR is often administered in prehospital setting and is often used in pediatric population; adults can receive 0.2 mg/kg up to a maximum of 20 mg. An EEG is necessary to ensure treatment has adequately controlled both convulsive and electrographic seizure activity. If epileptic cause is identified, initial AED therapy should be urgently instituted. Treatment options include phenytoin or fosphenytoin, levetiracetam, valproic acid, midazolam (continuous infusion),

or phenobarbital. Refer to Table 39.2 for additional information regarding loading and maintenance doses in SE.

Refractory SE is defined as either persisting clinical or electrographic seizures after the administration of a benzodiazepine and appropriate antiepileptic medication. Treatment options for refractory patients include midazolam, propofol, pentobarbital, valproic acid, levetiracetam, phenytoin or fosphenytoin, lacosamide, topiramate, and/or phenobarbital. Treatment of refractory SE is a challenge and there is not a defined treatment algorithm for therapy escalation, for treatment duration, or to drive therapeutic selection.

Pharmacogenetics

A patient's response to a given AED is dependent on both environmental and genetic factors. Pharmacogenetic variations exist that may impact therapeutic response, enzyme activity, transporter activity, or even drug-related toxicity. It is an area of increasing focus for many disease states including epilepsy. While pharmacogenetics may have a number of potential impacts on AED therapy, most available data focus on HLA alleles and risk for serious immune-mediated drug reactions. The presence of the HLA-B*1502 allele in patients of Chinese, Thai, Malaysian, and Indian populations has shown a strong association with carbamazepine-induced SJS/TEN. The FDA specifically recommends that HLA testing be completed prior to initiating CBZ in patients of Asian ancestry due to this risk of SJS/TEN. HLA variants and risk of serious immune-mediated reactions have been investigated with other AEDs including oxcarbazepine, lamotrigine, valproic acid, zonisamide, phenytoin, and phenobarbital with variable results. While pharmacogenetic testing is not routine, it is an ever-expanding field and may become a routine part of AED selection. The NIH-funded Web site pharmGKB.org provides useful resources on pharmacogenetics and drug dosing considerations with specific recommendations for carbamazepine and phenytoin.

Pediatric

The most common seizure syndrome in childhood is Lennox-Gastaut syndrome. This usually is associated with mental retardation. Characteristically, multiple seizure types can occur, including atypical absence, atonic (drop attacks), secondarily generalized tonic–clonic, and myoclonic and tonic seizures. EEGs show considerable slow-wave and spike-wave activity. Although patients respond to valproic acid, benzodiazepines, and lamotrigine, there is a poor prognosis for seizure control.

Simple febrile seizures are another important category of seizures that affect children between ages 6 months and 5 years. Febrile seizures occur in 4% of all children and are preceded by high fevers, underlying the importance of controlling high fevers in children. The seizure is generalized and usually lasts under 15 minutes. Approximately 33% of children experience a recurrence, although almost never within the first 24 hours. These patients usually have no preceding neurologic abnormality or family history of epilepsy.

Long-term anticonvulsant therapy is not indicated for this seizure type.

Geriatric

Understanding the basic pharmacologic principles involved in the administration of AEDs is the key to the optimal use of these drugs in older patients. Drug clearance and metabolism are significant issues in this population. Many older patients have decreased renal and liver function, which may have a profound effect on drug metabolism and excretion. Consequently, AED dosages may need to be adjusted.

AEDs are bound to different degrees by plasma proteins, particularly albumin. If a patient has a low albumin level (as elderly adults tend to have), higher free-drug concentrations are present in the blood and may lead to an increased risk of adverse events.

In patients with liver disease, which is common in the geriatric population, the rates of hepatic biotransformation of drugs and of hepatic blood flow are decreased. Therefore, protein binding of AEDs may also be affected by low protein and displacement by bilirubin or other substances. This has the net effect of increasing the serum concentration of free drug. In renal disease, there may be a decrease in the clearance of drugs eliminated entirely by the kidney. Renal failure also may complicate elimination of drugs principally cleared by the liver. Studies have shown that in the patients with uremia who are taking phenytoin, hepatic biotransformation processes continue or accelerate during the renal failure, but renal excretion of metabolites is decreased. Therefore, uremic patients tend to have lower total serum phenytoin concentrations but higher serum concentrations of the oxidized principal metabolite (hydroxyphenyl-phenylhydantoin).

Women

For women taking anticonvulsant therapy, a major point for discussion is the risk during pregnancy. Several anticonvulsants are listed as Pregnancy Category C or D (i.e., phenytoin, fosphenytoin, phenobarbital, primidone, valproic acid, ethosuximide, topiramate, and tiagabine), indicating a greater risk for fetal abnormalities. Pregnancy risk categories for each drug are listed in Table 39.2. The practitioner must work closely with women who wish to become, or are, pregnant to assess the risks involved and to choose the most effective drug that's safest for the fetus. In order to minimize the risk of congenital malformations, valproic acid and polytherapy should be avoided during the first trimester of pregnancy. Conversely, topiramate, oxcarbazepine, and lamotrigine may decrease serum concentrations of progestins and lead to oral contraceptive failure.

Monitoring Patient Response

For patients taking an AED, the health care practitioner should monitor

- Frequency and severity of seizures
- Adverse drug events
- Plasma drug levels, if applicable

Therapy is considered to be a failure if the AED dosage achieves and maintains optimal blood concentrations and seizures are still uncontrolled and/or adverse effects become intolerable. Some patients have good clinical responses at serum drug concentrations below the therapeutic range, while others can exhibit toxicity within the therapeutic range. Some require serum concentrations above normal therapeutic values for seizure control, and these patients may tolerate very high levels without signs of toxicity.

Drugs should be added or subtracted as needed. Whenever a new AED is started or a dosage change is made, it takes five elimination half-lives (or the period over which a drug's plasma concentration falls to 50% of the peak level after a single dose) before the new steady-state serum concentration is achieved. It is at this point the full therapeutic impact of the new medication or dosage change can be assessed. Therefore, too much haste in changing an AED or discarding it as ineffective may have significant therapeutic implications.

When AEDs are administered in combination, it is important to note the types of drug interactions that may occur. Even when monotherapy is used, some AEDs alter their own biotransformation when they are administered chronically (e.g., carbamazepine and valproic acid). The existence of these interactions complicates the design of the therapeutic regimen when more than one AED is used, underscoring the desirability of using monotherapy whenever possible.

Patient Education

More than 90% of patients with epilepsy lead normal lives. The patient should avoid sleep deprivation and excessive alcohol use, both of which can lower the seizure threshold and make recurrent seizure activity likely. The patient should avoid jobs that involve working at heights or near heavy machinery, flames, burners, or molten material, so there are some restrictions on careers (e.g., firefighter, commercial driver, or airline pilot). Patients should never swim alone. Most sports are permitted, but those with an increased risk of a sudden loss of consciousness, such as skydiving, hang gliding, mountain climbing, and scuba diving, could be deadly and should probably be avoided.

Drug Information

The American Academy of Neurology's practice guideline center (https://www.aan.com/Guidelines/) provides information about epilepsy and medications for practitioners. Other sources of information on AEDs include the American Epilepsy Society (https://www.aesnet.org/clinical_resources) and the National Institute of Neurological Disorders and Stroke (http://www.ninds.nih.gov/).

Patient-Oriented Information Sources

Patients often have questions about epilepsy prognosis and treatment, first aid, educational needs, pregnancy, and driving and insurance. The American Epilepsy Foundation or the many epilepsy societies around the country can help answer those questions. These organizations provide both professional and lay support assistance, including counseling and psychotherapy, access to social workers, and financial assistance.

Nutrition/Lifestyle Changes

The ketogenic diet has been advocated as a means of treatment for patients with epilepsy. This diet, high in fat and low in carbohydrates, is usually used in children refractory to AEDs. However, there does not appear to be reliable evidence supporting the use of the ketogenic diet in people with epilepsy.

Driving is, of course, one of the most serious restrictions. Laws concerning driving vary from state to state, but in general, driving is not advised for 6 months after the last seizure. Some exceptions are strictly nocturnal seizures or those related to the discontinuation of an anticonvulsant on a physician's advice. Individual state laws regarding the driving restriction need to be reviewed by the practitioner.

First aid for seizure activity consists primarily of protecting the patient's head and body from injury. It usually is not advisable to try to open the patient's mouth or to put objects in the patient's mouth. This can result in injury to the patient's mouth and airway as well as to the bystander. However, removing dentures, excessive secretions, and foreign materials from the mouth after a tonic–clonic seizure phase is completed may be helpful. Turning the patient into a semiprone position in the postictal period helps to prevent aspiration.

Complementary/Alternative Medicine

Self-reported use of complementary and alternative medicine (CAM) in patients with epilepsy has been described to be as high as 70%. CAM therapies utilized for epilepsy are wide ranging and include but are not limited to acupuncture, classical music, oxygen, herbal supplements, homeopathic regimens, meditation, aromatherapy, chiropractic manipulation, cranial–sacral therapy, and marijuana. Data showing benefit to these therapies are limited but patient reported satisfaction is often high. One of the most discussed CAM therapies for treatment of refractory seizures are cannabinoids. The cannabinoid, cannabidiol, has received the most interest as it does not bind to the cannabinoid 1 and 2 receptors in the brain and lacks the psychotropic side effects seen with other cannabinoids. Available animal data suggest potential for seizure reduction with the use of cannabidiol; however, clinical data in humans are lacking and are warranted before cannabidiol therapy can be a recommended component of epilepsy treatment.

Case Study*

Accompanied by her boyfriend, B.C., age 23, visits your office. Her boyfriend states, "She hasn't been herself the last month. She has headaches and is completely confused and tired for no reason." B.C. denies using illicit drugs and any recent traumatic injuries. She thinks her problem started approximately a month ago when she was at a club dancing. Her friends told her that she became confused and began tugging at her clothes. Then she fell down and was unconscious for a few minutes. When she awoke, she felt extremely tired and did not know what was going on. Her boyfriend recalls that she had been hit in the head with a softball during a game the day before they went dancing.

Past medical history discloses insulin use since early childhood (currently 10 units NPH in the morning and 10 units regular insulin before meals), Ranitidine at bedtime, and Ibuprofen (1 or 2 tablets twice a day) for headaches. She is interested in becoming pregnant in the next 12 to 24 months. The patient says she has no allergies and does not drink or use recreational drugs or tobacco.

On physical examination, B.C. is 5 foot 4 inches and 130 lb. Her temperature is 37°C, pulse rate 78, blood pressure 118/76, and glucose level 90. Skin appears normal. Head and neck are normal, chest is clear for anterior and posterior sounds, cardiovascular RRR and (2) r/m/g, and laboratory values are within normal limits. EEG findings include sharp-wave discharges.

At a follow-up visit 2 months later, B.C. and her boyfriend report that things have gotten worse. The boyfriend states that as B.C. was eating dinner one night, she had a seizure. She was completely stiff for a short time, and then her arms and legs began moving. He believes that he was unconscious for a few minutes. B.C. says he could not

remember what had happened when she woke up.

Diagnosis: Generalized Tonic–Clonic Seizure

1. Which of the following should be true regarding your initial AED regimen?
   a. Initial combination therapy is warranted due to increased success rates.
   b. Drugs that are taken two to three times daily are preferred due to a lower risk of seizure if a dose is missed.
   c. Levetiracetam is the preferred agent for all seizure types and patients.
   d. The risks of pregnancy must be discussed prior to starting any AED.

2. Which of the following is the most appropriate initial antiepileptic regimen for this patient?
   a. Levetiracetam 500 mg PO daily
   b. Phenytoin 100 mg PO three times daily
   c. Pregabalin 50 mg PO three times daily
   d. Clobazam 5 mg PO twice daily

3. The patient fails to respond and has significant side effects to her initial therapy. Her initial therapy is to be discontinued. Which of the following would be the MOST appropriate replacement?
   a. Valproic acid 500 mg twice daily
   b. Lamotrigine 100 mg twice daily
   c. Lacosamide 100 mg twice daily
   d. Rufinamide 200 mg twice daily

4. After several different AEDs, the patient ends up on carbamazepine and phenytoin. A serum concentration on week 2 of therapy was 6 mcg/mL. The patient presents after 8 weeks of therapy with increased seizures and she is found to have a serum concentration of 2 mcg/mL. Which of the following is a likely cause?
   a. Autoinduction of CYP3A4.
   b. Patient has the HLA-B*1502 subtype.
   c. The oral contraceptive that she recently started.
   d. Coadministration with alcohol.

5. Despite the use of oral contraception, the patient becomes pregnant. Her AED regimen consists of valproic acid and lacosamide. What is the most appropriate treatment intervention?
   a. Discontinue valproic acid and continue lacosamide monotherapy.
   b. Discontinue lacosamide and continue valproic acid monotherapy.

c. Continue combination therapy.
d. Discontinue valproic acid and add phenytoin.

40 Major Depressive Disorder

Jennifer A. Reinhold

Major depressive disorder (MDD) is a mood disorder characterized by alterations in cognition, behavior, and physical functioning. It is a constellation of symptoms that interfere with normal function and may render an individual unable to perform psychologically, emotionally, and cognitively at previously attainable levels. Among the cardinal symptoms associated with a depressive episode are depressed mood, sadness, hopelessness, sleep disturbance, changes in appetite and weight, loss of interest, guilt, difficulty concentrating, and suicidal ideation. Further delineated by its recurrence and chronicity, depression results in functional impairment in multiple life domains and is a leading predictor of worsened morbidity and mortality. The clinical course is further complicated by the strong correlation of depression to psychiatric and physical comorbidity.

It is estimated that MDD affects 151 million individuals worldwide, with 6.2% lifetime prevalence. In the United States alone, depression is associated with the loss of 225 million missed workdays and indirect annual costs exceeding $83 billion (Donohue & Pincus, 2007). Initial onset of depression may occur at practically any time throughout life; however, the peak onset is considered to be during the fourth decade of life. Earlier onset of presentation is inversely associated with successful treatment outcome; younger patients with depression tend to have a more severe and complicated clinical course with less likelihood of remission and an increased likelihood of recurrence. Today, although 80% to 90% of those affected can be treated effectively, only one third seek treatment.

Causes

There has not been a single causative factor for the development of depression elucidated. Rather, the development of depression is thought to be a multifactorial, complicated interplay among numerous physiologic, social, genetic, environmental, and biochemical factors. First-degree relatives of an individual with MDD have a relative risk of developing MDD that is 2.8 times that of the general population. Though not confirmed in large randomized controlled trials, some studies suggest an overall heritability of 37% to 43%. More than 50% of patients who have experienced one episode of major depression will experience a second; over 80% of patients who experience a second episode will experience a third.

Pathophysiology

Most current research focuses on neurochemical aspects of depression and has spurred several theories relating to the generation and maintenance of specific neurotransmitters in the central nervous system. The basis for these neurochemical theories is the hypothesis that abnormal neurotransmitter release or decreased postsynaptic receptor sensitivity is affected before and during a major depressive episode. At least four theories relate to this hypothesis (Box 40.1). Three of the four theories focus on a functional or absolute deficiency in the neurotransmitters serotonin, norepinephrine, or both. A functional deficiency suggests that neurotransmitters are produced but the postsynaptic receptors cannot fully transmit the neural impulse. This is in contrast to an absolute deficiency, in which no neurotransmitters are produced or the postsynaptic receptors cannot transmit the signal at all.

BOX 40.1 Pathophysiologic Hypotheses of Depression

Serotonin Hypothesis
A functional or an absolute deficiency in the neurotransmitter serotonin
Catecholamine Hypothesis
A functional or an absolute deficiency in the neurotransmitters norepinephrine, serotonin, or dopamine
Permissive Hypothesis
Diminished serotonin gives "permission" for a superimposed norepinephrine deficiency to manifest as depression
Beta-Adrenergic Receptor Hypothesis
Depression results from increased beta-adrenergic receptor sensitivity

Similar to the theories associated with the monoamine catecholamines norepinephrine and serotonin, new evidence suggests that dopamine may play a significant role in the pathogenesis and symptomatology of MDD. Genetic polymorphisms in the genes associated with dopamine transmission may contribute to an increased susceptibility to depression. Deficits in dopamine release or transmission have been linked to dysphoria, one of the most prominent features of MDD. The permissive hypothesis, a more contemporary theory, suggests that reduced serotonin activity sets the stage for a mood disorder, such as depression or mania, depending on the underlying norepinephrine level. A low serotonin level coupled with a low norepinephrine level suggests that depression results from an increased beta-adrenergic receptor sensitivity. This alteration in postsynaptic receptor sensitivity results in an imbalance between the effects of norepinephrine and serotonin and may create a functional deficiency in serotonin. Secondary to the interplay among the

catecholamines within the monoaminergic network, any impact on one of the monoamines will likely impact the others. This is applicable to the predisposition and development of MDD as well as the therapeutics of MDD.

Diagnostic Criteria

Mildly depressed patients meet the minimum criteria for diagnosis, whereas moderately depressed patients display a greater degree of dysfunction. Severely depressed patients experience symptoms well in excess of the diagnostic criteria. Their symptoms often greatly interfere with social and occupational functioning. A 2013 update of the American Psychiatric Association's publication, *The Diagnostic and Statistical Manual of Mental Disorders 5* (DSM-5), has established criteria for the diagnosis of depression, which are listed in Box 40.2. A patient must exhibit at least five of these signs or symptoms in the same 2-week period along with symptoms of depressed mood or anhedonia, the inability to gain pleasure from normally pleasurable experiences (American Psychiatric Association, 2013).

BOX 40.2 *Diagnostic and Statistical Manual of Mental Disorders 5:* Criteria for Diagnosing Major Depressive Episode

A. Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning. At least one of the symptoms must be #1 or #2.
   1. Depressed mood most of the day. In children or adolescents, the mood can be irritable instead of depressed.
   2. Diminished interest or pleasure in all or almost all of usual activities.
   3. Significant weight loss or weight gain or decrease or increase in appetite.
   4. Insomnia or hypersomnia.
   5. Psychomotor agitation or retardation as observed by others.
   6. Fatigue or loss of energy.
   7. Feelings of worthlessness or excessive or inappropriate guilt.
   8. Diminished ability to think or concentrate, indecisiveness.
   9. Recurrent thoughts of death, suicidal ideation, suicide attempt, or a specific plan for suicide.

B. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

C. The symptoms are not due to the direct physiologic effects of a substance or a medical condition.

In addition to the DSM-5 diagnostic criteria, numerous rating scales are employed in

clinical practice to assess the severity of depression as well as response to treatment. The 17-item Hamilton Depression Scale (HAM-D) and the Beck Depression Inventory (BDI) are clinician-rated scales that are frequently used for this purpose.

Subtypes of MDD delineate the etiology and severity of the illness or episode. These subtypes include mild, moderate, and severe depression. The descriptors (known as *specifiers*) refer to the severity of dysfunction and delineate comorbid or distinguishing features, such as melancholy, catatonia, and psychosis.

Types of Depression

The DSM-5 slightly modified the categorization of depressive disorders in its most recent iteration. MDD and dysthymia are now both included under the singular category of persistent depressive disorder. Dysthymia is a chronic but less severe form of depression that is characterized by 2 years of depressive symptoms and functional impairment. It shared the same common core set of features with MDD and potentially did separate clinically from MDD, which led to its absorption into a larger category and its cessation as an independent diagnosis. The diagnostic criteria for MDD did not change; however, two new specifiers (terms or qualifiers that further narrow the MDD presentation and allow for more tailored treatment based on symptomatology) have been added; "with mixed features" refers to MDD with the coexistence of at least three manic symptoms, and "with anxious distress" suggests the presence of an anxious component. The remainder of the depression categories and subtypes remain unchanged. The focus of this chapter will be MDD, as this is the most common presentation; however, the other types are reviewed below.

Postpartum Depression

The onset is usually within 6 weeks after childbirth, and symptoms last from 3 to 14 months. Prevalence of postpartum depression ranges from 5.2% to 74% in developed countries (Norhayati et al., 2015). Women with a history of postpartum depression have a 50% risk of recurrence, and 30% of women with a history of depression not related to childbirth have postpartum depression.

Seasonal Affective Disorder

Seasonal affective disorder (SAD) is a pattern of depressive or manic episodes that occurs with the onset of winter. As the days become shorter and the weather colder, there is an increase in depressive symptoms. SAD causes individuals to eat more, sleep more, experience chronic fatigue, and gain weight. In pronounced cases, significant social withdrawal may occur.

Major Depression with Melancholic Features

Melancholic depression is a severe form of depression characterized by a profoundly depressed mood, nonreactivity, and neurovegetative symptoms. This type of depression is markedly more difficult to treat; however, it tends to be highly responsive to drug therapy.

Major Depression with Psychotic Features

Patients suffering from psychotic depression, in addition to the typical depressive symptoms, will also experience mood-congruent delusions and hallucinations.

Initiating Drug Therapy

The most current guideline for the management of MDD is the American Psychiatric Association's practice guideline for the treatment of patients with MDD, third edition, published in 2010. When prescribing drug therapy, practitioners consider many indicators, among them the severity of symptoms (e.g., mild, moderate, or severe), type of depression (major, acute episode, postpartum, seasonal, dysthymia), duration of therapy, the patient's age, sex, comorbid conditions, and concomitant medications. In addition, if the patient has experienced depressive episodes in the past, the choice of drug may depend on what drug or drug class the patient responded to previously. An abundance of evidence supports the relative efficacy equivalence among antidepressant drug classes. Therefore, selection of the initial drug is generally not based on efficacy but rather on the side effect profile, patient preference, and target symptoms.

Initial staging of depression severity and ongoing assessment of response to treatment is generally accomplished by utilizing patient- or clinician-rated scales. The 17-item clinician-rated HAM-D is traditionally considered the inventory of choice for monitoring response to therapy. Other tools used in assessing the severity or source of depression include a typical health and medication history. Also useful is a physical examination with documentation of the patient's height, weight, and pertinent laboratory test findings, such as a complete blood count with differential, electrolytes, and kidney and liver function. Caution must be exercised in diagnosing MDD since certain medications and illnesses can induce depression. These conditions must be ruled out prior to making the diagnosis (Box 40.3).

BOX 40.3 Selected Conditions and Medications Associated with Depression

Endocrine disorders

- Addison disease
- Cushing syndrome
- Hypothyroidism

Gastrointestinal disease

- Irritable bowel syndrome
- Inflammatory bowel disease
- Cirrhosis

Infections

- AIDS

- Influenza
- Meningitis

Cardiovascular diseases

- Congestive heart failure
- Myocardial infarction

Neurologic disorders

- Alzheimer disease
- Multiple sclerosis
- Parkinson disease
- Stroke
- Chronic headache

Cancer

Alcoholism

Drug use

- Alcohol
- Antihypertensives
  - Reserpine
- Methyldopa
- Diuretics
- Propranolol
  - Clonidine
- Oral contraceptives
- Steroids

Rheumatologic

- Systemic lupus erythematosus
- Chronic fatigue syndrome
- Fibromyalgia
- Rheumatoid arthritis

Nonpharmacologic therapy for depression includes several psychotherapeutic techniques such as cognitive–behavioral therapy and interpersonal therapy. Psychotherapy is traditionally reserved for patients with concurrent psychosocial stressors. Although psychotherapy alone may be effective, patients meeting the criteria for major depression should be evaluated for medication therapy. Moderately depressed patients often need a combination of medication and psychotherapy. Severely depressed patients may be refractory to psychotherapy, and their risk for suicide should be assessed.

Goals of Drug Therapy

Although historically nearly unattainable secondary to poor tolerability of available drugs, the ultimate goal of therapy for depression is *remission* and resolution of residual symptoms. A *response* to therapy, defined as a 50% reduction in the HAM-D score from baseline, was previously accepted as an appropriate therapeutic outcome. However, with the advent of newer and more tolerable drug therapies, the paradigm has shifted such that full remission is considered the only acceptable goal of therapy. Remission represents a complete resolution of depressive symptoms and a full return to previous level of functioning. Patients who have remitted will no longer fulfill the *DSM-5* diagnostic criteria for depression and will score 7 or below on the HAM-D (consistent with normal).

Residual symptoms refer to symptomatology suggestive of depression that persists after a response to treatment. Even upon a successful course of treatment and clinical remission, some patients may continue to experience cognitive depressive symptoms, such as forgetfulness or apathy, or physical symptoms like fatigue. Patients who do not remit or who continue to have residual symptoms are at a greater risk for relapse or recurrence, have a shorter duration between depressive episodes, and have a worsened overall mortality. Optimal drug therapy not only resolves the acute symptoms of depression but also reduces the risk of relapse (American Psychiatric Association, 2010).

Monitoring Patient Response

Drug therapy for depression consists of three phases: acute, continuation, and maintenance. Usually, the patient needs additional contact with the practitioner or other health care provider (psychologist, social worker) during all phases of drug therapy. Assessments of efficacy, side effects, and adherence to the drug regimen should be made weekly, if possible.

Acute Treatment Phase

The goal of drug therapy in the acute treatment phase is to treat the patient until full remission and a return to the premorbid level of function. The duration of this phase is 6 to 8 weeks and potentially up to 12 weeks with apparent improvements occurring within the first 1 to 2 weeks. Though some clinicians attribute early response to a placebo effect, there is a preponderance of evidence that supports a true therapeutic effect within the first 14 days. In fact, newer research suggests that improvement by week 2 of therapy is a highly sensitive predictor of eventual response and remission.

Patients should have frequent contact with their practitioner throughout therapy, but especially in the first few weeks. Lack of efficacy early on may negatively impact patient adherence and motivation. Early improvements tend to include sleep satisfaction, appetite normalization, and recovery of cognitive function. Eventually, patients will experience an elevation in mood and resolution of anhedonia. Full assessment of the effects of the antidepressant should occur at the 4- to 6-week interval after drug therapy begins. At this point, the practitioner evaluates improvements in the target signs and symptoms, assesses adverse drug effects, and determines whether dosage increases or decreases are necessary. To assist the evaluation, several depression rating scales, such as the HAM-D, the Zung Self-Rating Scale for Depression, and the BDI, may again be used as an objective measure of the change, or lack thereof, in a depressive state.

Continuation Phase

The continuation phase represents the time after a treatment response is seen in the acute phase and usually lasts 9 months to 1 year. The practitioner should continue antidepressant therapy for 4 to 6 months after symptom resolution. Failure to continue medication beyond symptom resolution confers an increased risk of relapse. When therapy is eventually discontinued, the medication is typically tapered over a few weeks to avoid physical or psychological effects that occur with abrupt discontinuation of the medication (discontinuation syndrome). During this time, the patient should be monitored closely for reemergence of symptoms.

Maintenance Phase

For some patients, long-term or even indefinite therapy is indicated. Maintenance therapy should be considered in all patients with three or more prior episodes or any patient with two episodes within the past 5 years, a comorbid substance abuse or anxiety disorder, a family history of recurrent depression, or onset of depression earlier than age 20 or later than age 40. This phase of therapy uses the same effective antidepressant used during the acute and continuation phases for a minimum of 3 and up to 5 years or longer. The risk for recurrence increases with every subsequent episode of depression (Bulloch et al., 2014). Patients who have had two or more episodes of depression are candidates for indefinite antidepressant therapy.

Modification of Drug Therapy

Despite the availability of pharmacologic therapies for depression and the relative equivalence in efficacy among the classes, approximately 50% of patients will not respond to the first trial of a first-line antidepressant (American Psychiatric Association, 2010). Overall response rates to antidepressants in general are 50% to 75%. As evidenced by the pivotal STAR*D trial, subsequent trials of alternate medications after the initial failure yield success rates of 20% with a gradual decrease in rates of response and remission with each trial. Only about one third of patients will remit after the first trial, and almost 30% of patients will not remit even after a series of sequential therapies (Papakostas, 2009; Rush et al., 2003).

Initiation of an appropriate drug at an optimal dose, giving the drug an adequate trial (6 to 12 weeks), and educating the patient about the time frame for response and the importance of adherence are critically essential therapeutic concepts. If the patient is started on an appropriate drug for an adequate period, has been compliant with therapy, and does not respond or remit in a reasonable amount of time, drug therapy may need to be adjusted.

There are four common strategies used to modify drug therapy in the depressed patient: dosage increase/optimization, switching to a different drug within the same class or switching to a drug in a different class, augmenting the current drug, or combining medications. Increasing the dose of a drug is typically recommended if the patient has had a response or a partial response during the first few weeks. If an inadequate response or lack of response occurs within the first few weeks of therapy, a switch to a different drug may be warranted. Within-class and between-class switches are viable options depending upon the patient presentation. Lack of response to one drug within a class does not necessarily confer lack of response to all drugs within a class; therefore, switching within a class may be appropriate. Augmentation of the initial drug preserves any benefit experienced by the patient during the trial and also targets side effects or residual symptoms. The combination of two or more drugs with differing mechanisms of action has also been shown to be efficacious.

Antidepressant Drugs

Several drug classes are available for treating depression: selective serotonin reuptake inhibitors (SSRIs), serotonin norepinephrine reuptake inhibitors (SNRIs), tricyclic antidepressants (TCAs), monoamine oxidase (MAO) inhibitors, and atypical agents. They all exert a pharmacologic effect by impacting one or more of the primary neurotransmitters theorized to contribute to depression. In theory, each of the antidepressants increases the relative amount of neurotransmitter available in the synapse, either by inhibiting its metabolic degradation or by decreasing the rate at which it is recycled (by the process called *reuptake*) back into the presynaptic neuron (Figure 40.1). For example, SSRIs inhibit the reuptake of select isoforms of serotonin, thereby increasing the functional availability of serotonin in the synaptic cleft. SNRIs increase the relative concentrations of both serotonin and norepinephrine, with more serotonergic or noradrenergic activity depending upon the dose. TCAs are thought to work by inhibiting the reuptake of norepinephrine and serotonin from the synaptic cleft, thereby increasing the amount available to stimulate the postsynaptic neuron. Conversely, MAO inhibitors limit the metabolism of monoamines such as dopamine, serotonin, and norepinephrine. This nonselective inhibition also increases the relative amounts of each of these catecholamines available to stimulate the postsynaptic neurons. However, this nonselectivity may contribute to side effects.

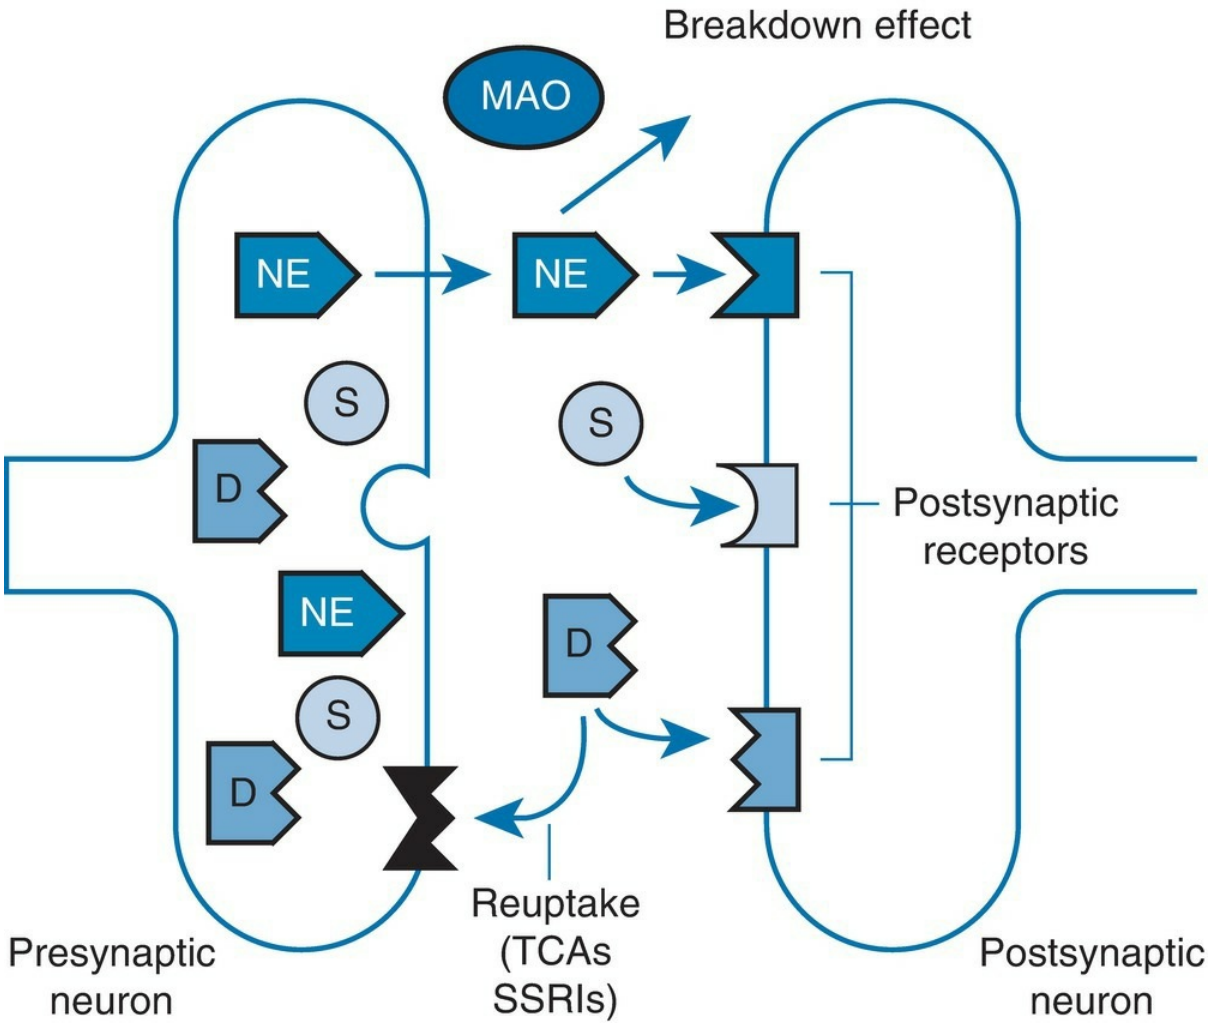

FIGURE 40.1 Schematic representation of the mechanism of action of antidepressant agents. Neurotransmitters (norepinephrine [NE], serotonin [S], dopamine [D]) are released from the presynaptic neuron into the synaptic space. They interact with the postsynaptic receptors and continue the neuronal transmission. After release from the postsynaptic neuron, these agents can be broken down by the enzyme monoamine oxidase (MAO) and the components recycled into the presynaptic neuron, or they can be taken up again through the reuptake mechanism. Antidepressant agents can (1) block the MAO enzymes, MAO inhibitors; (2) inhibit the reuptake of the neurotransmitter; or (3) agonize or antagonize an associated receptor. In effect, each mechanism increases the available concentration of the neurotransmitter.

Table 40.1 presents the antidepressants and the neurotransmitters primarily affected. Because all of these agents appear to have relatively equal efficacy, the practitioner should select the most appropriate initial therapy based on side effect profiles, predicted patient compliance, and cost of therapy. The following discussion and accompanying tables and charts will help the practitioner in selecting the optimal initial agent for treating depression.

TABLE 40.1 Classification of Antidepressant Agents and Neurotransmitters Affected

Generic Name	Brand Name	Primary Neurotransmitters Affected		
		NE	5-HT	D
Tricyclic Antidepressants				
amitriptyline	Elavil	++++	++++	0
desipramine	Norpramin	+	+++	0
doxepin	Sinequan	+	+++	0
imipramine	Tofranil	+++	++	0/+
nortriptyline	Pamelor	++	+++	0
protriptyline	Vivactil	+	++++	0
trimipramine	Surmontil	++	++	0
Selective Serotonin Reuptake Inhibitors				
citalopram	Celexa	0	++++	0
fluoxetine	Prozac	0	++++	0
fluvoxamine	Luvox	0	++++	
paroxetine	Paxil	0	++++	0
sertraline	Zoloft	0	++++	0
escitalopram	Lexapro	0	++++	0
Serotonin Norepinephrine Inhibitors				
venlafaxine	Effexor	++++	+++	+
desvenlafaxine	Pristiq	++++	+++	+
duloxetine	Cymbalta	++++	+++	+
levomilnacipran	Fetzima	++++	++++	0
Monoamine Oxidase Inhibitors				
phenelzine	Nardil			
Atypicals				
amoxapine	Asendin	+++	+++	0
bupropion	Wellbutrin	+	0/+	+
maprotiline	Ludiomil	++++	0	0
mirtazapine	Remeron	+	++++	0
nefazodone	Serzone	0/+	+++	0
trazodone	Desyrel	0	++	0
Novel Drugs				
vilazodone	Viibryd	0	++++	0
vortioxetine	Brintellix	0	++++	0

NE, norepinephrine; 5-HT, 5-hydroxytryptamine (serotonin); D, dopamine; + + + +, highly potent effect; +, minimally potent effect; 0, no effect.

Selective Serotonin Reuptake Inhibitors

The development of SSRIs changed the landscape of depression pharmacotherapy. Just as effective as TCAs and older antidepressants, SSRIs boast improved tolerability and reduced lethality in overdose. The leading cause of death in the depressed patient population is suicide, and therefore, utilizing a drug class with minimal risk of successful overdose is paramount. The tolerability profile, relative safety in overdose, and the need for fewer titrations have resulted in SSRIs effectively replacing TCAs as the drug class of choice for treating depression. SSRIs work primarily by binding to the serotonin transporter and inhibiting the reuptake of this neurotransmitter into the presynaptic neurons. Relative efficacy is comparable within the class. Table 40.2 identifies starting dosages and expected dosage ranges of SSRIs.

TABLE 40.2 Overview of Antidepressant Agents

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Tricyclic Antidepressants			
amitriptyline (Elavil) Start: 25 mg tid Range: 50–300 mg	Sedation, dry mouth	History of cardiovascular disease	Therapeutic plasma concentration range: 60–200 ng/mL
amoxapine (Asendin) Start: 50 mg tid Range: 100–600 mg	Anticholinergic, sedation	History of epilepsy or cardiac dysfunction	Therapeutic plasma concentration range: 180–600 ng/mL
clomipramine (Anafranil) Start: 25 mg hs Range: 150–200 mg	Sedation, orthostatic hypotension	History of cardiovascular disease	Blood levels not used clinically
desipramine (Norpramin) Start: 25 mg tid Range: 50–300 mg	Sedation, dry mouth	Same as above	Therapeutic plasma concentration range: 125–250 ng/mL
doxepin (Sinequan) Start: 25 mg tid Range: 75–300 mg	Sedation, orthostatic hypotension	Same as above	Therapeutic plasma concentration range: 110–250 ng/mL
imipramine (Tofranil) Start: 25 mg tid Range: 50–300 mg	Sedation, orthostatic hypotension	Risk of falling, history of cardiovascular disease	Therapeutic plasma concentration: 180 ng/mL
maprotiline (Ludiomil) Start: 25 mg tid Range: 50–300 mg	Anticholinergic effects, sedation, seizures	History of epilepsy or cardiac dysfunction	Therapeutic plasma concentration range: 200–400 ng/mL
nortriptyline (Pamelor) Start: 25 mg tid Range: 50–200 mg	Sedation	History of cardiovascular disease	Therapeutic plasma concentration range: 50–150 ng/mL
protriptyline (Vivactil) Start: 5 mg tid Range: 15–60 mg	Sedation, orthostatic hypotension	Same as above	Therapeutic plasma concentration range: 100–200 ng/mL
trimipramine (Surmontil) Start: 25 mg tid Range: 15–90 mg	Sedation, cardiac conduction disturbances	Same as above	
Selective Serotonin Reuptake Inhibitors			
citalopram (Celexa) Start: 20 mg qd Range: 20–40 mg qd	Nausea, dry mouth, increased sweating, somnolence, insomnia	MAO inhibitor therapy	In trials, ~6% of men experienced difficulty with ejaculation, and 3% reported impotence.
fluoxetine (Prozac) Start: 10–20 mg each morning Range: 10–80 mg	Insomnia	Same as above	Take in morning to avoid insomnia.
fluvoxamine (Luvox) Start: 75 mg bid Range: 100–300 mg	Increases in blood pressure	Same as above	Monitor blood pressure.
paroxetine (Paxil) Start: 20 mg qd Range: 10–50 mg	Mild sedation, delayed ejaculation	Same as above	May be useful in patients displaying insomnia as depressive symptom
sertraline (Zoloft) Start: 50 mg qd Range: 50–200 mg	Insomnia	Same as above	Take in morning to avoid insomnia. May be agitating
escitalopram (Lexapro) Start: 10 mg qd Range: 10–20 mg qd	Nausea, diarrhea, increased sweating, somnolence, insomnia, fatigue	Same as above	Extensively metabolized in the liver The dose for hepatic impairment is 10 mg qd.

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Serotonin Norepinephrine Reuptake Inhibitors			
venlafaxine (Effexor) Start: 25 mg tid or 37.5 mg bid Range: 75–375 mg	Increases in blood pressure, sexual dysfunction	Do not use within 14 d of MAO inhibitor therapy; caution in narrow-angle glaucoma	Monitor blood pressure closely.
desvenlafaxine (Pristiq) Start: 50 mg Range: 50–100 mg (no additional benefit above 50 mg)	Same as above	Same as above	May cause significant dose-related increases in total cholesterol, LDL, and triglycerides; nausea occurs in up to 30% of patients
duloxetine (Cymbalta) Start: 40–60 mg Range: 60–120 mg (no additional benefit above 60 mg)	Same as above	Same as above	May worsen psychosis in some patients or precipitate a shift to mania or hypomania in patients with bipolar disorder; nausea occurs in up to 30% of patients
levomilnacipran (Fetzima) Start: 20 mg daily (increase by 20–40 mg intervals every 2 d per schedule) Range: 40–120 mg	Orthostatic hypotension (dose related), nausea, erectile dysfunction (dose related)	Same as above	Specific dosing titration over several days
Atypicals			
trazodone (Desyrel) Start: 50 mg tid Range: 50–600 mg	Orthostatic hypotension, priapism	Contraindicated in recovery phase of myocardial infarction	
bupropion (Wellbutrin, Wellbutrin SR, Wellbutrin XL) Start: 100 mg twice daily (IR); 150 mg daily (SR) Range: 300–450 mg	Headache, insomnia, xerostomia	Do not use within 14 d of MAO inhibitors; do not use during an abrupt cessation of sedatives or ethanol.	Lowers seizure threshold at dose >450 mg; avoid concomitant alcohol ingestion
Novel Drugs			
vilazodone (Viibryd) Start: 10 mg daily (increase to 20 mg after 7 d and to 40 mg after more days) Usual dosing: 40 mg daily	Diarrhea, nausea, dizziness	Do not use within 14 d of MAO inhibitors; do not use during an abrupt cessation of sedatives or ethanol	Significantly less risk of sexual dysfunction compared to other antidepressants with similar mechanisms
vortioxetine (Brintellix) Start: 10 mg daily (increase to 20 mg daily as tolerated) Range: 10–20 mg daily (5 mg available for patients intolerant of usual doses)	Sexual dysfunction, nausea	Do not use within 14 d of MAO inhibitors; do not use during an abrupt cessation of sedatives or ethanol.	Metabolized primarily by CYP2D6—specific dosing adjustments recommended when concomitantly prescribed with strong inducers or inhibitors of CYP2D6

Time Frame for Response

The effects of these drugs become apparent within 4 to 6 weeks of treatment. The length of therapy for first episodes of depression is 4 to 6 months after recovery. Continued treatment beyond the point of recovery drastically reduces the relapse potential over 1 to 3 years. Measures of efficacy include improved scores in the initial rating scales, self-reported improvement in the target symptoms originally described by the patient, and improved affect observed by the practitioner.

Adverse Events

SSRIs are usually administered in the morning because of the potential to induce anxiety and insomnia. Serotonin and serotonin receptors have diverse and variable effects on sleep architecture. SSRI-induced insomnia is thought to be largely related to the suppression of rapid eye movement (REM) sleep, which results in an overall decrease in sleep quality and total sleep time. Insomnia that presents as part of the clinical picture of depression itself or that is treatment emergent may be treated with a sedative–hypnotic drug such as a benzodiazepine or a nonbenzodiazepine GABA-A receptor agonist (zolpidem, etc.). Some patients do, however, experience sedation with an SSRI, and these patients may be advised to take their medication at bedtime.

SSRIs have virtually no potential for inducing orthostatic hypotension or cardiac conduction abnormalities, which makes them ideal for elderly patients or those with a history of arrhythmias. They do have epileptogenic potential, so caution must be used in patients with a history of seizures. Weight gain is another common adverse effect that occurs with various frequencies depending upon the medication. GI upset occurs transiently during the onset of therapy in approximately one third of patients.

Among the most commonly reported SSRI-associated adverse effects is pervasive sexual dysfunction, which may impact any or all of the phases of sexual response and function. This is potentially due to the increased serotoninergic activity at the 5-HT2c receptor. Sexual dysfunction is often a reason cited by patients for prematurely stopping their antidepressants. All SSRIs have the potential to induce sexual dysfunction. The incidence varies from about 24% to 73%, depending on the individual drug. Paroxetine is comparatively associated with the highest rate of sexual side effects, and fluvoxamine may be the least likely in the class to cause sexual dysfunction. The manifestations include reduced libido, arousal difficulties, and delayed or absent orgasm in both men and women. Risk of this side effect must be communicated to the patient prior to starting therapy. Treatment of this dysfunction is available, but lowering the dose without compromising efficacy may be the first strategy. If the symptoms persist, one pharmacologic strategy to consider is the addition of bupropion, which has been successfully used to mitigate the sexual dysfunction and provide an additive and different antidepressant mechanism of action. In addition, sildenafil (Viagra), tadalafil (Cialis), or vardenafil (Levitra) may benefit

some male patients who suffer from erectile dysfunction. Patients often become tolerant to the sedation and the gastrointestinal adverse effects, but rarely do patients become tolerant to the sexual dysfunction, and therefore it tends to persist throughout the course of therapy.

The SSRIs are associated with a discontinuation syndrome, particularly upon abrupt discontinuation, but sometimes even after an appropriate taper. The constellation of symptoms include not only a worsening and return of depressive symptoms but also a flu-like presentation, insomnia, irritability, GI effects, and anxiety.

Recently, the question of increased suicidality has been raised with respect to SSRIs and antidepressants in general. SSRIs specifically are associated with an increase in attempted and completed suicide in patients younger than age 25. They have no effect on suicidality in patients ages 25 to 64, and they reduce suicidal behaviors in patients over age 65.

Interactions

The selection of a specific SSRI for an individual patient is determined by the drug interaction profile. SSRIs inhibit various components of the cytochrome P-450 (CYP450) system, thus causing elevations in other medications that are metabolized by this system. Before prescribing an SSRI, the practitioner should conduct a medication history and identify the potential for altering the pharmacokinetics or pharmacodynamics of medications that the patient will be taking concomitantly. (Table 40.3 offers a guide to the major drug–drug interactions with common SSRIs.)

TABLE 40.3 Selected Antidepressant Drug Interactions Involving the Cytochrome P-450 System

Agent–Drug Interaction Potential	Isozyme Inhibited	Drugs Affected
Addition of this agent…	*will inhibit this isoenzyme…*	*resulting in increased levels of these drugs:*

Of special note, SSRIs are contraindicated with MAO inhibitors because the combination can lead to a sudden increase in systemic serotonin. The MAO inhibitor–mediated inhibition of the serotonin metabolism (thereby increasing its circulating availability) coupled with the action of the SSRI itself can result in serotonin excess. The manifestation of excessive serotonin, which is potentially life threatening, is termed *serotonin syndrome*. Signs and symptoms include heat stroke, vascular collapse, fever, and tachycardia.

Serotonin Norepinephrine Reuptake Inhibitors

The pharmacologic effect of SNRIs is primarily mediated through the potent inhibition of neuronal uptake of serotonin and norepinephrine and the weak inhibition of dopamine reuptake. SNRIs have no significant activity for muscarinic cholinergic, H_1-histaminergic, or alpha$_2$-adrenergic receptors and do not possess MAO inhibitor activity. Since the inception of SNRIs, there has been clinical debate regarding whether or not this newer class is superior to SSRIs because of its dual inhibition of serotonin and norepinephrine. It is postulated that this confers a broader antidepressant effect. Venlafaxine (Effexor), the first drug developed in this class, has been extensively studied in terms of its comparative efficacy to SSRIs. Numerous studies suggest that there may in fact be a slight but significant advantage in using venlafaxine over SSRIs with respect to remission rates. Literature also supports the use of SNRIs in more severe depression and in treatment-resistant depression (Bauer et al., 2009). There are currently four SNRIs available in the United States: venlafaxine, desvenlafaxine (Pristiq), duloxetine (Cymbalta), and the newly approved levomilnacipran (Fetzima). Desvenlafaxine, the R-isomer of venlafaxine, differs from its parent compound with respect to its simpler dosing regimen, greater bioavailability, and improved ability to inhibit norepinephrine reuptake. Duloxetine has a once-daily dosing schedule, reduced risk of treatment-emergent hypertension, and fewer discontinuation symptoms. An enantiomer of milnacipran, levomilnacipran is a potent and selective inhibitor of serotonin and norepinephrine reuptake, with preferential inhibition of norepinephrine over serotonin. Its efficacy, as evidenced in multiple clinical trials, is similar and possibly slightly less impressive than that of other members of this class. However, it has demonstrated weight neutrality and good tolerability. Please see Table 40.2.

Time Frame for Response

Similar to SSRIs, SNRIs require approximately 4 to 6 weeks (and potentially up to 12 weeks) to exert a full pharmacologic effect. Some cognitive and physical symptoms of depression may begin to remit within the first week of therapy, but the full effect is slightly more protracted. As with any of the antidepressants, SNRIs should be taken through the continuation and maintenance phases to reduce the risk of relapse.

Adverse Events

SNRIs have the potential to produce more adverse effects as compared to SSRIs secondary to the noradrenergic activity; there are higher rates of dry mouth, constipation, nausea, and insomnia. Treatment-emergent hypertension has occurred in patients taking venlafaxine, although the majority of cases occur in patients who are predisposed to developing hypertension. Increases in blood pressure of approximately 10 mm Hg have also been reported in patients who are hypertensive prior to starting venlafaxine therapy. Two dose-related side effects occur with venlafaxine: nausea and hypertension. Starting therapy with lower doses and gradually increasing the dose as tolerated minimizes the nausea. The

prevalence of sexual dysfunction in patients taking venlafaxine, desvenlafaxine, or duloxetine approximates that of SSRIs.

Abrupt discontinuation of SNRI therapy is not recommended, especially venlafaxine. This can produce a discontinuation syndrome similar to that of SSRIs. Duloxetine has not been shown to elicit these types of symptoms to the extent that the other two members of this class have.

Interactions

SNRIs are metabolized by the CYP450 system, namely, the CYP1A2, CYP3A4, and CYP2D6 isoenzymes. Coadministration of SNRIs with other drugs that are substrates of or that otherwise impact those isoenzymes may result in drug interactions. Concomitant administration of MAO inhibitors with SNRIs is contraindicated because this may result in serotonin syndrome.

Tricyclic Antidepressants

Prior to the emergence of SSRIs, TCAs were the mainstay of therapy for MDD. There are no proven significant differences in terms of efficacy between TCAs and SSRIs; however, the improved tolerability of the SSRIs has served as the impetus for a shift away from the TCAs. TCAs are potent inhibitors of the reuptake of norepinephrine and serotonin, with differences in the extent to which each member of this class impacts each neurotransmitter. Clomipramine (Anafranil) is a potent serotonin reuptake blocker, and its metabolite is a potent norepinephrine reuptake blocker (see Table 40.2). Amitriptyline (Elavil), for example, significantly increases the amount of norepinephrine and serotonin available to the postsynaptic neuron. In contrast, nortriptyline (Pamelor) has a relatively low effect on both norepinephrine and serotonin. These drugs, therefore, attempt to restore the balance of neurotransmitters and work in accord with several of the aforementioned theories.

TCAs are also active at acetylcholine and histamine receptors, which contribute to their adverse effect profile. This complex pharmacology, coupled with the anticholinergic side effects, relegates TCAs to second- or third-line therapy for MDD.

Adverse Events

The selection of a TCA for treating depression is based on the adverse effect profile (Table 40.4) in addition to response to previous treatments, if applicable. In varying degrees, all TCAs can cause sedation, which is an important consideration, especially if the depression is characterized by insomnia. Administering a TCA at bedtime may help alleviate this symptom.

TABLE 40.4 Major Adverse Event Profile of Antidepressant Agents

Drug	Major Adverse Events					
	Anticholinergic	Cardiac Conduction	Seizures	Orthostatic Hypotension	Sedation	Sexual Dysfunction

*High rate of nausea and diarrhea.

+ + + + = highly potent effect; + = minimal effect; 0 = no effect.

In addition, the hypotensive effect of each agent varies and should be considered when selecting a particular agent. For example, nortriptyline and desipramine (Norpramin) have less potential for inducing orthostatic hypotension, making them advantageous in elderly patients. Anticholinergic adverse effects are common among this class as is weight gain. Moreover, the epileptogenic potential and life-threatening cardiac conduction abnormalities associated with the TCAs must be considered. TCAs may contribute to atrioventricular block, QT prolongation, and ventricular tachycardia. Preexisting epilepsy and cardiac conduction abnormalities are often considered contraindications to the use of TCAs. TCAs are traditionally lethal in overdose secondary to their proarrhythmic properties.

Therapeutic Ranges

Because the pharmacokinetic properties of the individual agents may vary according to the

patient and few TCAs have established therapeutic ranges, routine monitoring of drug levels is not common. However, establishing the drug level at which a patient has improved is reasonable. In this way, the practitioner has documentation of an effective drug concentration for that patient. Later, if needed, changes in drug therapy may be determined based on this baseline information. Otherwise, drug levels should be evaluated only if the practitioner suspects that the patient is not adhering to therapy or if drug toxicity becomes a concern.

Interactions

Drug interactions with TCAs tend to be pharmacodynamic, although some pharmacokinetic interactions do occur. Pharmacokinetically, TCA drug levels may increase in combination with certain SSRIs (see Table 40.3) and other CYP450 enzyme inhibitors, such as cimetidine (Tagamet), human immunodeficiency virus protease inhibitors, and some antipsychotic agents. There are additive central nervous system effects with TCAs and anticholinergic drugs, such as diphenhydramine (Benadryl). In addition, TCA–MAO inhibitor interactions may significantly increase the level of circulating catecholamines and lead to a potentially fatal hypertensive crisis.

Atypical Antidepressants

The class of drugs labeled *atypical* represents compounds used to treat depression that elude the traditional classification schema. The mechanisms of action are not consistent within the atypical group but all impact one or more monoamines. These agents are generally considered alternatives to SSRIs, SNRIs, or TCAs; however, the utilization of bupropion has rivaled that of the SSRIs and SNRIs. See Table 40.2 for starting dosages and dosage ranges.

Bupropion

Bupropion is a structurally distinct compound from the aminoketone class. It is a relatively weak inhibitor of neuronal uptake of norepinephrine and dopamine, and its metabolite also inhibits the reuptake of norepinephrine. It does not inhibit the reuptake of MAO, and unlike all of the other available drugs, it does not impact the serotonergic system. Bupropion is among the preferred pharmacologic agents, possibly second only to SSRIs and SNRIs. Owing to its virtual absence of sexual adverse effects, bupropion is frequently used in patients who cannot tolerate the sexual adverse effects of SSRIs and SNRIs or may be used adjunctively with these drugs to diminish sexual dysfunction. Rates of somnolence, fatigue, and weight gain are markedly reduced compared to SSRIs, TCAs, and SNRIs (Papakostas, 2009). Bupropion has been implicated in lowering the seizure threshold, especially when combined with alcohol. This tends to occur when dosing exceeds 450 mg daily or more than 150 mg per dose, although the reported risk is less than 1%.

Trazodone

Trazodone (Desyrel) is a weak serotonin receptor antagonist that also blocks serotonin reuptake to a lesser degree. Trazodone is highly sedating at therapeutic doses secondary to its antihistamine properties. Patients whose target symptoms or residual symptoms include insomnia may benefit from the use of trazodone as adjunctive therapy. Trazodone monotherapy is not recommended secondary to modest efficacy. Antidepressant effects will be realized within a few weeks; however, the intended sedative effects occur several hours after the first dose. Also an anxiolytic drug, trazodone has a place in therapy for anxiety disorders as well as depression with comorbid anxiety. Important adverse effects include orthostatic hypotension, nausea, blurred vision, and priapism.

Nefazodone

Nefazodone (Serzone), structurally related to trazodone, acts similarly to trazodone but also inhibits the reuptake of norepinephrine and produces fewer side effects. Because it lacks significant anticholinergic and antihistamine effects, reports of blurred vision, urinary retention, and weight gain are relatively infrequent. Nefazodone interferes with the CYP3A4 system, and caution should be used in patients taking drugs metabolized by this enzyme system. In addition, nefazodone increases the levels of agents such as alprazolam (Xanax) and triazolam (Halcion); practitioners should avoid prescribing these agents concomitantly (see Table 40.3). Prior to initiating nefazodone, the washout period after discontinuing an SSRI should generally be 4 to 5 days for paroxetine (Paxil) and sertraline (Zoloft) and several weeks for fluoxetine (Prozac). Nefazodone carries a black box warning for hepatotoxicity, which led to the removal of the brand name product (Serzone) from the market. Generic nefazodone remains available but has fallen out of favor in practice secondary to its risk of liver damage because safer and more efficacious antidepressants are available.

Mirtazapine

Mirtazapine (Remeron) is a selective alpha$_2$-adrenergic receptor antagonist affecting both the norepinephrine and serotonergic systems. The role of mirtazapine in treating depression is similar to that of the TCAs. It has significant histamine-1 receptor blocking activity, thus causing sedation. In addition, because of its appetite stimulation, it may be a good choice for low-weight elderly or ill patients. This agent may be useful in combination therapy because there have been no reports of drug interactions. However, there have been rare cases of reversible agranulocytosis.

Novel Drugs

Vilazodone

Vilazodone is a novel compound and a potent selective serotonin reuptake inhibitor and partial 5-HT1A receptor agonist. Approved in the United States for the treatment of depression at doses of 10 to 40 mg once daily, vilazodone's antidepressant effects are

attributed to its modulation of serotonergic activity at pre- and postsynaptic serotonin transporters. Vilazodone is classified as a selective serotonin reuptake inhibitor (SSRI)/5-HT1A receptor partial agonist and not a pure SSRI.

Traditional antidepressants (SSRIs, SNRIs, TCAs) increase the amount of available serotonin by inhibiting its reuptake or otherwise modulating its transmission. In doing so, they also stimulate the 5-HT1A autoreceptors, which acutely decreases the amount of available serotonin, as stimulation of an autoreceptor would facilitate the reuptake of serotonin back into the presynaptic neuron. Only after several weeks do the autoreceptors become desensitized and begin to function normally again, thereby normalizing serotonergic transmission. Traditional antidepressants' effects at the 5-HT1A autoreceptor may underlie the delay in therapeutic effect (of several weeks). Vilazodone, in contrast, is a *partial* agonist at the 5-HT1A autoreceptor and does not seem to induce this effect, resulting in an onset of effect that is significantly earlier than traditional antidepressants.

Time Frame for Response

In multiple randomized, double-blinded, placebo-controlled studies, vilazodone-treated patients experienced a response as early as week 1. This may represent a therapeutic advantage over traditional antidepressants, which generally produce a therapeutic effect after 4 to 6 weeks of treatment. To date, all clinical trials involving vilazodone have been placebo controlled and have not included an active comparator, thereby limiting a comparison to existing therapy with respect to efficacy.

Adverse Events

Vilazodone has demonstrated good tolerability and safety in all of the published clinical trials. The most commonly reported adverse effects have consistently been nausea and diarrhea, both occurring in approximately 25% of patients enrolled in trials. These gastrointestinal disturbances emerged early in treatment and tended to dissipate within a few days. Vilazodone does not appear to produce treatment-related effects on sexual function, and, based on score reductions over the course of the pivotal studies, it may have resulted in a slight improvement of sexual functioning. The partial agonism at the 5-HT1A receptor is thought to be the pharmacologic reason for the low risk of sexual dysfunction. Sexual dysfunction is frequently part of the clinical picture in depressed patients, independently of treatment-emergent sexual dysfunction. The majority of pharmacotherapeutic treatment options have the potential to induce some level of sexual dysfunction in patients in whom it exists already and in patients who did not previously experience sexual dysfunction. As previously discussed, the rates of sexual dysfunction associated with the SSRIs are greater than 70%. This is an important consideration when selecting drug therapy, as worsening of existing sexual dysfunction or development of new-onset sexual dysfunction can directly influence medication compliance and therapeutic outcomes.

Another important consideration in the selection of drug therapy for MDD is impact on weight. Many existing drug therapies cause weight gain, sometimes significant, which may influence treatment adherence. Thus far, vilazodone is considered weight neutral, resulting in approximately a 1.7-kg (3.74-lb) increase in weight after 1 year of treatment.

Interactions

Vilazodone is a major substrate of CYP3A4, and it weakly inhibits CYP2C8 and weakly induces CYP2C19. The clinically relevant drug–drug interactions are limited to strong CYP3A4 inhibitors, which have the ability to increase serum concentrations of vilazodone. In particular, ketoconazole, a prototypical strong CYP3A4 inhibitor, increases the Cmax and AUC of vilazodone by 50%, necessitating a dose reduction to 20 mg of vilazodone daily. A 20-mg maximum daily dose of vilazodone is recommended when vilazodone is administered concurrently with a strong CYP3A4 inhibitor. Because of extensive hepatic metabolism and lack of renal elimination, mild to moderate renal impairment does not impact vilazodone concentrations. Vilazodone has not been studied in patients with severe renal dysfunction. Mild to moderate hepatic impairment does not result in a clinically meaningful impact on vilazodone concentrations.

Vortioxetine

Vortioxetine is a multimodal antidepressant, which acts as an inhibitor of serotonin reuptake by antagonizing the 5-HT3, 5-HT7, and 5-HT1D receptors, agonizing the 5-HT1A receptor, partially agonizing the 5-HT1B receptor, and inhibiting the 5-HT transporter. Vortioxetine's activity at multiple receptors results in modulation of the serotonergic, noradrenergic, dopaminergic, and histaminic systems, which results in antidepressant effects. Similar to vilazodone, vortioxetine's action at the 5-HT1A receptor is thought to cause an earlier onset of action as compared to traditional antidepressants. Results from several randomized controlled trials are inconsistent with regard to efficacy and tolerability. Response to 2.5 to 20 mg daily was demonstrated in most of the studies, but not all. Remission rates tended to not differ from placebo.

Time Frame for Response

Onset of therapeutic effect, as evidenced by available clinical studies, is variable. Some evidence suggests that an onset of effect occurs as early as week 1 of treatment. Other studies failed to see a difference until week 4 or 6; and some studies did not observe a difference at all through study end. To date, there are no published trials that directly compare vortioxetine to another antidepressant.

Adverse Events

The most commonly reported adverse effects include dizziness, diarrhea, vomiting, and xerostomia. Sexual dysfunction in men and women occurs at a rate of 34% to 50%.

Interactions

Vortioxetine is a major substrate of CYP3A4 and does not inhibit or induce any of the CYP isoenzymes. Bupropion and buspirone, however, should not be used concurrently with vortioxetine due to their ability to enhance the serotonergic effects of vortioxetine.

Monoamine Oxidase Inhibitors

MAO inhibitors were the first effective medications that were developed for the treatment of depression. They work by nonspecifically and irreversibly inhibiting type A and type B MAO, leading to a decreased degradation of norepinephrine, serotonin, and dopamine in the synapse. However, the adverse effect profile and potential for life-threatening hypertensive crises have limited their use and relegated them a last-line treatment in clinical practice. Only skilled practitioners with extensive clinical expertise should prescribe MAO inhibitors. See Table 40.2 for starting dosages and dosage ranges.

Adverse Events

Adverse reactions to MAO inhibitors are more common than in any other class of antidepressant. Orthostatic hypotension occurring with high-dose therapy is probably the most common adverse effect. Attempts to prevent this reaction by applying support stockings, prescribing stimulants such as methylphenidate, or adding the mineralocorticoid have met with reasonable success. However, caution must be used and the patient must be monitored carefully, especially when receiving the corticoid or the stimulant drug concomitantly. Hypertensive crisis can occur when MAO inhibitors are taken with medications that stimulate excessive release of the neurotransmitters dopamine, epinephrine, and norepinephrine. In addition, patients taking MAO inhibitors must be on a strict diet that eliminates tyramine-containing foods. Box 40.4 identifies certain foods that have an extremely high tyramine content and, if ingested by patients taking MAO inhibitors, may cause a hypertensive crisis.

BOX 40.4 Foods with High Tyramine Content

- Aged cheese (cheddar, blue, Gouda, Swiss)
- Yeast products
- Aged meats, processed meats, nonfresh meat
- Beef liver or chicken liver
- Sauerkraut
- Licorice
- Tap beer

Concomitant use of TCAs and MAO inhibitors can lead to a hyperpyretic crisis resulting in seizures and death. Similarly, using SSRIs or SNRIs and MAO inhibitors together can lead to a serotonergic syndrome. Carefully monitored, these agents can be used together safely, but they should be prescribed and monitored only by experienced clinicians.

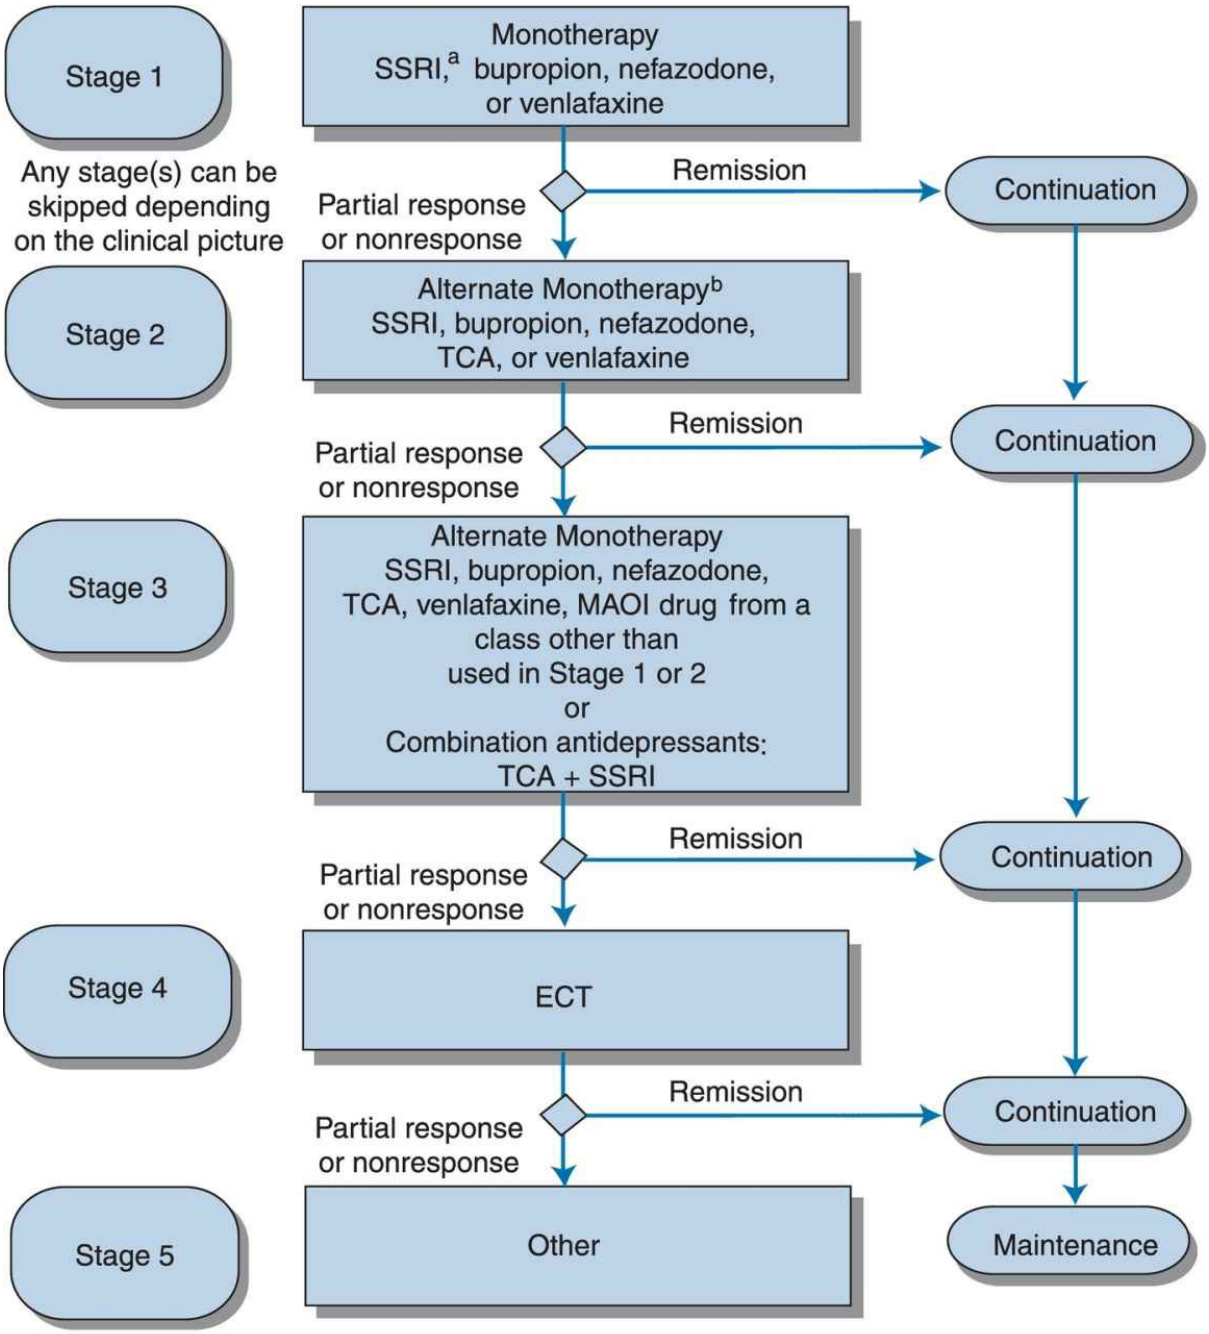
Selecting the Most Appropriate Drug

Selection of an initial pharmacotherapeutic treatment option involves numerous factors, the most important of which include the patient's target symptoms, comorbid medical or psychiatric conditions, concomitant medications, previous response to an antidepressant, and potential adverse effect and drug interaction profile. A patient's past experience with antidepressants should impact the decision regarding the choice of initial drug because past response tends to predict future response. Another consideration is the patient's perception about the efficacy and side effects she, he, or a family member has experienced. A negative perception of a drug may suggest potential for lack of adherence to drug therapy or an erosion of confidence in the therapy.

Scores of meta-analyses have evaluated the relative efficacy among antidepressants and assert that SSRIs consistently demonstrate relative efficacy as compared to SNRIs, TCAs, bupropion, trazodone, mirtazapine, and nefazodone. Patient-specific considerations will dictate the choice of drug as opposed to efficacy.

First-Line Therapy

Multiple large-scale trials have demonstrated that efficacy within drug classes and among drug classes is relatively equal, save for a few exceptions. Safety, tolerability, and lethality in overdose are the considerations that tend to drive drug selection, not efficacy. SSRIs and SNRIs are considered first-line therapy for depression and are generally used initially in patients without contraindications. In the absence of specific target symptoms, any of the available SSRIs or SNRIs are acceptable first choices. Recent studies purport the superiority of escitalopram over other members of its class, although this claim has not been substantiated with large randomized, controlled trials. If insomnia is problematic in the patient, paroxetine (Paxil) may be the best choice within the SSRI class. If the patient is taking drugs metabolized by CYP3A4, then avoiding fluoxetine (Prozac) is recommended. If the spectrum of depression-related symptoms includes sexual dysfunction, SSRIs and SNRIs should be avoided. If weight gain needs to be avoided, then bupropion is arguably a more appropriate option versus SSRIs (particularly paroxetine, which has the greatest potential to induce weight gain) or mirtazapine. See Figure 40.2 and Table 40.5 for an overview of treating a patient with depression.



Abbreviations: EC = electroconvulsive therapy, MAOI = monoamine oxidase inhibitor, SSRI = selective serotonin reuptake inhibitor, TCA = tricyclic antidepressant.
[a] SSRIs preferred.
[b] Consider TCA or venlafaxine if not tried.

Association (APA). (2011). *Practice guideline for the treatment of patients with major depressive disorder* (3rd ed., p. 152). Arlington, VA: American Psychiatric Association (APA).)

TABLE 40.5 Recommended Order of Treatment in Antidepressant Therapy

Order	Agents	Comments
First line	SSRIs	Fluoxetine and sertraline may be good for patients with somnolence. Paroxetine may be good for patients with insomnia. Selection of agent should be based on patient's past experiences with medications and drug interactions. Cost may be a consideration.
Second line	TCA (desipramine or nortriptyline) or atypical antidepressant	These agents have the better side effect profile of the class and should be considered as agents of choice for the TCA class.
Third line	Atypical antidepressant or TCA	Depending on past response to other agents and side effect profile

Second-Line Therapy

When a patient fails an adequate trial of a first-line antidepressant and therapy needs to be modified, options include dose optimization, augmentation, and switching. If some clinical benefit, but not a true response or remission, is derived from the initial medication and it is well tolerated, an *increase in dose* is appropriate.

If the dose is optimized and some benefit (a response, but not remission) is realized, then *augmentation* with another nonantidepressant may be appropriate. Lithium, thyroid hormone, and stimulant medications have been used traditionally to augment the response to the initial antidepressant. Not common in practice any longer, this recommendation remains in the treatment guidelines.

If a patient fails an SSRI or an SNRI (does not realize any benefit or cannot tolerate the drug), then *switching* to another member of the same class could serve as the second choice,

as each member of the class is chemically distinct from the others. Switching to a medication in a different class can also be an option. Atypical antidepressants (bupropion, mirtazapine, etc.) are generally chosen prior to attempting TCAs given the safety and tolerability concerns associated with the TCAs.

Combination therapy implies adding a second drug with a different mechanism of action to the initial therapy. Drugs that are commonly used adjunctively to the initial medication include trazodone, bupropion (though this is often used as initial therapy), mirtazapine, buspirone, and the atypical antipsychotics (AAPs). Generally, the second drug is tailored to address residual symptoms that did not improve on initial therapy; residual symptoms like insomnia or anxious symptoms. There is clinical controversy surrounding the use of AAPs to treat depressed patients that do not have a psychotic component. Even though aripiprazole (Abilify) now carries an FDA indication for the adjunctive treatment of depression, many practitioners are reluctant to use them, given their extensive adverse effect profile. Quetiapine and risperidone are sometimes used off-label as an adjunctive medication. The AAPs have activity at serotonergic, noradrenergic, dopaminergic, and histaminergic receptors; all of which contribute to their therapeutic effects as well as their adverse effects. AAPs as a class are associated with serious and often irreversible metabolic sequelae including significant weight gain, insulin resistance, new-onset diabetes, and dyslipidemia. QT prolongation has also been observed. Given the serious nature of these adverse effects, and the extent to which they occur, the use of AAPs as an augmentation strategy is frequently met with resistance, particularly by psychiatrists.

The definitive selection should include an assessment of the patient's underlying cardiac, neurologic, and comorbid conditions. For example, venlafaxine should be avoided in patients with uncontrolled hypertension because of its potential to increase blood pressure. Similarly, for an elderly man with a history of benign prostatic hyperplasia, TCAs and atypical agents with significant anticholinergic activity should be avoided because this action aggravates the condition.

Current treatment guidelines have not been updated since the approval or vilazodone, vortioxetine, and levomilnacipran; therefore, there is no official guidance on their place in therapy. Given the available efficacy and safety data and the absence of direct comparison to existing therapy, these newer medications will probably be integrated into the second-line tier.

Third-Line Therapy

If the first- and second-line agents fail and augmentation strategies are unsuccessful, the clinician can attempt a medication from one of the remaining classes (TCAs, MAOIs). Again, patient-specific indicators help the clinician decide on the next treatment regimen. For the most part, inexperienced general practitioners should not prescribe MAO inhibitors. The side effects and the potential for dangerous drug and food interactions suggest that only clinicians well versed in managing this kind of therapy prescribe these

agents.

Special Population Considerations

Children and Adolescents

The risk for underdiagnosis and undertreatment is extremely prevalent in this patient population. Children of parents who have been diagnosed with serious depression are at risk for developing anxiety and MDD in childhood. Early childhood depression may manifest as acting out, changes in eating or sleeping patterns, or social withdrawal. These patients can seldom communicate a feeling of sadness because of the early language development level. From ages 5 to 8, low self-esteem, underachievement at school, and aggressive or antisocial behaviors (including stealing and lying) may indicate depression. Depressed adolescents experience symptoms similar to depressed adults such as sleep disturbances, irritability, difficulty concentrating, and loss of energy.

Currently, fluoxetine (Prozac) is the only SSRI approved by the US Food and Drug Administration (FDA) for the treatment of depression in children age 8 and up. Escitalopram (Lexapro) is labeled for use in children age 12 and older. Caution has been recommended in using other agents, such as paroxetine (Paxil) or venlafaxine (Effexor), with depressed children and adolescents. Compared to adults, adolescents are more likely to become agitated or to develop a mania while they are taking an SSRI. The FDA has issued a black box warning due to increased risk of suicide in children and adolescents taking SSRIs.

Geriatrics

Late-onset depression commonly occurs in elderly patients, with nursing home residents nearly three times more likely to be depressed than the general population. These patients may also have an underlying neurologic or vascular disorder. Determining the root of the depression is essential to resolution. Elderly patients tend to endorse more vegetative symptoms and cognitive disturbances than they do subjective dysphoria, which differs from the presentation of a younger patient. Recognition and appropriate treatment of depression in this population are essential as the occurrence of depression worsens morbidity and mortality and worsens outcomes of somatic diseases.

Effort should be made to minimize pharmacologic burden on elderly patients and to proactively address possible drug interactions and adverse effects when selecting pharmacotherapy. Geriatric patients often have significant changes in physiologic function, including reduced renal and hepatic function, decreased muscle mass, decreased serum albumin, and dietary alterations. These changes may affect the absorption, distribution, metabolism, and excretion of a variety of drugs, particularly antidepressants. Elderly patients are also more sensitive to anticholinergic effects and orthostatic hypotension; adverse effects that are associated with several of the antidepressant drug classes. Most practitioners agree that antidepressant therapy should be prescribed at one third to one half

the usual starting adult dosage.

Women

As noted earlier, younger women are more likely to experience depression than older women or men in general. Women of childbearing age are at the greatest risk; however, some women are especially sensitive to hormonal fluctuations and therefore may experience new-onset depression associated with menopause. The decision to initiate antidepressant medication in a pregnant woman is a difficult one, and the risk of fetal exposure to the drug must be balanced against the risk of continued depression.

Pregnancy-related and postpartum depression is especially prevalent in women with a history of depression and a previous episode of postpartum depression, although the independent prevalence is 10% to 15%. The risk is increased with concomitant marital problems, lack of social support, and medical issues with newborn children. The decision about which drug to use depends on the factors previously discussed as well as on the issue of breast-feeding and the risk of transmission of drugs through breast milk. The potential for antidepressant-associated fetal harm varies by drug and varies by trimester.

Ethnic

There are genetic variations in the metabolism of drugs in patients with varying ethnicity. The CYP2D6 enzyme system, responsible for the metabolism of many psychotherapeutic agents, is influenced by age, gender, and ethnicity. Up to 10% of Whites and nearly 19% of African Americans are considered "poor metabolizers" of drugs via CYP2D6. Similarly, 33% of African Americans and 37% of Asians are poor metabolizers of drugs metabolized by CYP2C19. The result of this poor metabolism can include quicker responses to drugs, greater than expected action of the agent, or even more pronounced side effects. As more data accrue on the effects of genetics on depression and CYP450 metabolism, the effects of race and ethnicity on treating depression and selecting antidepressants will play a more prominent role.

Emergencies

Suicide is the most feared consequence of inadequately treated (or unrecognized) depression. Up to two thirds of depressed patients have suicidal ideation, and 10% to 15% actually commit suicide (Box 40.5). The practitioner should be ever-vigilant for suicidal ideation and the potential for suicide. This is another reason for frequent contact between the practitioner and the patient. If the patient discloses thoughts of suicide, the practitioner and patient need to develop a plan for psychiatric referral or hospitalization. Contracting with the patient, such as by developing a written agreement to continue treatment without doing self-harm, may also be an effective means for minimizing the risk of suicide. All plans and actions should be documented in the patient's medical record.

BOX 40.5 Warning Signs of Suicidal Ideation

- Pacing, agitated behavior, frequent mood changes, and chronic episodes of sleeplessness
- Actions or threats of assault, physical harm, or violence
- Delusions or hallucinations
- Threats or talk of death (e.g., "I don't care anymore," or "You won't have to worry about me much longer")
- Putting affairs in order, such as giving possessions away or writing a new will
- Unusually risky behavior (e.g., unsafe driving, abuse of alcohol or other drugs)

Patient Education

Patients and caregivers should be instructed on the full range of issues surrounding depression and antidepressant therapy. Patients should be assured that depression is a biologic illness that occurs in a variety of people, and they should not feel ashamed of the disease. Moreover, the caregivers or significant others should also be counseled on the role they play in aiding in the patient's recovery. The more informed patients and significant others are of the illness, the more likely they will adhere to recommendations.

Expectations for a quick recovery can be detrimental to the healing process. Patients and caregivers should be informed that the antidepressant medication takes several (4 to 6) weeks to begin working and the patient might be required to continue taking the medication.

Teaching patients to recognize early signs and symptoms of behavior that may indicate a recurrence is crucial. Patients and family members should be instructed to contact the clinician if symptoms resume. A support group may also be a good resource for family and patients as a strategy for managing the illness.

Antidepressants and Suicide

Depression is the leading cause of suicide, and up to 80% of depressed patients experience suicidal impulses. Since 1990, whether antidepressant drugs are linked to suicide has been an acrimonious debate. Some argue that depressed adolescents who are suicidal and treated with antidepressants may regain initiative and energy before improvement in cognition and mood, thereby becoming mobilized to attempt suicide. Others argue that the medication prescribed to treat depression is responsible for causing adolescents to attempt suicide. In 2003, British drug regulators warned that SSRIs, with the exception of fluoxetine, were unsuitable in minors experiencing depression. As a result, the FDA began public hearings in February 2004 to discuss this controversy. Currently, fluoxetine (Prozac) is the only FDA-approved antidepressant in patients as young as age 8. However, other antidepressants, such as sertraline (Zoloft), venlafaxine (Effexor), and paroxetine (Paxil), have been widely prescribed for adolescent depression. Current data suggest that the increase in suicidality impacts patients younger than age 25 to a greater extent than patients older than age 25. Therefore, a practitioner needs to be diligent in assessing the patient's risk of suicide.

Patient Information

The National Foundation for Depressive Illness, Inc. (NAFDI) (http://www.depression.org), was established in 1983 to educate the public and health care professionals about depression. This Web site contains useful information on the signs and symptoms of depression and provides public awareness on depression through a national "800" number.

The National Institute of Mental Health's Web site (http://www.nimh.nih.gov/publicat/depressionmenus.cfm), also available in Spanish, is an excellent resource for depression. It describes the different types of depression along with the causes and treatments. This Web site also offers valuable information on how family and friends may contribute and assist in therapy.

The National Mental Health Association (NMHA) (http://www.nmha.org) is a nonprofit organization that provides beneficial information to the public and practitioners on mental illness. This Web site contains news releases along with an online bookstore. A calendar notes coming events relating to mental health. This Web site provides access to comprehensive mental health care and increases public awareness of mental health issues.

The Depression and Bipolar Support Alliance (DBSA) (http://www.dbsalliance.org) is a nonprofit organization that provides a wide range of information and support on depression and bipolar disorders. Their mission, as stated on the Web site, is to improve the lives of those affected by depression and bipolar disorder. The DBSA is a patient-directed national organization focusing on the most prevalent mental illnesses, with a network of approximately 1,000 support groups. This Web site is updated regularly to provide up-to-date, scientifically based information. The DBSA is guided by a scientific advisory board comprising researchers and clinicians in the field of mood disorders.

Complementary and Alternative Medications

The use of herbal products in the United States has dramatically increased in the past few decades, resulting in consumer sales of $250 million in 2007. Subsequent research with respect to drug–drug interactions and safety concerns made available to consumers caused a significant decrease in sales over the next decade. Depression is the most common diagnosis associated with complementary and alternative medication use. Despite the decline in popularity of St. John's wort, herbal sales continue to steadily rise. The FDA does not classify herbal products as drugs, and as such, they are not regulated under the same scrutiny as other medications.

St. John's wort (*Hypericum perforatum*) has been used for centuries for a variety of illnesses, but it is currently used almost exclusively as a herbal antidepressant. Most clinical trials have studied 300 to 1,800 mg/d of standardized extract (usually standardized to 0.3% hypericin content) divided in three daily doses. The clinical effect is usually seen within 2 to 3 weeks of initiating therapy. The mechanism of action is unknown, although it is theorized that it inhibits MAO and the synaptosomal uptake of serotonin, dopamine, and noradrenaline.

St. John's wort appears to be well tolerated, with the most frequent side effects reported as nausea, fatigue, restlessness, rash, and photosensitivity. There have been reported cases of increase in heart rate, but no significant effect was seen on the PR interval. Efficacy has not been well established, with some evidence to support its use and a wealth of studies in which it did not separate from placebo.

St. John's wort may activate hepatic CYP450, so it has the potential to interact with medication that is metabolized by the CYP450 system. Therefore, it has been reported that St. John's wort decreases serum levels of theophylline, cyclosporine, warfarin, oral contraceptives, and indinavir. St. John's wort should not be taken in combination with any other antidepressant because of the risk of serotonin syndrome, especially in the elderly. Symptoms include changes in mental status, tremor, gastrointestinal disturbances, myalgia, restlessness, and headache.

S-adenosylmethionine (SAMe) is a naturally occurring methyl donor in the synthesis of dopamine and serotonin. Though not regulated by the FDA and not recommended in any of the treatment guidelines, there is some data that supports the use of this compound in MDD. Omega-3 fatty acids have also been evaluated as an adjunctive therapy for MDD. Cardiovascular benefits of omega-3 fatty acids have been established and, given their relative safety and tolerability, could be added to conventional therapy. However, their efficacy in MDD has not been affirmed. Folate, however, has been associated with a positive response to antidepressant therapy. When used adjunctively to antidepressants, folate is recommended in patients who have not fully responded to their initial drug therapy. This is considered a low-risk intervention, given its general health benefits and lack of safety concerns.

Case Study*

L.B. is a 55-year-old white female who presents to her family physician's office for a yearly routine physical. Her husband passed away 5 months ago after a 2-year battle with lung cancer. She has three children, two of whom are still in college. Her daughter accompanies her to the doctor's office and says she is concerned about her mother's recent behavior. She explains that her mother has been "sleeping all the time" and has lost 25 lb in the past 2 months without being on a diet. When the doctor examines L.B., she explains that she has become increasingly fatigued and complains of a lack of energy. She no longer has any desire to participate in her lifelong hobbies of painting and photography because of frequent feelings of sadness. L.B.'s medical history is significant for hypothyroidism, hypercholesterolemia, and recently diagnosed hypertension. Her medications are levothyroxine 0.075 mg daily, simvastatin 20 mg daily, hydrochlorothiazide 25 mg daily, lisinopril 10 mg daily, multivitamins 1 tab daily, and aspirin 81 mg daily. In the office today, L.B.'s blood pressure is 138/88 mm Hg.

Diagnosis: Major Depression

1. List specific goals for treatment for L.B.
2. What drug therapy would you prescribe? Why?
3. What are the parameters for monitoring success of the therapy?
4. Discuss specific patient education based on the prescribed therapy.
5. List one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What would be the choice for second-line therapy?
7. What over-the-counter and/or alternative medications would be appropriate for L.B.?
8. What lifestyle changes would you recommend to L.B.?
9. Describe one or two drug–drug or drug–food interaction for the selected agent.* Answers can be found online.

41 Anxiety Disorders

Laura A. Mandos ■ Jennifer A. Reinhold

Though related and with some inherent overlap, the anxiety disorders are a compendium of similar but clinically distinct disorders that share clinical features of excessive fear, worry, anxiety, and associated behavioral manifestations. Patients with anxiety disorders generally endorse psychic and somatic symptoms at varying degrees, which may include tension, apprehension, fear, restlessness, and worry along with physical symptoms such as increased heart rate, pupillary dilation, trembling, and increased perspiration.

One of the complications in identifying the presence of an anxiety disorder is that the core symptoms are mainly normal experiences in the human condition; but what delineates "normal" feelings of anxiety, worry, or fear is the extent to which they occur (severity and frequency) and the extent to which they impact functionality.

With 10 different types, the anxiety disorders represent the largest group of psychiatric disorders (Table 41.1). The focus of this chapter will be primarily generalized anxiety disorder (GAD), with an additional review of panic disorder (PD) and social anxiety disorder (SAD, also known as social phobia). There were several meaningful changes in the classification of anxiety disorders in the newest iteration of the Diagnostic and Statistical Manual (DSM), with the publication of the DSM-5 in 2013. Obsessive–compulsive disorder is no longer considered part of the anxiety disorder spectrum and will not be covered in this chapter. The agoraphobia specifier has been removed from PD and now is considered an independent diagnosis under the anxiety disorder umbrella.

TABLE 41.1 Summary of Anxiety Disorders

Anxiety Disorder	Definition
Panic disorder	Recurrent unexpected panic attacks (discrete periods, in which there is a sudden onset of intense apprehension, fearfulness, or terror, often associated with feelings of impending doom, shortness of breath, palpitations, chest pain or discomfort, choking or smothering sensations, and fear of "going crazy" or losing control).
Agoraphobia	Anxiety about, or avoidance of, places or situations from which escape might be difficult (or embarrassing) or in which help may not be available in the event of having a panic attack or panic-like symptoms.
Separation anxiety	Recurrent, excessive distress when anticipating or experiencing separation from home or from an attachment focus (person, object, etc.) or worry about losing attachment figures.
Selective mutism	Failure to speak in specific social situations in which there is an expectation to do so.
Specific phobia	Clinically significant anxiety provoked by exposure to a specific feared object or situation, often leading to avoidance.
Social anxiety disorder (social phobia)	Clinically significant anxiety provoked by exposure to certain types of social or performance situations, often leading to avoidance behavior.
Generalized anxiety disorder	Characterized by at least 6 months of persistent and excessive anxiety and worry.
Anxiety disorder due to a general medical condition	Characterized by prominent symptoms of anxiety that are judged to be a direct physiological consequence of a general medical condition.
Substance/medication-induced anxiety disorder	Characterized by prominent symptoms of anxiety that are judged to be a direct physiological consequence of a drug abuse, a medication, or toxin exposure.
Anxiety disorder not otherwise specified	Used for coding disorders with prominent anxiety or phobic avoidance that do not meet the criteria for any of the specific anxiety disorders defined in this list (or anxiety symptoms about which there is inadequate or contradictory information).

Adapted from American Psychiatric Association. (2013). *Diagnostic and statistical manual of mental health disorders: DSM-5* (5th ed.). Washington, DC: American Psychiatric Publishing.

More than 30 million Americans have a lifetime history of anxiety, and anxiety disorders cost an estimated $42 billion per year in the United States, counting direct and indirect costs. Epidemiologic studies report that 2% to 6% of adults and twice as many women as men have GAD. Approximately 1% of all patients have PD with resulting significant impairment, and 4% to 5% have agoraphobia. Approximately 12% of patients seen in anxiety disorder clinics present with GAD. Between 35% and 50% of individuals with major depression meet criteria for GAD. Coexisting anxious distress (formerly referred to as comorbid GAD in depressed patients), now considered a specifier for major depressive disorder, in depressed patients may worsen the outcome by increasing the suicide rate, worsening overall symptoms, conferring a poorer response to treatment, increasing the number of unexplained symptoms, and increasing functional disability.

The neurobiological and conceptual models that form the basis for anxiety disorders are grounded in the belief that pathologic anxiety is a result of abnormal fear processing, intolerance of uncertainty, anxiety about worry itself, or emotional hyperarousal. Humans have naturally evolved to be able to apply past experiences and responses to new experiences. For a simple example, if an individual had a traumatic experience with a small animal at some point in his or her life and escaped that fearful situation by running away, that individual may repeat that behavior when faced with a small animal in the future. While evolutionarily helpful in some respects, this response may be maladaptive in that the responses may not only be exaggerated and inappropriate but also may extend beyond a specific experience, hence generalization.

Anxiety disorders most commonly begin in early adulthood. They tend to be chronic, with interspersed periods of remissions and relapses of varying degrees, and they frequently

continue into old age. Late onset of an anxiety disorder is rare, although the prevalence of GAD increases with increasing age. In the elderly, anxiety disorders as a whole are the most common psychiatric disorders. It is unknown whether they are a continuation of an illness with an onset from a younger age or whether they appear for the first time in old age.

GAD is a highly prevalent, chronic, debilitating, relapsing, and often underdiagnosed anxiety disorder. Characterized by excessive and pathological worry that is difficult to control, a diagnosis of GAD also incorporates physical, psychological, and cognitive symptoms as well as a potentially profound functional impairment. The core symptom of excessive worry must be present for a minimum of 6 months and must occur in conjunction with at least three of six physiological arousal symptoms: restlessness, fatigue, muscle tension, irritability, concentration deficit, and sleep disturbance. As the most commonly occurring anxiety disorder with a lifetime prevalence of 4% to 7%, GAD is characterized by a waxing and waning episodic clinical course with periods of remission and relapse. Many patients with GAD report feeling as though they have "felt anxious" for their entire lives. The median onset, however, is 30 years; though age of onset is spread over a broad age range, this represents the latest age of onset of all the anxiety disorders (APA, 2013).

The pathologic worry is typically based on dangers with an overestimated likelihood of realistically occurring (e.g., a loved one being kidnapped), which then rapidly devolves into generalized worry that involves multiple life domains. For some patients, this worry leads to avoidant behavior where activities or places with perceived danger are avoided. Left untreated, the patient's sphere of comfort may continue to constrict until daily activities become limited and normal function is impaired.

Causes

Physiologic Factors

The majority of patients with GAD initially seek attention from a primary health care provider with vague somatic complaints, such as pain, headaches, or gastrointestinal (GI) disturbances. Patients also may casually endorse a nonspecific complaint of insomnia, irritability, sexual dysfunction, or trouble concentrating or remembering.

Although the etiology of anxiety disorders is largely unknown, a wide range of medical illnesses, such as cardiovascular disease, respiratory disease, hyperthyroidism, hypothyroidism, hyperadrenocorticism, pheochromocytoma, Cushing disease, hypoglycemia, vitamin B_{12} deficiency, and neurologic conditions, may cause symptoms of anxiety. In addition, amphetamines, cannabis, caffeine, cocaine, bronchodilators, corticosteroids, sympathomimetics, and thyroid hormone may cause substance-induced anxiety.

Genetic Factors

A family history is seen frequently in people with anxiety disorders. Twin studies suggest that heredity accounts for 30% of the cases of various anxiety disorders; environmental factors seem to be responsible for the remaining cases. More than 50% of people with PD have relatives with the disorder. A twin study reported that anxiety disorder with panic attacks occurs five times more frequently in monozygotic twins than in heterozygotic twins.

Pathophysiology

Anxiety is a phenomenon that all people experience. One type of anxiety, fear, is a normal fight-or-flight response to an observable threat. In contrast, pathologic anxiety is a fight-or-flight response to an internal or external threat that is real or imagined and causes the person to experience an unpleasant emotional state. During this response, the person's autonomic nervous system, which consists of the sympathetic and parasympathetic nervous systems, prepares the person to deal with a threat (Box 41.1).

BOX 41.1 Physiologic Reactions to the Fight-or-Flight Response

The fight-or-flight response causes the following:

1. Epinephrine, norepinephrine, and cortisol are released into the blood.
2. The liver releases stored sugar into the blood to meet energy needs.
3. Digestion slows, allowing blood to be shifted to the brain and the muscles.
4. Breathing becomes rapid to allow for greater oxygen supply to the muscles.
5. The heart rate and blood pressure increase.
6. Perspiration increases to cool the body.
7. Muscles tense in preparation for action.
8. The pupils dilate.
9. All senses become more acute.
10. Blood flow to the extremities becomes constricted to protect the body from bleeding from injury.

This response is appropriate for extremely threatening situations, but the response would cause considerable damage to the body if people responded to all stressful situations in this manner.

Neurobiologic Factors

The modulation of normal and pathologic anxiety states is associated with multiple regions of the brain and dysregulation in several neurotransmitter systems (norepinephrine [NE], serotonin [5-HT], gamma-aminobutyric acid [GABA], corticotrophin-releasing factor [CRF], and cholecystokinin). Furthermore, treatment with medications that modulate these systems have produced short-term and sustained anxiolytic responses, further substantiating the implication of noradrenergic, serotonergic, and GABA system involvement.

Norepinephrine, serotonin, and GABA are the major neurotransmitters studied in relation to the pharmacologic treatment of anxiety. People with anxiety disorders, especially PD, are found to have malfunctioning noradrenergic systems with a low threshold for arousal. This, coupled with an unpredictable increase in activity, causes the anxiety symptoms.

GABA and its associated receptors function as central nervous system (CNS) inhibitors. Although psychopharmacologic interventions support this role, the exact pharmacology of GABA receptors is still being examined.

Diagnostic Criteria

Anxiety disorders most commonly begin in early adulthood, tend to be chronic with waxing and waning periods of remission and relapse, and frequently continue into old age. In children, anxiety may develop, particularly in relation to school, and late onset of an anxiety disorder is rare but can occur. In the elderly, anxiety disorders are the most common psychiatric disorders seen.

Prior to diagnosis of an anxiety disorder, a medical evaluation should be conducted to rule out medical disease, neurologic problems, current medications that may be anxiogenic, vitamin B_{12} deficiency, and drug or alcohol misuse. The history should focus on anxiety disorders in family members, environmental factors, family dynamics, cognitive functioning, work or school situations, or exposure to chemical substances.

If the anxiety is not reasonably related to a physical or exogenous chemical (drug, alcohol, etc.) consideration, the practitioner should apply the American Psychiatric Association's (APA) *Diagnostic and Statistical Manual of Mental Disorders, 5th Edition* (DSM-5, 2013) diagnostic criteria. See Boxes 41.2, 41.3, and 41.4 for the diagnostic criteria for GAD, PD, and SAD, respectively.

BOX 41.2 APA DSM-5 Criteria for Diagnosing Generalized Anxiety Disorder

A. Excessive anxiety and worry (apprehensive expectation), occurring more days than not for at least 6 months, about a number of events or activities (such as work or school performance).
B. The person finds it difficult to control the worry.
C. The anxiety and worry are associated with three (or more) of the following six symptoms (with at least some symptoms present for more days than not for the past 6 months).
   Note: Only one item is required in children.
   1. Restlessness or feeling keyed up or on edge
   2. Being easily fatigued
   3. Difficulty concentrating or mind going blank
   4. Irritability
   5. Muscle tension
   6. Sleep disturbance (difficulty falling or staying asleep, or restless, unsatisfying sleep)
D. The anxiety, worry, or physical symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
E. The disturbance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition (e.g., hyperthyroidism).

F. The disturbance is not better explained by another mental disorder (e.g., anxiety or worry about having panic attacks in PD, negative evaluation in SAD social phobia, contamination or other obsessions in obsessive–compulsive disorder, separation from attachment figures in separation anxiety disorder, reminders of traumatic events in posttraumatic stress disorder, gaining weight in anorexia nervosa, physical complaints in somatic symptom disorder, perceived appearance flaws in body dysmorphic disorder, having a serious illness in illness anxiety disorder, or the content of delusional beliefs in schizophrenia or delusional disorder).

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, (Copyright 2013). American Psychiatric Association. All Rights Reserved.

BOX 41.3 APA DSM-5 Criteria for Diagnosing Panic Disorder

A. Recurrent unexpected panic attacks. A panic attack is an abrupt surge of intense fear or intense discomfort that reaches a peak within minutes and during which time four (or more) of the following symptoms occur:

Note: The abrupt surge can occur from a calm state or an anxious state.

1. Palpitations, pounding heart, or accelerated heart rate
2. Sweating
3. Trembling or shaking
4. Sensations of shortness of breath or smothering
5. Feelings of choking
6. Chest pain or discomfort
7. Nausea or abdominal distress
8. Feeling dizzy, unsteady, lightheaded, or faint
9. Chills or heat sensations
10. Paresthesias (numbness or tingling sensations)
11. Derealization (feelings of unreality) or depersonalization (being detached from oneself)
12. Fear of losing control or "going crazy"
13. Fear of dying

Note: Culture-specific symptoms (e.g., tinnitus, neck soreness, headache, uncontrollable screaming or crying) may be seen. Such symptoms should not count as one of the four required symptoms.

B. At least one of the attacks has been followed by 1 month (or more) of one or both of the following:

1. Persistent concern or worry about additional panic attacks or their consequences (e.g., losing control, having a heart attack, "going crazy")
2. A significant maladaptive change in behavior related to the attacks (e.g., behaviors designed to avoid having panic attacks, such as avoidance of exercise or unfamiliar

situations)

C. The disturbance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition (e.g., hyperthyroidism, cardiopulmonary disorders).

D. The disturbance is not better explained by another mental disorder (e.g., the panic attacks do not occur only in response to feared social situations, as in SAD; in response to circumscribed phobic objects or situations, as in specific phobia; in response to obsessions, as in obsessive–compulsive disorder; in response to reminders of traumatic events, as in posttraumatic stress disorder; or in response to separation from attachment figures, as in separation anxiety disorder).

Reprinted with permission from the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, (Copyright 2013). American Psychiatric Association. All Rights Reserved.

BOX 41.4 APA DSM-5 Criteria for Diagnosing Social Anxiety Disorder

A. Marked fear or anxiety about one or more social situations in which the individual is exposed to possible scrutiny by others. Examples include social interactions (e.g., having a conversation, meeting unfamiliar people), being observed (e.g., eating or drinking), and performing in front of others (e.g., giving a speech).

B. The individual fears that he or she will act in a way or show anxiety symptoms that will be negatively evaluated (e.g., will be humiliating or embarrassing; will lead to rejection or offend others).

C. The social situation(s) almost always provoke fear or anxiety.
Note: In children, the fear or anxiety may be expressed by crying, tantrums, freezing, clinging, shrinking, or failure to speak in social situations.

D. The social situation(s) are actively avoided or endured with intense fear or anxiety.

E. The fear or anxiety is out of proportion to the actual threat posed by the social situation and the sociocultural context.

F. The fear, anxiety, or avoidance is persistent, typically lasting 6 or more months.

G. The fear, anxiety, or avoidance cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

H. The fear, anxiety, or avoidance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.

I. The fear, anxiety, or avoidance is not better explained by the symptoms of another mental disorder such as panic disorder, body dysmorphic disorder, or autism spectrum disorder.

J. If another medical condition (e.g., Parkinson disease, obesity, disfigurement from burns or injury) is present, the fear, anxiety, or avoidance is clearly unrelated or is excessive.

Specify if: Performance only: If the fear is restricted to speaking or performing in public.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, (Copyright 2013). American Psychiatric Association. All Rights Reserved.

Comorbidity with major depression is common in patients with anxiety. These patients may self-medicate with alcohol or other substances to relieve their symptoms.

Initiating Drug Therapy

A multitude of special challenges exists with respect to the diagnosis and successful treatment of GAD. As previously discussed, many patients present with physical complaints and no recognition whatsoever of an emotional or psychiatric component. Patients may lack an understanding of mental illness, may deny symptoms or its existence when given the diagnosis of a mental illness, or be so ashamed of the stigma associated with mental illness that they are prevented from being open to discussing treatment options. Careful, tactful interventions on the part of the clinician will set the stage for a healthy patient–provider relationship, which will increase the likelihood of successful outcomes. This may be achieved by creating an environment in which the patient is comfortable discussing personal and potentially uncomfortable topics. Empathetic listening, open-mindedness, and acknowledgment that psychiatric disease is a legitimate medical disorder and not a personality flaw are critical. Also, aside from misconceptions about mental illness itself, many patients are reluctant to accept drug therapy as a treatment option. Although there is certainly a place in the treatment spectrum for psychotherapy, drug therapy often is a necessary component in achieving true remission of symptoms.

Successful treatment of anxiety disorders also implies a longer-term commitment from the patient and the clinician, as GAD and the other anxiety disorders are chronic illnesses. Thorough explanation at the beginning of therapy is crucial. The patient education from the outset should include not only explanations of the illness itself but also what the patient should expect during treatment in terms of duration of therapy, when to follow-up, expected length of time before pharmacotherapy will be optimized, and how to respond to potential adverse drug effects (ADEs). Nonpharmacologic therapy includes psychoeducation, supportive counseling, behavioral therapy, cognitive therapy, stress management techniques, meditation, and exercise. Today, in many cases, these therapies can be helpful and useful in conjunction with drug therapy.

Behavioral therapists treat anxiety as a learned behavior, arguing that anxiety is an internal conditioned response to a perceived threat or stimulus in the environment. They propose that people with anxiety learn to avoid the stimulus in order to reduce anxiety; therefore, behavior modification is the vehicle for changing behavior. Systematic desensitization is used to control external stimuli and internal sensations as well as anticipation of fear of a panic attack.

Cognitive therapists treat anxiety as a faulty thought pattern that evokes the physiologic symptoms of anxiety, feelings of loss of control, and fear of dying. Cognitive–behavioral therapy (CBT) and drug therapy complement each other and tend to produce a greater therapeutic response. CBT is considered the most effective psychotherapy for GAD, according to the literature. CBT for GAD involves self-monitoring of worry, cognitive restructuring, relaxation training, and rehearsal of coping skills. However, CBT requires special training and may not be readily available to all patients.

Goals of Drug Therapy

The long-term goal of therapy for GAD is remission: a complete resolution of anxious symptoms and a return to premorbid functionality and quality of life. In GAD specifically, *response* to treatment is realized by 50% to 60% of patients, yet *remission* is achieved by approximately one third to one half of patients who respond. Failure to remit fully confers a greater risk of relapse, a reality experienced by 45% of patients with generalized anxiety. Acutely, the goal is to reduce the severity and duration of the anxious symptoms and improve overall functioning. Once target symptoms are improved or resolved, the focus shifts to chronic or maintenance therapy; the goal of which is to completely resolve symptoms and return the patient to a premorbid level of social and occupational functionality (remission). Coupled with the goal of remission is also relapse prevention.

The ideal anxiolytic medication should promote calmness without resulting in daytime sedation and drowsiness and without producing physical or psychological dependence. Pharmacologic options used in the treatment of anxiety disorders can be classified into the following categories: antidepressants, benzodiazepines (BZDs), azapirones, novel antianxiety agents, and atypical antipsychotics (AAPs).

For most anxiety disorders, a single drug, generally an antidepressant, is initiated at a low dose and is titrated upward according to clinical response and tolerability. Four to eight weeks is the generally accepted time at which a preliminary assessment of response can be gauged. Patients who endorse some level of appreciable symptom resolution and are tolerant of the medication are considered to have achieved a durable remission. This is considered predictive of an eventual sustained remission, which persists for several months beyond this acute treatment phase.

Absence of response at the initial 4- to 8-week follow-up visit or intolerance of adverse effects may prompt either a re-evaluation of diagnosis or an adjustment in medication therapy. Reasonable interventions include increasing the dose of medication (if the initial drug was tolerated but the clinical effect was not of the magnitude desired), switching to a different drug within the same pharmacologic class (if there was some level of improvement but questionable tolerability), switching to a drug outside of the pharmacologic class (if there was lack of response and/or poor tolerability), or augmenting the initial drug (if the dose of the initial drug was already optimized but the full therapeutic effect has not been achieved).

Upon resolution of the presenting anxious symptoms, it is recommended that treatment be continued beyond initial symptom resolution for 12 months, particularly in GAD, in order to minimize the risk of relapse. In some anxiety disorders, treatment may continue indefinitely depending on the level of severity. The follow-up intervals also may differ based upon individual patient presentation.

Antidepressants

Antidepressants are generally considered first-line pharmacotherapeutic options for the chronic management of patients with anxiety disorders (see Table 41.2).

TABLE 41.2 Antidepressants Used in Treating Anxiety Disorders

Generic (Trade) Name	Initial Dose (mg)	Usual Dose (mg)
Tricyclic Antidepressants		
imipramine (Tofranil)	10–50	150–300
Selective Serotonin Reuptake Inhibitors		
citalopram (Celexa)	20	20–40
escitalopram (Lexapro)	10	10–20
fluvoxamine CR (Luvox CR)	100	100–300
paroxetine (Paxil)	10–20	10–60
(Paxil CR)	12.5	12.5–75
sertraline (Zoloft)	25–50	75–200
Serotonin–Norepinephrine Reuptake Inhibitors		
venlafaxine (Effexor, Effexor XR)	37.5–75	75–225
duloxetine (Cymbalta)		
Monoamine Oxidase Inhibitors		
phenelzine (Nardil)	15	45–90

Selective Serotonin Reuptake Inhibitors

Considered one of the two first-line pharmacotherapeutic options for the management of GAD in the United States, the selective serotonin reuptake inhibitors (SSRIs) are thought to improve anxious symptoms by inhibiting the reuptake of serotonin in the synaptic cleft. While the 2- to 4-week delay until onset of therapeutic effect may be discouraging and may impact patient compliance, significant reductions in "anxious mood" have been documented as early as week 1 in paroxetine (Paxil) trials. Remission rates in paroxetine responders at 32 weeks are as high as 73% with only 11% relapsing, a statistic that demonstrates much improvement over the spontaneous remission rate of 20% to 25%. In patients with moderate to severe GAD, sertraline (Zoloft) 50 to 100 mg/d has demonstrated superiority to placebo. Clinical response criteria were met by 55% of patients in the sertraline group as compared to 32% in the placebo group by week 12. Escitalopram (Lexapro) has been evaluated for the long-term treatment of GAD and prevention of relapse. A randomized, double-blind, placebo-controlled study reported significantly superior results for escitalopram at every time point starting at week 1.

Adverse Events

Class adverse effects include weight gain, insomnia, GI sequelae, and agitation. Sexual dysfunction, often a presenting symptom in anxious patients, may be exacerbated or caused by SSRIs in up to 40% or 50% of patients. Clinical experience shows that this adverse effect is likely underreported. Another unfortunate pharmacologic phenomenon of the SSRI class is its ability to cause agitation and jitteriness in the acute phase of treatment.

Paroxetine (Paxil) may cause more weight gain and sexual inhibition than the other drugs. Approximately 15% of patients discontinue treatment because of side effects. Caution should be used when SSRIs are given in combination with TCAs because SSRIs can inhibit one or more liver microsomal enzyme systems and increase plasma concentrations of the TCA. This can translate into conduction abnormalities due to toxic levels of TCA. The combination of SSRIs and MAO inhibitors has resulted in serious reactions such as hyperthermia, rigidity, and autonomic dysregulation that can be fatal. SSRIs are generally well tolerated, and toxicity in overdose is rare as compared to the TCAs, which partially explains why the SSRIs and serotonin–norepinephrine reuptake inhibitors (SNRIs) have largely supplanted the TCAs as first-line options. See Chapter 40 for more information.

Serotonin–Norepinephrine Reuptake Inhibitors

Members of this class inhibit the reuptake of serotonin and norepinephrine, though the selectivity and balance with respect to the extent of inhibition are variable among the SNRIs. Venlafaxine XR 75 mg to 225 mg (Effexor XR) daily consistently demonstrated superior efficacy compared to placebo in improving anxious symptom. The additional benefit of venlafaxine's efficacy in treating anxious symptoms in patients with comorbid depression as well as in pure GAD has made it a commonly prescribed first-line drug. The comorbidity of nonspecific somatic pain complaints is common in patients with GAD, which negatively impacts quality of life, worsens outcomes, hampers achievement of remission, and increases the risk of relapse. Response rates for treatment with venlafaxine approach 70%, and remission rates are as high as 43% acutely and as high as 61% long term.

Duloxetine's (Cymbalta) inhibition of serotonin and norepinephrine is more balanced as opposed to venlafaxine, which is more serotonergic at lower dose and more noradrenergic at higher doses. Its dual impact on anxious symptoms and somatic pain has resulted in 53% to 61% of treated patients achieving symptomatic remission and an approximate 47% achieving functional remission.

Adverse Effects

Adverse effects are similar in scope and magnitude to those of the SSRI class; however, the risk of clinically meaningful increases in blood pressure has also been documented, particularly with venlafaxine.

Tricyclic Antidepressants

TCAs are effective in GAD and PD. Imipramine (Tofranil) is the only TCA with an indication for the treatment of GAD and has proven effective in controlling panic attacks in patients with PD and GAD. TCAs are typically most useful in attenuating the psychological symptoms of GAD as opposed to the somatic symptoms. TCAs have largely

been supplanted by SSRIs and SNRIs as first-line therapy for the treatment of anxiety disorders.

Mechanism of Action

TCA inhibition of 5-HT and norepinephrine reuptake are thought to produce anxiolytic and antidepressant effects. Imipramine does not have any direct effects on anticipatory anxiety or phobic avoidance behavior. The response is gradual, over a period of weeks.

Adverse Events

TCAs cause anticholinergic adverse effects such as dryness of the mouth and other mucosal surfaces, blurred vision, tachycardia, constipation, and urinary hesitancy. Other adverse effects are postural hypotension, carbohydrate craving, weight gain, and sexual dysfunction. They lower the seizure threshold and are a relative contraindication in patients with seizure disorders. These drugs are contraindicated in patients with narrow-angle glaucoma, urinary hesitancy, BPH, and heart conduction abnormalities. TCAs enhance the CNS effects of alcohol. Plasma measurements of TCAs should be done in selected situations as needed. The profound risk of toxicity in overdose coupled with these undesired effects has resulted in TCAs being replaced by newer, more tolerable, possibly more effective drugs that are less toxic in overdose. See Chapter 40 for more information.

Benzodiazepines

BZDs are important and widely prescribed sedative–hypnotics. Their pharmacologic properties include reduction of anxiety, sedation, muscle relaxation, anticonvulsant, and amnestic effects. Among the prominent BZDs are alprazolam (Xanax), clonazepam (Klonopin), diazepam (Valium), lorazepam (Ativan), and oxazepam (Serax). They are best utilized in patients with acute anxiety to a time-limited stressor.

Mechanism of Action

BZDs exert a therapeutic effect by binding to GABA-A receptors in the brain. They cause the GABA-A receptors to increase the opening of chloride channels along the cell membrane, leading to an inhibitory effect on cell firing. Other neurotransmitters, such as serotonin and norepinephrine, may play a role in the therapeutic effect of BZDs. The exact mechanism of BZDs' antianxiety effect is not yet fully understood. Most of the drugs in this class possess anxiolytic, sedative–hypnotic, and anticonvulsant properties.

BZDs can be used for treating GAD and PD. Approximately 75% of patients with GAD respond moderately or better to BZDs. Benzodiazepines are indicated for the short-term management of the acute phase of anxiety (first 2 to 4 weeks) as well as any subsequent exacerbations of anxiety during stable treatment with an antidepressant. Their rapid onset and tolerability allow them to ease anxious symptoms when immediate anxiolytic effects are necessary. Although more marked improvement is realized in the first

2 weeks of treatment with BZDs, antidepressants consistently achieve the efficacy of BZDs or even surpass it after 6 to 12 weeks of treatment, particularly in alleviating psychic symptoms. Though still a common practice, the utilization of BZDs long term or as monotherapy is not recommended and is inconsistent with evidence-based guidelines. BZDs are most adept at alleviating somatic symptoms but have no effect to a somewhat detrimental effect on the psychic symptoms of GAD. At this time, there is no evidence that one BZD is superior to another for this disorder. The high-potency BZDs, alprazolam, clonazepam, and lorazepam, have been effective in controlling panic attacks and anticipatory anxiety in panic attacks. The clinical indications for a specific BZD are not absolute, and considerable overlap in their use exists. Not only are they effective in pathologic anxiety but also their calming effect is useful in nonpathologic anxiety states (temporary episodes of anxiety due to fear). BZDs have a wider therapeutic window than most other CNS depressants and are associated with fewer side effects.

The various BZDs differ little in their pharmacologic properties, but they differ significantly in their potency, their ability to cross the blood–brain barrier, and their half-lives. High-potency BZDs, such as alprazolam, clonazepam, and lorazepam, have a great affinity for the BZD receptor. The onset and intensity of action of an oral dose of a BZD is determined by the rate of absorption from the GI tract. BZDs are highly bound to plasma proteins (70% to 90%) and are highly lipid soluble. The duration of action is related to their lipid solubility as well as hepatic biotransformation to active metabolites. Oxazepam and lorazepam are metabolized to inactive compounds and therefore have shorter half-lives and durations of activity than other BZDs. This one-step inactivation to an inactive compound makes them the preferred drugs for the treatment of anxiety in elderly patients and patients with liver disease.

Accumulation of BZDs with a long half-life (long-acting BZDs) occurs from one dose to another. Long-acting BZDs take a longer time to reach steady-state levels, are removed more slowly, and cause more pronounced side effects (e.g., sedation). However, use of these preparations reduces the likelihood and intensity of withdrawal symptoms when discontinued. Ultra-short–acting BZDs do not accumulate. High lipid solubility results in faster absorption, greater distribution in tissues, and faster entrance and exit from brain sites. Diazepam is a BZD with high lipid solubility used for anxiety. (See Table 41.3 for more information.)

TABLE 41.3 Overview of Selected Drugs Used to Treat Generalized Anxiety Disorder

Generic Name	Trade Name	Usual Adult Dosage Range (mg/d)	Oral Peak (h)	Half-Life (h) Parent + Active Metabolite	Metabolite Activity	Contraindications
alprazolam	Xanax	0.75–4	1–2	6–20	Inactive	Hypersensitivity to alprazolam or any component of the formulation (cross-sensitivity with other benzodiazepines may also exist), narrow-angle glaucoma, concurrent use of ketoconazole or itraconazole
chlordiazepoxide	Librium	15–40	0.5–4	30–100	Active	Hypersensitivity to chlordiazepoxide or any component of the formulation (cross-sensitivity with other benzodiazepines may also exist)
clonazepam	Klonopin	0.5–3	1–2	18–50	Inactive	Hypersensitivity to clonazepam or any component of the formulation (cross-sensitivity with other benzodiazepines may also exist), narrow-angle glaucoma
clorazepate	Tranxene	7.5–30	1–2	30–100	Active	Hypersensitivity to clorazepate or any component of the formulation (cross-sensitivity with other benzodiazepines may also exist), narrow-angle glaucoma
diazepam	Valium	6–40	0.5–1	30–100	Active	Hypersensitivity to diazepam or any component of the formulation (cross-sensitivity with other benzodiazepines may also exist), myasthenia gravis, severe respiratory insufficiency syndrome, severe hepatic insufficiency syndrome, sleep apnea syndrome, narrow-angle glaucoma
Generic Name	**Trade Name**	**Usual Adult Dosage Range (mg/d)**	**Oral Peak (h)**	**Half-Life (h) Parent + Active Metabolite**	**Metabolite Activity**	**Contraindications**
lorazepam	Ativan	1–6	2–4	10–20	Inactive	Hypersensitivity to lorazepam or any component of the formulation (cross-sensitivity with other benzodiazepines may also exist), severe respiratory insufficiency syndrome (except during mechanical ventilation), sleep apnea syndrome (parenteral), narrow-angle glaucoma
oxazepam	Serax	15–120	2–4	8–12	Inactive	Hypersensitivity to oxazepam or any component of the formulation (cross-sensitivity with other benzodiazepines may also exist), narrow-angle glaucoma
buspirone	BuSpar	15–60	—	2–3	Active	Hypersensitivity to buspirone or any component of the formulation
hydroxyzine HCl hydroxyzine pamoate	Atarax Vistaril	75–150	2–4	3	Inactive	Hypersensitivity to hydroxyzine or any component of the formulation

Table is adapted from the following references: Arana, G. W., & Jerrold, R. (2000). *Handbook of psychiatric drug therapy* (4th ed., p. 176). Philadelphia, PA: Lippincott Williams & Wilkins; and Schatzberg, A. F., Cole, J. O., & DeBattista, C. (2010). *Manual of clinical psychopharmacology* (7th ed., pp. 382–384). Washington, DC: American Psychiatric Publishing.

On discontinuation of BZD therapy, relapse may occur. Longer-acting drugs, such as clonazepam, can minimize dose-rebound anxiety. Similarly, rapid-onset agents, such as diazepam or alprazolam, can provide acute anxiolysis, whereas short-acting agents such as lorazepam can minimize accumulation and oversedation. In the elderly, use of long-acting BZDs is discouraged because the active metabolites have a tendency to accumulate.

Tolerance and Dependence Issues

Tolerance to the sedative (but not anxiolytic) effects of BZDs develops at moderate doses. BZDs can cause dependence if used continuously for more than several weeks. If the patient's anxiety is episodic, episodic use of BZDs may control symptoms. If anxiety is prolonged, BZDs may control anxiety, but this therapeutic benefit must be weighed against their capacity to cause dependence. Abuse potential does not appear to be a problem in people who do not abuse alcohol or other substances. See "Monitoring Patient Response" for information on tapering technique and withdrawal issues.

Adverse Events

The major adverse events of BZDs are drowsiness and psychomotor impairment. Mild, transitory cognitive and memory impairments are seen occasionally. This is more significant in elderly people and those with high sensitivity to these drugs. Reactions of rage, excitement, and hostility, although rare, have been reported in children, the elderly, and brain-injured patients. Other reported side effects include increased depression, confusion, headache, GI disturbances, menstrual irregularities, and changes in libido. Urticaria may occur in people with drug hypersensitivity, and drug interactions may occur with a variety of medications (Table 41.4).

TABLE 41.4 Benzodiazepine Drug Interactions

Drug	Interaction	Description	Management
Alcohol/CNS depressants	↑ BZD levels	Increased CNS effects (sedation, psychomotor impairment)	Avoid combination
Antacids	↓ BZD levels	Antacids alter the rate but not the extent of GI absorption	Stagger administration times to avoid possible interaction
Azole antifungals (itraconazole, ketoconazole, voriconazole)	↑ BZD levels	Azole antifungals decrease the metabolism of BZDs, leading into increased CNS depression and sedation	Alprazolam is contraindicated with itraconazole and ketoconazole
Carbamazepine	↓ BZD levels	May increase hepatic metabolism and result in decreased pharmacologic effects	Consider increasing the benzodiazepine dose
Carisoprodol	↑ BZD levels	Increased depressant effects	Strong association between illicit use of carisoprodol, alprazolam, and oxycodone. Be vigilant for legitimacy of the prescriptions
Clozapine	↑ BZD levels	Increased risk of respiratory suppression, delirium, and ataxia	Do not start simultaneously. It may be better to add clozapine to an established BZD routine
Contraceptives, oral	The clearance rate of benzodiazepines that undergo glucuronidation may be increased (lorazepam and oxazepam) May see decreased clearance and increased free concentrations of chlordiazepoxide, diazepam, and alprazolam, e.g., benzodiazepines that undergo oxidative metabolism		Monitor clinical effects
CYP3A4 inhibitors (cimetidine, diltiazem, disulfiram, isoniazid, omeprazole, macrolide antibiotics, metoprolol, propranolol, valproic acid)	↑ BZD levels	The elimination of benzodiazepines that undergo oxidative hepatic metabolism (alprazolam, chlordiazepoxide, clonazepam, diazepam) may be decreased by the following drugs due to inhibition of hepatic metabolism	May need dosage reduction
Digoxin		Digoxin serum concentrations may be increased	Monitor digoxin levels
Hydantoins (e.g., phenytoin)	↓ BZD levels	Serum concentrations of benzodiazepines may be decreased due to induction of hepatic metabolism by hydantoins. Pharmacologic effects of hydantoins may be increased by benzodiazepines	Monitor clinical effects carefully—consider monitoring serum levels of phenytoin
Probenecid	↑ BZD levels	Probenecid may interfere with benzodiazepine conjugation in the liver, resulting in prolonged effect	Consider decreasing BZD dose

Drug	Interaction	Description	Management
Protease inhibitors (e.g., ritonavir, nelfinavir)	↑ BZD levels	May decrease the oxidative metabolism of benzodiazepines leading to severe sedation and respiratory depression	Decrease BZD dose
Ranitidine	↓ Diazepam	Ranitidine may reduce the GI absorption of diazepam	Stagger doses
Rifampin	↓ BZD levels	The oxidative metabolism may be increased due to enzyme induction. Pharmacologic effects of BZDs may be decreased	Monitor clinically
Sodium oxybate	↑ BZD levels	Concurrent use may result in an increase in sleep duration and CNS depression	Avoid combination
Theophylline	↓ BZD levels	Theophylline may antagonize the sedative effects of benzodiazepines	

Treatment of Benzodiazepine Overdose

Flumazenil (Mazicon) is a competitive BZD receptor antagonist that reverses the sedative effects of BZDs. Antagonism of BZD-induced respiratory depression is less predictable. Flumazenil is the only BZD receptor antagonist available for clinical use. It blocks many of the actions of BZDs but does not antagonize the CNS effects of other sedative–hypnotics such as ethanol, opioids, or general anesthetics. It is used for BZD overdose and after the use of drugs in anesthetic and diagnostic procedures. When given intravenously, it acts rapidly and has a short half-life (0.7 to 1.3 hours). Because all BZDs have a longer duration of action than flumazenil, sedation commonly recurs and repeated doses of flumazenil may be needed. Adverse effects of flumazenil include confusion, agitation, dizziness, and nausea.

Azapirones

Buspirone is a partial agonist at the 5-HT1A receptors and a full agonist at the presynaptic serotonergic autoreceptors. Though buspirone's effectiveness in treating GAD has been demonstrated inconsistently in several studies, its delayed onset of action, tolerability, and relative lack of efficacy with respect to most comorbid conditions (with the exception of MDD) has resulted in buspirone being used primarily as adjunctive therapy. It has comparable but slightly weaker efficacy compared to diazepam, clorazepate, lorazepam, and alprazolam but has a clearly slower onset of action. Buspirone's utility is mainly associated with its propensity to relieve the cognitive aspects, but it lacks long-term efficacy, particularly in managing the behavioral and somatic manifestations. It is rapidly absorbed from the intestinal tract but undergoes extensive first-pass metabolism. People with liver dysfunction have a decreased clearance of buspirone. Buspirone has no hypnotic, anticonvulsant, or muscle relaxant properties. Patients taking buspirone do not acquire a cross-tolerance for alcohol or BZDs. It is generally well tolerated, with only a few patients experiencing adverse effects. When adverse effects do occur, they include nausea, dizziness, and headache (see Table 41.3). Doses over 70 mg have caused jitteriness and dysphoria.

In contrast to BZDs, buspirone's therapeutic effect may take 2 to 3 weeks. Because of its delayed effects, this drug is not useful in patients who need immediate relief from anxiety, and patient education is needed to enhance compliance with the medication regimen.

Novel Drugs

Recently, a number of novel entities and also existing medications not initially labeled for use in GAD have been evaluated. Pregabalin (Lyrica) has shown some promise in clinical trials, but does not have an indication for the treatment of any anxiety disorder. Two similarly designed randomized, placebo and active comparator-controlled double-blinded studies evaluated the efficacy of pregabalin versus lorazepam for the treatment of GAD. The pregabalin groups and the lorazepam group all experienced improvements by week 4 as compared to placebo, with no observed statistically significant differences among the active

groups. Pregabalin at its highest study dose (600 mg) produced statistically superior reductions in the psychic and somatic symptoms compared to placebo, whereas the lorazepam group only reached statistical significance versus placebo with respect to the somatic symptoms. The relative efficacy and early onset of effect of pregabalin versus commonly used BZDs have been established, and this may represent a new therapeutic intervention for GAD as both a monotherapy (after failure of an initial monotherapy) or as an augmentation strategy.

Monoamine Oxidase Inhibitors

MAO inhibitors are effective in controlling panic attacks in most patients with PD. Their effectiveness in GAD has not been explored because of the necessary dietary restrictions and dangerous drug interactions that make their use cumbersome.

Mechanism of Action

MAO inhibitors inhibit the breakdown of 5-HT and norepinephrine in the synaptic cleft. The most commonly used MAO inhibitor is phenelzine (Nardil), which is given in a dose range of 45 to 90 mg/d.

Adverse Events

MAO inhibitors have anticholinergic side effects such as blurred vision, dry mouth and other mucosal surfaces, constipation, urinary hesitancy, and tachycardia. Weight gain, insomnia, and sexual dysfunction frequently occur. Hypotension that is aggravated by postural changes may develop, but it usually diminishes in a few weeks. Palliative measures such as increased fluid intake, salt tablets, and low-dose fludrocortisone (Florinef) can be used to manage hypotension. The greatest danger with MAO inhibitors is hypertensive crisis, which can be caused by food or drug interaction and can result in cerebral hemorrhage and death. MAO inhibitors prevent the breakdown of monoamines, so the patient taking an MAO inhibitor must avoid sympathomimetic substances and foods that contain tyramine, such as cheese, liver, yogurt, yeast, soy sauce, red wine, and beer. For further information, see Chapter 40.

Other Antianxiety Medications

Hydroxyzines are sometimes used to relieve anxiety and tension associated with an anxiety state or as an adjunct in organic disease states with anxiety.

The use of hydroxyzine for long-term treatment of anxiety (more than 4 months) has not been assessed. Hydroxyzine hydrochloride (Atarax) and hydroxyzine pamoate (Vistaril) are drugs more commonly used for sedating patients before and after surgery and for managing pruritus, chronic urticaria, and atopic contact dermatitis. See Table 41.3 for doses and adverse events.

Atypical Antipsychotics

The AAPs have been evaluated mostly for purposes of adjunctive therapy when patients do not respond to, are intolerant of, or do not fully remit with conventional therapies. None of the AAPs have labeled indications for any anxiety disorder, though some do as adjunctive treatments for major depressive disorder. Of the eight available AAPs, there are studies evaluating the benefit of five of them in GAD (aripiprazole, quetiapine, risperidone, ziprasidone, and olanzapine). Thus far, AAPs have mostly been studied in short-term trials as adjunctive therapies in treatment-resistant GAD; however, some monotherapy studies exist. The unfavorable side effect profiles limit their use as first-line long-term drug of choice.

Selecting the Most Appropriate Agent

General Anxiety Disorder

First-Line Therapy

SSRIs and SNRIs are considered drugs of choice for GAD. No evidence exists to support the superiority of any of these drugs individually; however, there are significant differences in adverse effects and drug interactions. Patients may have to try several SSRIs or SNRIs prior to realizing a therapeutic benefit balanced with appropriate tolerability.

Antidepressants all require several weeks to become effective, so BZDs may be given along with an antidepressant until it begins to work. Once this occurs, the patient is slowly tapered off the BZD. BZDs also have a role chronically for purposes of treating exacerbations of anxiety when quick relief is desired. BZDs are considered first-line therapy only for acute anxiety related to a time-limited stressor. The BZDs used most frequently are alprazolam, clonazepam, and diazepam. There is no evidence that one BZD is superior to another in this disorder. When choosing the specific BZD for treatment, the practitioner must consider the drug's onset of action and its half-life and the patient's metabolism (Figure 41.1 and Table 41.5).

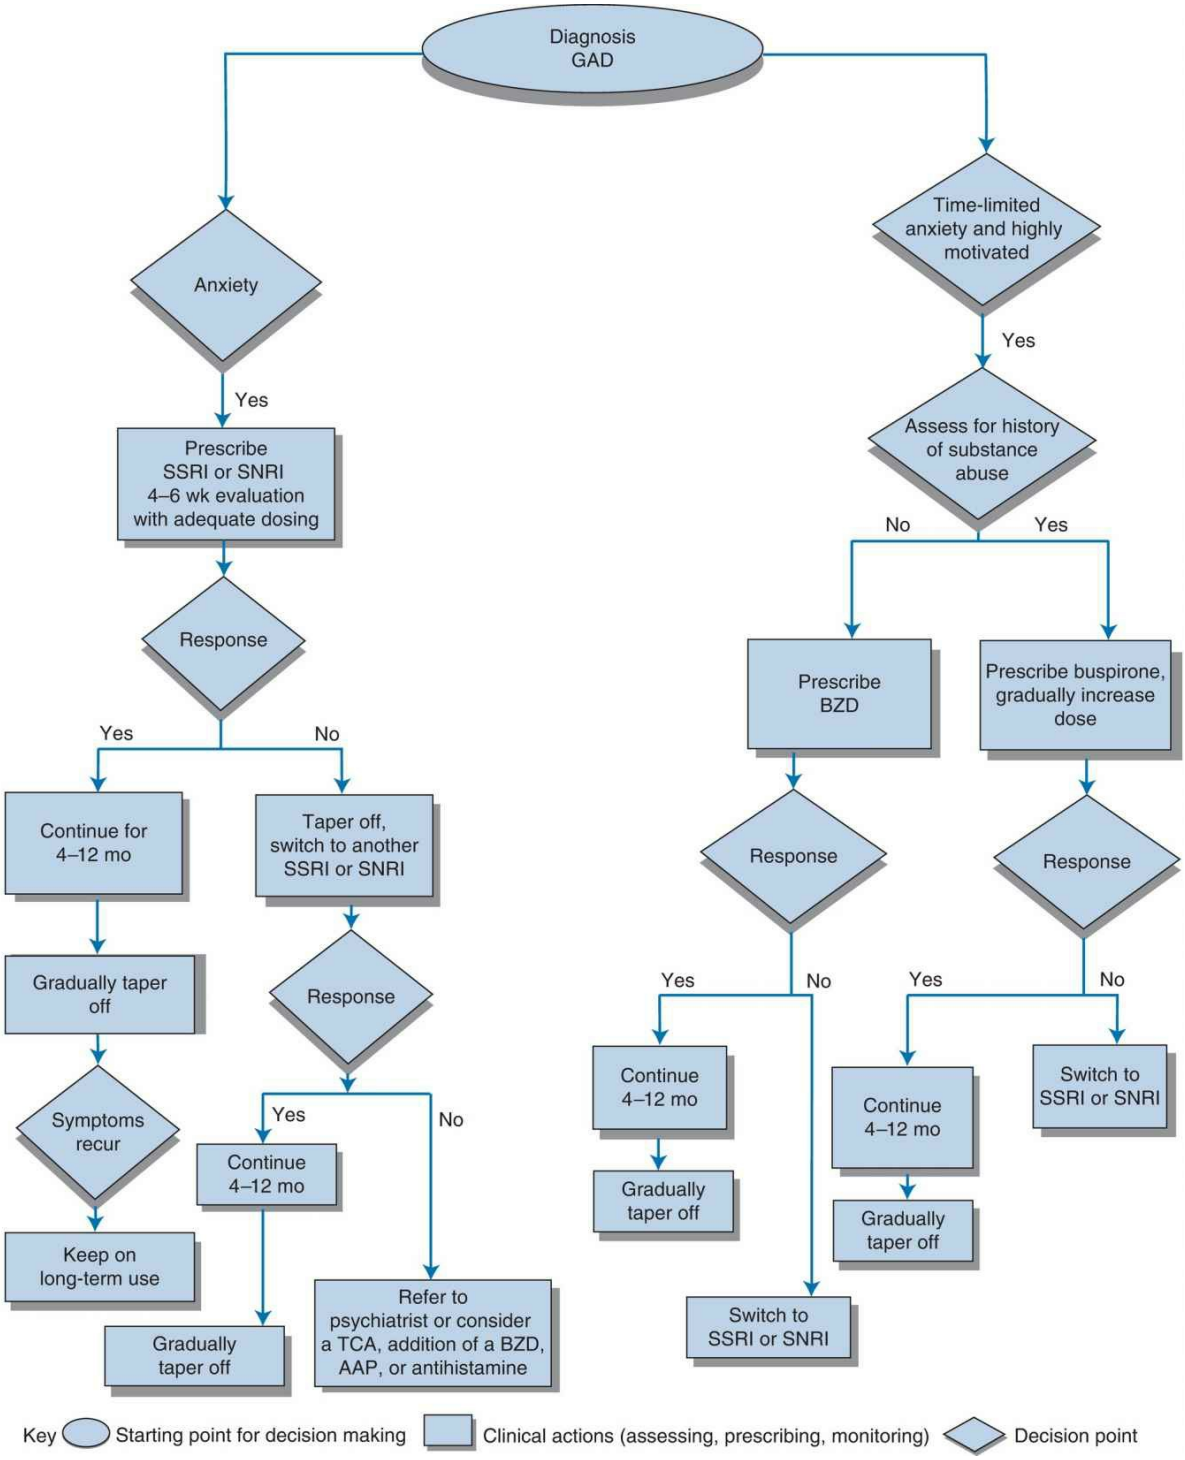

FIGURE 41.1 Treatment algorithm for GAD.

TABLE 41.5 Recommended Order of Long-Term Treatment for Generalized Anxiety Disorder

Order	Agents	Comments
First line	SSRI or SNRI	Useful for anxiety disorder as well as a coexisting comorbidity.
Second line	Buspirone or imipramine	Takes 1–2 wk for effect.
Third line	Adjunctive therapy with pregabalin, buspirone	Select agent based on drug onset, half-life, and patient metabolism. Do not use if the patient is alcohol or drug dependent. May be first-line drug in motivated patients with acute anxiety to a time-limited stress.

Second-Line Therapy

After confirmed failure or intolerance to multiple members of the SSRI and SNRI classes at appropriate doses for an appropriate period of time, imipramine or buspirone may be considered.

Buspirone may be more appropriate if sedation or psychomotor impairment would be dangerous. Buspirone differs from the SSRIs in its efficacy spectrum and side effect profile and has fewer adverse effects compared to BZDs and minimal abuse potential. However, the therapeutic effect of the drug may take 1 to 4 weeks. Buspirone may be the most appropriate drug for patients with a history of substance abuse, personality disorder, or sleep apnea.

Third-Line Therapy

Third-line therapy consists of a TCA alone or buspirone.

Fourth-Line Therapy

After the SSRIs, SNRIs, buspirone, and imipramine are exhausted; combination or adjunctive therapy may be considered. Practitioners may even consider combination or adjunctive therapy prior to attempting buspirone or imipramine (third line). Generally, buspirone, pregabalin (not approved for this indication in the United States), or an AAP (not approved for this indication in the United States) could be added to standard therapy in the event that a therapeutic effect is not realized with monotherapy. An SSRI or SNRI plus an AAP, an SSRI or SNRI plus an antihistamine (hydroxyzine), a combination of an SSRI and imipramine, or a combination of an SSRI and a BZD are all reasonable strategies.

Panic Disorder

First-Line Therapy

Nonpharmacologic therapy is especially critical in the treatment of PD. Patients need to be educated on the avoidance of substances that can precipitate panic attacks; these include caffeine, drugs of abuse, and nonprescription stimulants. CBT is associated with short-term improvement in symptoms.

PD is episodic, and patients with PD frequently do well with SSRIs or venlafaxine. Alprazolam (Xanax) is the only BZD that is approved by the U.S. Food and Drug

Administration (FDA) for PD, but clonazepam or lorazepam can also be used. These drugs are used along with an SSRI if rapid relief from anxiety is needed and there is no history of substance abuse. The practitioner needs to monitor symptoms, assess for side effects, and gradually increase the dosages of SSRIs, venlafaxine, alprazolam, lorazepam, or clonazepam if needed (Figure 41.2).

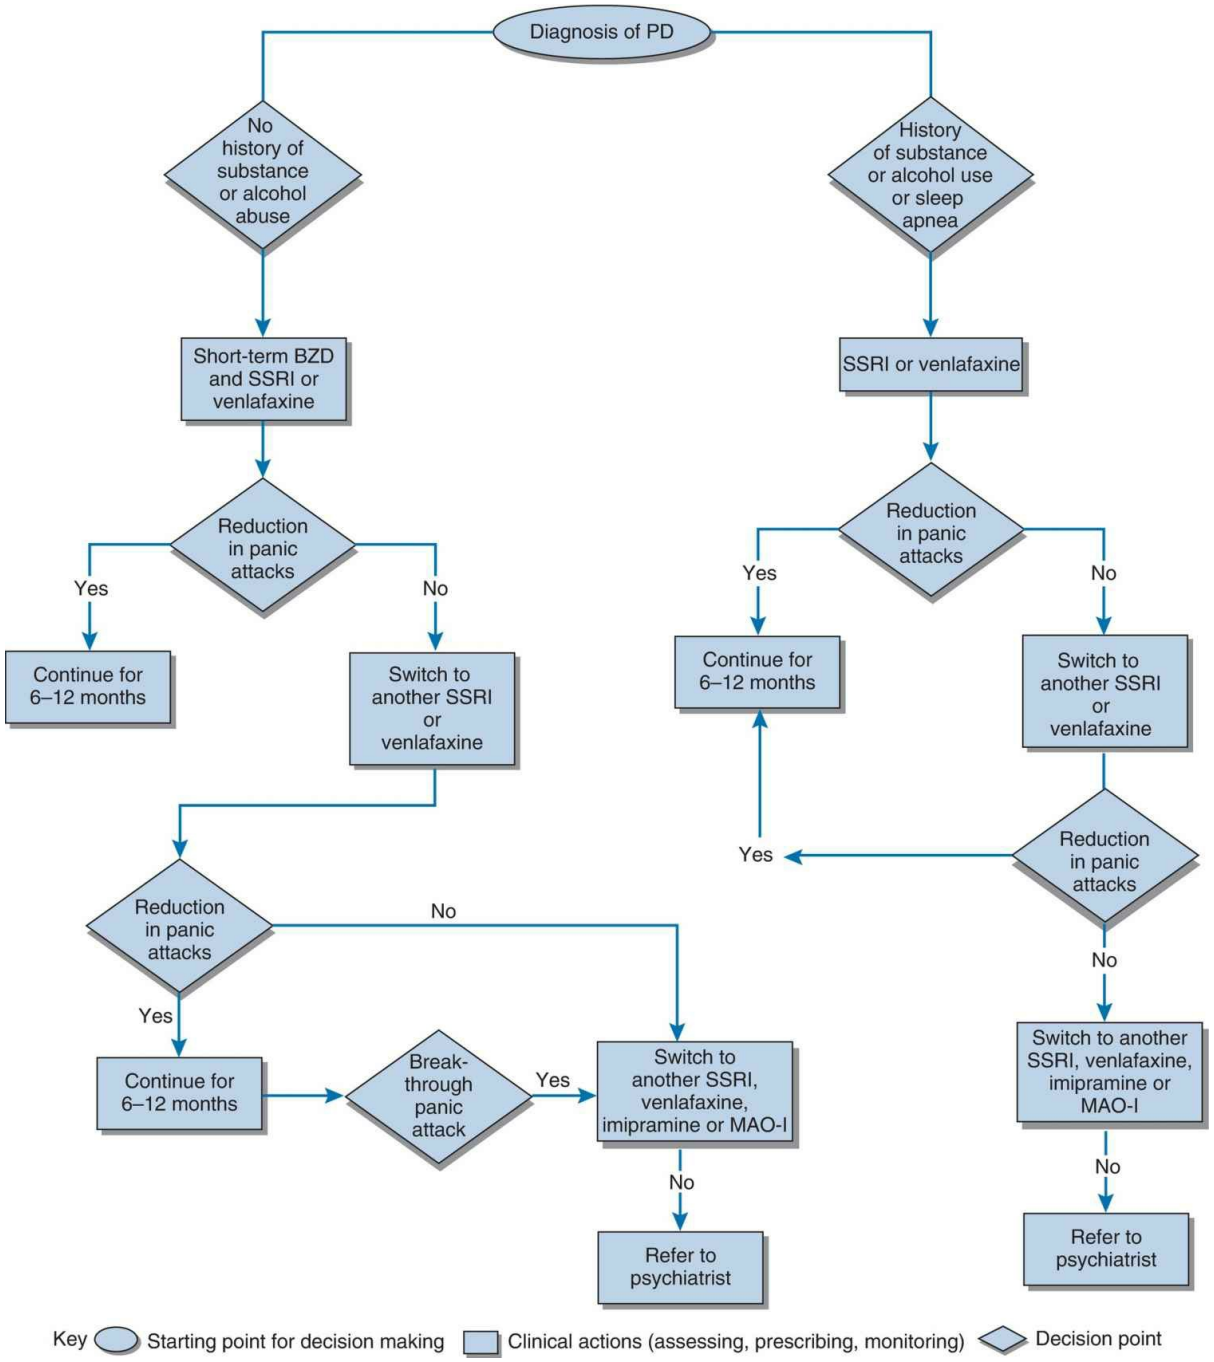

FIGURE 41.2 Treatment algorithm for PD.

Second-Line Therapy

Patients who do not respond to SSRIs may be changed to another SSRI or venlafaxine and monitored for effectiveness in decreasing panic attacks and controlling the severity of anxiety or panic symptoms while causing tolerable adverse events.

Third-Line Therapy

Patients who do not respond to venlafaxine or several SSRIs may be switched to yet another

SSRI, imipramine, or an MAO inhibitor. MAO inhibitors can be very effective in controlling panic attacks. Before the patient begins therapy, however, the practitioner must assess his or her willingness to avoid the many tyramine-containing sympathomimetic drugs and foods, which can interact with MAO inhibitors to precipitate serious, life-threatening reactions. Washout periods are critical before beginning an MAO inhibitor due to the risk of serotonin syndrome. In addition, the patient should be referred to a psychiatrist for intensive therapy, particularly if combination therapy is required. When a TCA is given for PD, approximately 33% of patients feel overstimulated when treatment begins. To reduce this problem, the patient may need to start with a lower dose and gradually increase the dose until a therapeutic dose response occurs. BZDs can be used on a short-term basis to lessen these initial symptoms. Because PD is episodic, it is considered a chronic condition that requires long-term management with TCAs. However, approximately 33% of patients on TCAs discontinue their treatment because they cannot tolerate the side effects of the drugs.

Social Anxiety Disorder (SAD, or Social Phobia)

Social anxiety disorder or social phobia is characterized by an intense, irrational fear of scrutiny or negative evaluation of others in social situations. In generalized SAD, fear and avoidance extend to various social situations, but in the specific form of socialized and anxiety disorder, fear and avoidance are confined to only one or two social situations, such as performing in public. Symptoms most commonly experienced include blushing, shaking, sweating, and heart palpitations.

First-Line Therapy

Generally, the SSRIs and venlafaxine are considered first-line therapies for SAD. Cognitive behavioral therapy is also a potential initial therapy along with a medication or as monotherapy.

Second-Line Therapy

After failure of cognitive behavioral therapy and an adequate trial of either an SSRI or venlafaxine, the MAO-I phenelzine can be attempted in selected patients (see Figure 41.3). Given the adverse effect profile, toxicity in overdose, and drug and food interaction potential, phenelzine should be reserved for refractory cases. Table 41.6 summarizes drug therapy for GAD, PD, and SAD.

FIGURE 41.3 Treatment algorithm for social anxiety disorder.

TABLE 41.6 Pharmacotherapy for Selected Anxiety Disorders

	SSRIs	TCAs	Buspirone	BZDs	MAOIs	CBT
GAD	+	+	+/−	+	+	+
PD	+	+	+	+	−	+
SAD	+	−	+/−	+	+	+

GAD, generalized anxiety disorder; PD, panic disorder; SAD, social anxiety disorder; SSRIs, selective serotonin reuptake inhibitors; TCAs, tricyclic antidepressants; BZDs, benzodiazepines; MAOIs, monoamine oxidase inhibitors; CBT, cognitive–behavioral therapy.

Special Population Considerations

Patients who have previously been treated for an anxiety disorder may have had drug treatment or psychotherapy that they found unsatisfactory. The practitioner should review with them what the treatments were, what adverse reactions they had, and the number of previous health care providers who treated them. Check with them for any history of drug withdrawal symptoms. If they report that a drug or treatment was unacceptable, plan a different but effective treatment. Assess for adverse effects to the new program. Also assess for drug-seeking behavior to rule out BZD dependence. Sometimes, patients "shop around" for new health care providers when their previous provider has advised withdrawing from BZDs.

Patients with a history of prescription medication abuse and substance or alcohol abuse can become drug dependent. Buspirone, a nonaddicting drug, is a choice for their treatment regimen.

Pediatric

Four BZDs—clorazepate, chlordiazepoxide, diazepam, and alprazolam—have been approved by the FDA for use in children. Doses vary according to the child's age and weight. Similar to adults, the first-line treatment for GAD in children are SSRI antidepressants. SNRI and TCA have also shown efficacy in the treatment of pediatric anxiety disorders but, due to their side effect profiles, are less easily tolerated. A meta-analysis of 16 randomized trials found a number of SSRI and SNRI antidepressants superior to placebo in the treatment of pediatric anxiety (Uthman and Abdulmalik, 2010). The risks associated with SSRIs/SNRI antidepressants for pediatric anxiety should be carefully weighed against their potential benefits whenever their use is considered. Risks and benefits should be discussed with both the parent and the child before beginning treatment. The FDA recommends close monitoring of the child's clinical status during the early weeks of antidepressant treatment and limiting the duration of their use.

Geriatric

Elderly patients may have decreased liver and renal function and metabolize and excrete drugs more slowly. They also may have neurologic disorders, cardiac disease, hypertension, hypotension, and glaucoma and may be taking drugs for these conditions. Elderly patients may be started on low doses of shorter-acting BZDs, TCAs, SSRIs, and buspirone, and the dosage may be gradually increased. Elderly patients may also experience paradoxical reactions to drugs (see Tables 41.3 and 41.4).

Women

Women are more likely than men to seek treatment for anxiety and depression. Women who are taking oral contraceptive drugs may have adverse drug interactions with BZDs (see

Table 41.4). The practitioner needs to be alert for signs of anxiety disorders in men because they are not as likely as women to report these symptoms. Rather, men are likely to report physical signs of anxiety and not identify the problem as emotional in origin.

Pregnancy

Treatment considerations (to use or not to use antidepressants) during pregnancy *may* pose both maternal and fetal risks: risk of untreated depression or anxiety in the mother and the risk of teratogenicity, malformations, and low birth weight in the fetus, respectively. All antidepressants cross the placenta; however, this does not consistently equate with a risk of teratogenicity. Though somewhat contradictory and arguably not completely clear, some studies have found a modestly increased risk of fetal cardiovascular malformations in fetuses exposed to SSRIs in utero. Other studies have failed to demonstrate this increased risk and suggest that the risk of the aforementioned issues is consistent with that of the general, unexposed population. Thus far, SSRIs have not been associated with maternal complications with the exception of postpartum hemorrhage. The newest evidence, resulting from a large-scale meta-analysis, reveals that fluoxetine may cause fetal heart wall defects and craniosynostosis and paroxetine may cause fetal heart defects, anencephaly, and abdominal wall defects (Reefhuis et al., 2015). The SNRIs, trazodone, bupropion, and the TCAs are also not generally associated with teratogenicity. The observed cases of fetal defects seem to be dependent on the trimester; therefore, the potential risks associated with antidepressant use during pregnancy vary over the course of the pregnancy. All of the antidepressants discussed in this chapter are pregnancy category C, with the exception of bupropion, which is category B, and paroxetine, which is category D.

The risks of not treating depression in pregnant patients include premature delivery, low birth weight, miscarriage, preeclampsia, and gestational hypertension. Unfortunately, pregnant patients sometimes self-discontinue their antidepressants due to a fear of harming their baby. This can lead to withdrawal in some cases and also rebound or worsened anxious symptoms. Fetal organs begin developing early in pregnancy, and therefore, a conversation as early as possible is recommended. The patient and practitioner need to design a plan that is acceptable for all parties and will minimize risks to the fetus as well as the patient.

Ethnic

Understanding a patient's cultural orientation or ethnic background is necessary for making a correct diagnosis and establishing an appropriate treatment plan. What we view as a problem such as anxiety or depression is not always perceived the same way by patients from other cultures. Complaints of anxiety or depression may not be reported by some patients because this is considered to be a mental disorder that is to be kept secret from people outside the family.

Research findings indicate that people from various racial or ethnic groups may

metabolize some drugs differently because of their genetic makeup. An example of a drug that is metabolized differently is the antitubercular drug isoniazid (Laniazid). Researchers are beginning to examine other drug classifications for variations. Practitioners need to keep current with research that examines genetic differences in the metabolism of drugs (see Chapters 2 and 3).

Monitoring Patient Response

Patients need to be monitored for self-reports of decreased anxiety symptoms. The practitioner should monitor patients closely for compliance with the medication regimen as well as side effects.

Most side effects from SSRIs are transient. Dose-related sexual effects, such as decreased libido or delayed ejaculation in men and anorgasmia in women, are common and typically do not resolve without intervention. Management of treatment-related sexual dysfunction includes reducing the SSRI dosage reduction and adding or switching to an antidepressant not associated with sexual dysfunction, such as bupropion (Wellbutrin, Wellbutrin SR), nefazodone, or mirtazapine (Remeron). Another strategy includes the use of sildenafil (Viagra) or buspirone.

A non–life-threatening discontinuation syndrome of flu-like symptoms may occur after abrupt cessation of an SSRI. This syndrome can be minimized by gradually tapering the dose.

An overdose of TCAs can lead to anticholinergic delirium, ventricular arrhythmias, significant hypotension, seizures, and death. A TCA overdose is a medical emergency and requires close clinical and cardiac monitoring.

Many patients do not like buspirone because it takes 1 to 4 weeks to take effect. Frequently, patients stop taking this medication because they think it is not helping their symptoms. Patient education and monitoring for compliance must be ongoing.

There have been no well-documented fatal overdoses of BZDs, but deaths have resulted from the ingestion of multiple drugs and overdoses of BZDs and other drugs. Prolonged use of BZDs can lead to dependence and withdrawal on discontinuation. Although the duration of therapy is not standardized, most clinicians prescribe the medication for 4 to 6 months and then try decreasing the dosage; however, the relapse rate of anxiety is approximately 60% to 80% within the first year that the patient is off the medication.

There are three components of a withdrawal syndrome: relapse is the return of the original symptoms of anxiety, rebound is a return of symptoms at greater severity than originally experienced, and withdrawal is the appearance of new symptoms.

When a BZD is discontinued, the severity of the withdrawal syndrome depends on how rapidly the drug is tapered, the half-life of the drug, and the duration of therapy. The withdrawal syndrome increases in severity with increased dosage and duration of use: for instance, more patients experience withdrawal symptoms after taking a BZD for 8 months than those taking it for less than 3 months. Withdrawal is relatively infrequent with short-term use, but it can occur with therapy as brief as 3 weeks. Abrupt discontinuation is frequently associated with withdrawal, usually of greater severity. Therefore, the rate of discontinuation should be slowed to moderate the symptoms. Drugs with shorter half-lives are also more associated with withdrawal phenomena than those with longer half-lives. The

tapering period should be at least 4 weeks, and the rate of tapering should be approximately a 10% dosage decrease every 3 to 4 days. Box 41.5 lists BZD withdrawal symptoms.

BOX 41.5 Symptoms of Benzodiazepine Withdrawal

Frequent
Anxiety
Insomnia
Irritability
Muscle problems

Rare
Psychosis
Seizures
Delirium
Confusion

Common
Nausea
Depression
Ataxia
Hyperreflexia
Blurred vision
Fatigue

Adapted with permission from Schweizer, E., & Rickels, K. (1998). Benzodiazepine dependence and withdrawal: A review of the syndrome and its clinical management. *Acta Psychiatrica Scandinavica, Supplementum*, 393, 95–101. Copyright © John Wiley and Sons.

Patients on long-term (more than 4 months) BZD therapy need periodic blood counts and liver and thyroid function testing. BZDs can cause elevations in lactate dehydrogenase, alkaline phosphatase, alanine aminotransferase, and aspartate aminotransferase levels. Use of BZDs may cause leukopenia, blood dyscrasias, anemia, thrombocytopenia, eosinophilia, and decreased uptake of I^{125} and I^{131} sodium iodide. (See Table 41.3; see also Chapter 40 for a discussion of monitoring concerns related to antidepressant medications.)

Patient Education

Drug Information

The patient should know the name of the drug prescribed, dose, frequency of administration, expected outcome of therapy, drug interactions, adverse events, and the amount of time it will take for the drug to take effect. The patient should also know how to report adverse events to the primary caregiver. The patient should be taught to take the drug as ordered and not to increase the dose or stop the drug without first contacting the primary care provider.

The patient should know that the therapeutic effect of the drug needs to be monitored and that the dosage may need to be increased or another drug may be more helpful. If laboratory tests are needed, the patient should know the name of the laboratory test, what the test is, and the frequency of monitoring. The patient also needs to tell all health care providers what medications he or she is taking.

The National Institutes of Health's Web site (www.nih.gov/medlineplus/anxiety.html) provides useful patient information, as does the Anxiety Disorder Association of America's Web site (www.adaa.org).

Lifestyle Information

The patient should know that the physical symptoms of anxiety (e.g., increased heart rate, palpitations, pupillary dilatation, trembling, increased perspiration, muscle tension, and sleep disturbances) are not life threatening. The practitioner should instruct the patient about how combination treatment consisting of medications, psychotherapy, and relaxation therapy can control anxiety. Instruction on performing relaxation exercises is helpful. The practitioner should describe the various psychotherapeutic modalities so that the patient may select the one thought to be most appropriate. If the patient does not seek psychotherapy, the primary caregiver may need to provide emotional support. The patient who does not respond well to drug and relaxation therapy must be referred to a psychiatric specialist.

Providing written instructions is important because the patient may have trouble concentrating on or fully comprehending verbal instructions. After providing all instructions and materials, the practitioner should review the patient's comprehension of the instructions and willingness to comply with the medication regimen. This review should be part of each patient visit.

Case Study*

L.P., age 23, is a white woman who graduated from college last year. She began working as an accountant 1 month after graduating. Approximately 2 months ago, she moved into a two-bedroom apartment with another woman who works at the same accounting firm. She states that her roommate recommended that she see a doctor to find out if she has anemia or "some sort of fatigue syndrome." She states that she has felt "restless" and "on edge" for most of the past 9 months. She becomes easily fatigued and irritable and has difficulty concentrating and falling asleep. She states that sometimes her mind "just goes blank," and she is worried that her work performance is no longer excellent. She reports that all her life she had good grades in school and was very successful in everything she attempted. Although she has been "a worrier from the day I was born," now she worries more than she ever has and feels nervous "all the time." L.P. reports that she has a good relationship with her boyfriend, but they do not get to see each other very often because he is attending graduate school 100 miles away. She reports having a satisfying sexual relationship with him. She denies having any problems with relationships with her parents, roommate, or peers. She denies having any financial worries unless she is fired from her job for poor work performance. She reports that she has always been healthy and has taken good care of herself. The only medication she takes is birth control pills, which she has taken for the past 4 years without any adverse effects.

Diagnosis : Generalized Anxiety Disorder

1. List specific treatment goals for L.P.
2. What drug therapy would you prescribe? Why?
3. What are the parameters for monitoring the success of the therapy?
4. Describe specific patient monitoring based on the prescribed therapy.
5. List one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What would be the choice for second-line therapy?
7. What dietary and lifestyle changes should be recommended for this patient?
8. Describe one or two drug–drug or drug–food interactions for the selected agent.

42 Insomnia and Sleep Disorders

Veronica F. Wilbur

Sleep, a naturally recurring state of restfulness for the body, is a necessary element of our daily life and occurs in a daily rhythmic pattern. Sleep disorders can affect the quality of sleep and therefore how individuals function on a daily basis. Poor sleep can often be a symptom of other underlying physical or psychiatric problems. Sleep disorders include insomnia, snoring and sleep apnea, narcolepsy, and chronic sleep deprivation. Pharmacologic therapy is not appropriate for snoring and sleep apnea but has a role in the management of the other diagnoses. The key to an appropriate treatment plan is to recognize the type of sleep disorder.

Insomnia

Although most people occasionally have problems falling or staying asleep, insomnia can be defined as persistent trouble sleeping. Some experts argue, however, that problems sleeping at any time may be referred to as *insomnia*; they define the condition as loss of sleep for a short period. The loss of sleep may be due to physiologic causes such as restless leg syndrome, gastroesophageal reflux, or fibromyalgia, or sleep loss may simply be due to ignoring sleep cues. Sleep that is not refreshing also can be classified as insomnia. According to the Sleep in America Poll (The National Sleep Foundation, 2014), over 45% of respondents between ages of 18 and 64+ reported problems with sleep, but only 17% discussed their complaints with a health care professional. The 2014 Sleep Poll compared sleep complaints among African Americans, Whites, Asians, and Hispanics, finding variations in bedtime routines, meeting sleep needs, sleep partners, and general health related to sleep. Results also show that African Americans and Hispanics are more likely to have poor sleep. Complaints are more prevalent in women and increase with age, especially in those over age 65; up to 67% of elderly people have frequent sleep problems, but only 17% are diagnosed and treated (The National Sleep Foundation, 2014).

Insomnia can have social and economic consequences, as measured through direct and indirect costs. The America Insomnia Survey (2012) estimated that the cost of sleep deprivation and sleep disorders equals 63.2 to 100 billion annually. This cost is seen in lost productivity, medical expenses, sick leave, and property and environmental damages (Rosekind et al., 2010). Up to 40% of people medicate themselves, commonly treating their insomnia with a host of over-the-counter (OTC) drugs and other remedies before seeking the help of a health care provider. In the United States, more than $1 billion is spent yearly on sleep medications. According to a more recent Sleep in America Poll, little has changed regarding these demographics since the early 1990s.

Causes

Insomnia can be of physiologic or psychological origin, and it is important to rule out the physiologic causes before labeling insomnia as psychological (Box 42.1). Changes in a patient's biological clock can contribute to insomnia (e.g., hyperarousal states, time zone, and schedule changes), as can the sleep environment. Estimates are that up to half of all cases of insomnia are psychological in origin. Previously, the *International Classification of Sleep Disorders,* second edition (2001) classified insomnia as primary or secondary; however, experts found it difficult to differentiate each category due to overlapping of symptoms and associated features. Therefore, the *International Classification of Sleep Disorders (ICSD),* third edition (2014), changed the categories to *chronic insomnia disorder*, *short-term insomnia disorder*, and *other insomnia disorder*. In general, insomnia is a serious problem that can adversely impact comorbid conditions. Whether insomnia is labeled as short term or chronic, Rosekind (2015) argued that insomnia is significant for any length of time and needs thoughtful evaluation and possible treatment. Finally, ICSD third edition standardizes the diagnostic criteria for all types of insomnia and does not differentiate between pediatric, adult, and geriatric populations.

BOX 42.1 Causes of Insomnia

Medical
- Cardiac problems (e.g., ischemia and congestive heart failure)

Endocrine problems (e.g., hypothyroidism, hyperthyroidism, degenerative disease)

Neurologic problems (e.g., stroke, degenerative conditions, dementia, peripheral nerve damage, myoclonic jerks, restless leg syndrome (Willis-Ekbom disease), hypnic jerk, and central sleep apnea)

Pulmonary problems (e.g., COPD, obstructive sleep apnea)

Renal problems (e.g., urinary frequency)
- Pain

Psychiatric
- Anxiety

Excess stress

Major depression

Maladaptive sleep habits
- Sleep performance anxiety

Drug and alcohol abuse
- Sedatives and stimulants

Primary sleep disorders
- Excessive arousal and wakefulness

Poor sleep hygiene: related to lifestyle

Sleep state misperception: achievement of adequate sleep but not perceived by patient

Chronic Insomnia

The prevalence of chronic insomnia in the general public is between 10% and 35% and affects more women than men (ICSD, 2014). Previously classified as primary, secondary, or comorbid insomnia, chronic insomnia is a more accurate nomenclature due to difficulties with overlapping symptoms and features. To make the diagnosis of chronic insomnia, specific criteria assist the provider and help to define the features of the disorder (see Box 42.2). While all criteria are important for diagnosis, the most essential feature per the ISCD (2014) is frequent and persistent difficulty with initiating sleep and general sleep dissatisfaction.

BOX 42.2 Stages of Sleep

Stage I
- Light NREM: dreamlike state and lasts a few minutes

Stage II
- Relatively light NREM: fragmented thoughts and lasts 15–20 min

Stages III–IV
- Deep NREM: lowering of blood pressure, cerebral glucose metabolism, heart rate, and respiratory rate, starts 35–40 min after falling asleep, and lasts 40–70 min

REM sleep
- Starts after 90 min of sleep and lengthens toward the end of the night
- This cycle alternates throughout the night at intervals of 90–100 min, four to six times per night.

Characteristics of chronic insomnia include somatized tension and acquired habits that prevent either the initiation or maintenance of sleep. Life stresses such as shift work, a family tragedy, or physical pain can exacerbate chronic insomnia. More recent neurobiologic research about insomnia points to a dysregulation of the neurotransmitters in the brain that regulate wakefulness, NREM, and REM sleep contributing to chronic insomnia. Insomnia can start with an initially stressful event, but the hyperarousal state of chronic insomniacs extends well beyond the heightened levels of stress.

Short-Term Insomnia Disorder

The prevalence among adults is 15% to 20% of the general population, more often in women than men and those who are older. Short-term insomnia has been previously classified as acute or adjustment insomnia. Diagnosis is similar to chronic insomnia, but with fewer question categories, see Box 42.3. The essential feature here is short-term difficulty initiating or maintaining sleep with general sleep dissatisfaction. Short-term insomnia can be in isolation or as a comorbid with mental disorders, medical conditions, or substance abuse (ICSD, 2014). Short-term insomnia is often related to environmental factors, such as sleeping in an unfamiliar place or excessive heat, noise, light, or movement of the bed partner. Additionally, short-term insomnia can be related to stress either positive or negative. Many features of short-term insomnia are shared with chronic insomnia with the primary difference of duration. Circadian rhythm disorders, jet lag, and rotating shift work should be considered in the differential.

BOX 42.3 Selected Sleep History Questions

- What kind of work does the patient do? Is there shift work involved, and which shift?
- What time does the patient go to bed?
- What kind of bed partner does the patient have (restless, still, wakeful sleeper), if any?
- Does the patient regularly take any prescription or over-the-counter drugs?
- How many times during the night does the patient awaken?
- What does the patient do if he or she cannot go to sleep?
- Does the patient take daytime naps?

Other Insomnia Disorders

The use of *other insomnia disorders* is reserved for those who have difficulty with initiating and maintaining sleep but do not meet the full criteria for either chronic or short-term insomnia. Other sleep disorders, such as restless leg syndrome (Willis-Ekbom disease) and obstructive sleep apnea, should be considered for patients within this category.

Pathophysiology

To understand how insomnia develops, it is first necessary to understand the physiologic process of sleep. The brain seeks to balance alertness and sleepiness on a continuum between sleep debt, biological alerting, and environmental stimulation. Sleepiness is a function of the brain fighting to get enough sleep to cover the debt. This system of sleep debt versus sleep arousal is intricately linked to circadian rhythms and exposure to light. Additionally, various internally regulated biologic systems govern the circadian pattern of the sleep–wake cycle. The interaction of these biologic systems includes changes in body temperature, cardiac and renal functions, and hormone secretion throughout the day. The term *circadian* means "approximately 1 day" and refers to the fact that endogenous rhythms last approximately 24 hours.

Normal sleep is divided into two phases: rapid eye movement (REM) sleep and non-REM (NREM) sleep. During the REM stage, which accounts for approximately 20% of the sleep cycle, the brain is active and most dreaming occurs. NREM, which constitutes approximately 80% of the sleep cycle, is a phase of deep rest in which pulse, respiration, and brain activity all slow. NREM sleep can be divided into four phases. Stages I and II are called light NREM sleep. Stage I is the lightest sleep, and fleeting dreams often occur during the transition between the awake state and stage I. Stage II, which accounts for 50% of NREM sleep, lasts approximately 15 to 20 minutes and is characterized by fragmented thoughts with distinctive EEG changes. Hypnotics commonly increase stage II. Stages III and IV are called delta or deep NREM sleep. This stage begins after approximately 30 to 45 minutes and lasts 40 to 70 minutes. During stages III and IV, blood pressure, cerebral glucose metabolism, and heart and respiratory rates are at the lowest in the circadian cycle. The total sleep pattern begins with light NREM, by deep NREM, and then by REM. This cycle lasts approximately 90 to 100 minutes and occurs four to six times per night. Box 42.2 summarizes the sleep stages.

Required amounts of sleep and of NREM sleep vary with age. Newborns sleep approximately 17 to 18 hours each day but have only two phases of sleep: NREM and REM. These two phases cycle every 60 minutes instead of every 90 minutes like adults. Children require 10 hours of sleep. In the early adult years, the total amount of sleep decreases to around 8 hours, which is normal for older adults as well as younger adults, with some variation among individuals. The total amount of REM sleep stays more constant at 15% to 20% throughout an adult's lifetime. Deep NREM sleep constitutes approximately 20% to 30% of total sleep in young children.

Insomnia is seen more often in people over age 65. The stages and architecture of sleep change, resulting in lighter stage II and decreases in stage III and IV sleep. This results in a decrease in deep NREM sleep. The circadian clock also becomes advanced, causing early morning awakening in the elderly.

Light cues are important in the process of sleep. The absence of light cues tends to promote longer sleep–wake cycles. Two peaks in the daily need for sleep have been identified: the first at bedtime and the second in midafternoon. A study by Regestein et al. (1993) suggested that insomniacs have higher daytime alertness compared with normal subjects, which leads to higher hyperarousal states. Desseilles et al. (2008) studied normal sleepers and found that sleep deprivation reduces metabolism in the prefrontal and parietal areas of the brain and produces a primary hyperarousal state. They concluded that insomniacs become more aware of small defects in the quality of sleep and daytime fatigue.

Diagnostic Criteria

Typical complaints of insomnia are malaise, fatigue, and too little sleep. These problems can lead to mild or moderate impairment in concentration and psychomotor abilities. The diagnosis is based on the patient's history, although a complete workup includes evaluating all potential medical and psychological causes. The practitioner must determine the onset and duration of symptoms, along with the patient's regular sleeping schedule and general quality of sleep. The practitioner should interview other family members and significant others regarding any psychiatric or substance abuse problems. If the patient does not sleep alone, the practitioner also should elicit information from the bed partner. Questions about sleep also should be included in the review of systems; Box 42.4 lists suggested questions.

A complete physical examination is important to rule out medical causes of insomnia. Insomnia can be drug related (e.g., stimulating medications or alcohol). Finally, the practitioner should investigate psychiatric causes of insomnia.

The use of sleep questionnaires or diaries and screening tools for depression and anxiety can add to the evaluation of insomnia. Sleep patterns may be measured by using a special wristwatch that measures wrist movements, a process called *actigraphy*. In humans, movement of the wrist throughout the night is much less frequent than during the day, which enables the practitioner to estimate the patient's sleep and wake times. This tool, however, is not very accurate in assessing total sleep time of insomniacs. Polysomnography (all-night monitoring of EEG, respiration, muscle activity, and other physiologic parameters) may reveal shallow sleep that is fragmented by multiple arousals. If the patient is depressed, the polysomnogram manifests changes in the REM latency stage.

Polysomnograms are indicated when the primary suspected cause of insomnia is sleep apnea. The American Sleep Disorders Association, however, does not recommend the routine use of polysomnography because a patient may not sleep normally at a sleep disorder center.

Initiating Drug Therapy

In combination with behavioral management, the practitioner can consider using certain pharmacologic agents, but only with caution. According to the most recent clinical guidelines for evaluation and management of sleep (Schutte-Rodin et al., 2008), hypnotics should be used at the lowest dose for the shortest time. There is a potential for the drugs that treat insomnia to be habit forming; therefore, it should be used only for brief periods.

A wide range of therapies may be necessary to treat insomnia, because multiple causes of insomnia are the rule rather than the exception. Nonpharmacologic therapy includes evaluating for the key causes and treating with the appropriate intervention first: counseling, behavioral management, and lifestyle alterations for psychiatric problems. Patients with insomnia often have major depression, anxiety, obsessive disorders, or dysthymic disorders, and psychotherapy needs to focus on the specific psychiatric disorder.

Adjunctive to drug therapy, reviewing proper sleep hygiene can enhance the patient's sleep pattern. A thorough examination of sleep hygiene issues can help identify important lifestyle changes that may enhance sleep, and its importance should not be underestimated. The practitioner should implement only one or two behavioral changes at a time. Follow-up and a strong patient–provider relationship are key. Additional measures, such as exposure to bright light, may help those with circadian rhythm disturbances. Light therapy can retrain the light pacemaker and may be effective for night-shift workers, travelers, and those with delayed or advanced sleep phase disorders.

Goals of Drug Therapy

There are two goals of pharmacotherapy. The first goal is to improve sleep quality and quantity, and the second goal is to improve the insomnia-related daytime impairment. The selection of drugs is based on matching the onset and duration to the sleep defect. If given in adequate doses, all hypnotics promote sleep, and the key is to determine the *minimal* dose that will provide efficacy with few or no side effects. Factors in selecting a pharmacologic agent should be directed by (1) symptom pattern, (2) treatment goals, (3) past treatment responses, (4) patient preference, (5) cost, (6) medication interactions, and (7) side effects. An additional goal of pharmacologic treatment is to achieve a favorable balance between therapeutic effects and potential side effects (Schutte-Rodin et al., 2008).

Hypnotics are the primary drugs used for insomnia, including benzodiazepines and benzodiazepine receptor agonists. Other drugs utilized to treat insomnia are orexin receptor agonists, melatonin receptor agonist, and first-generation antihistamines. Some sedating antidepressants are useful if the patient has comorbid depression. The practitioner should carefully consider selection of a hypnotic and prescribe use for as short a time as possible. Short-term use is defined as no more than 2 to 3 weeks combined with behavioral interventions; however, specific patients require occasional chronic hypnotic therapy. They may need to use a hypnotic agent two or three times a week over longer periods than 2 to 3 weeks. Further, it is important to wean patients off of hypnotics when not needed due to rebound effects. Careless use of sedative–hypnotics can be dangerous in patients with sleep apnea or a history of substance abuse.

Benzodiazepines

Benzodiazepines are synthetically produced sedative–hypnotics. This group of structurally related chemicals selectively acts on polysynaptic neuronal pathways throughout the CNS. Benzodiazepines appear to enhance the effects of gamma-aminobutyric acid (GABA) in the ascending reticular activating system, which increases inhibition and blocks thalamic, hypothalamic, and limbic arousal.

When choosing a benzodiazepine, the practitioner should select an agent with an onset of action that matches the patient's complaint yet has a short duration of effect, lacks rebound insomnia, and causes few or no cognitive problems (e.g., hangover, lack of motor coordination, or memory disturbance) (see Table 42.1). The prescriber also should consider the patient's metabolic requirements. Benzodiazepines can be categorized as short acting, intermediate acting, and long acting as defined by the pharmacokinetic characteristics. The most commonly used short-acting agent was triazolam, but now, it is not commonly used due to high incidence of rebound insomnia even after using only a short time, as well as neuropsychiatric adverse effects. Temazepam and lorazepam are examples of intermediate-acting agents, with flurazepam in the long-acting category. When a drug has a longer half-life, there is greater potential for untoward effects such as excessive residual sedation or dizziness. Agents with short-term effects and rapid onset are best for patients who have difficulty falling asleep. Agents with intermediate onsets and usually longer half-lives are useful for patients with sleep maintenance issues. These include temazepam (Restoril) and estazolam (ProSom). Two agents with a rapid onset of action, flurazepam and quazepam, assist with falling asleep and also have a longer duration of action, which can assist in maintaining sleep.

TABLE 42.1 Overview of Selected Drugs Used to Treat Insomnia

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Benzodiazepines			
alprazolam (Xanax) tablets 0.25, 0.5, 1, 2 mg Start: 0.25–0.5 mg PO tid; maximum 4 mg/d in divided doses Range: 0.25–2 mg tid–qd	*CNS:* transient mild drowsiness, sedation, depression, lethargy, apathy, fatigue, light-headedness, disorientation, headache, mild paradoxical excitatory reaction in first 2 wk *GI:* constipation, diarrhea, dry mouth, nausea	Hypersensitivity to benzodiazepines, acute narrow-angle glaucoma, pregnancy, lactation	Use cautiously with impaired liver or kidney function debilitation Drug dependence and withdrawal result when abruptly discontinued, especially when used for longer than 4 mo Use cautiously with elderly patients and gradually increase as tolerated
estazolam (ProSom) tablets 1, 2 mg Start: 0.5–1 mg qhs Range: 0.5–2 mg qhs	*CNS:* transient mild drowsiness, sedation lethargy, apathy, fatigue, light-headedness, asthenia, mild paradoxical excitatory reaction in first 2 wk *GI:* constipation, diarrhea, dyspepsia *CV:* bradycardia, tachycardia *GU:* incontinence, urinary retention, changes in libido	Same as above	In addition to above, drug–drug interactions: increased CNS depression with ethanol, omeprazole; increased effects of estazolam with cimetidine, increased sedative effects of estazolam with theophylline Drug dependence, withdrawal syndrome
flurazepam (Dalmane) 15–30 mg PO qhs Start: 15 mg PO qhs Range: 15–30 mg PO qhs	*CNS:* transient mild drowsiness, sedation lethargy, apathy, fatigue, light-headedness, asthenia *GI:* constipation, diarrhea, dyspepsia *CV:* bradycardia, tachycardia *GU:* incontinence, urinary retention, changes in libido	Same as above	Same as above Has a long half-life
lorazepam (Ativan) 2–4 mg PO qhs	*CNS:* transient mild drowsiness, sedation, depression, lethargy, apathy, fatigue, light-headedness, disorientation, headache, mild paradoxical excitatory reaction in first 2 wk *GI:* constipation, diarrhea, dry mouth, nausea	Same as above	Use cautiously with patients with impaired liver or kidney function Debilitation, drug dependence, and withdrawal result when abruptly discontinued, especially when used for more than 4 mo Use cautiously with elderly patients and gradually increase as tolerated
quazepam (Doral) 7.5–15 mg PO qhs	*CNS:* transient mild drowsiness, sedation, depression, lethargy, apathy, fatigue, light-headedness, disorientation, restlessness, confusion *GI:* constipation, diarrhea *CV:* bradycardia, tachycardia *GU:* incontinence, urinary retention, changes in libido	Same as above	Drug–drug interactions: increased CNS depression with ethanol, quazepam; increased effects of cimetidine, disulfiram, oral contraceptives; increased sedative effects with theophylline
temazepam (Restoril) Start: 15 mg PO qhs Range: 15–30 mg PO qhs	Same as above	Same as above	Drug–drug interactions: increased CNS depression; increased sedative effects with theophylline
triazolam (Halcion) Start: 0.125 mg PO qhs Range: 0.125–0.5 mg PO qhs Elderly: 0.125–0.25 mg PO qhs	Same as above	Hypersensitivity to benzodiazepines, acute narrow angle glaucoma, pregnancy, lactation	Same as above

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Benzodiazepine Receptor Agonist			
eszopiclone (Lunesta) Start: 1–2 mg PO qhs Range: 1–3 mg Elderly: start at 1 mg	*CNS:* morning drowsiness, headache, dizziness *GI:* nausea	Hypersensitivity to eszopiclone	Caution in patients taking strong inhibitors or inducers of CYP3A4
zolpidem (Ambien, Ambien CR) Ambien Start: 10 mg PO qhs Range: 5–10 mg PO qhs Ambien CR *Female:* 6.25 mg PO qhs; max 12.5 mg *Male:* 6.25–12.5 mg PO qhs	*CNS:* morning drowsiness, hangover, headache, dizziness, suppression of REM sleep *GI:* nausea Same as above Same as above	Hypersensitivity to zolpidem Use with sodium oxybate (Xyrem)	Use cautiously in patients with acute intermittent porphyria, impaired hepatic or renal function, in addiction-prone patients, and in pregnancy and lactation Useful for patients with problems falling asleep and middle night awakening
zolpidem tartrate (Intermezzo) Starting: 3.75 mg SL Elderly: 1.75 mg SL			Pregnancy category C Used for middle night awakening but must have more than 4 h to sleep Caution with elderly and hepatic impairment
zaleplon (Sonata) Start: 10 mg PO qhs Range: 5–20 mg PO qhs	*General:* back pain, chest pain *CV:* migraine *GI:* constipation, dry mouth *MS:* arthritis *CNS:* depression, hypertonia, nervousness *Derm:* rash, pruritus	Pregnancy, lactation	Pregnancy category C Patient must use just before bedtime because of quick onset
Orexin Receptor Antagonist			
Suvorexant (Belsomra) Start: 10 mg PO within 30 min of bed Maximum: 20 mg	Most common side effects were somnolence, headache, dizziness	Obese women have increased side effects Care with patients with respiratory compromise	Risk of impaired alertness and motor coordination Must have 7 h to sleep Re-evaluate for persistent insomnia after 7–10 d treatment Caution with depression

Adverse Events

Benzodiazepines have various actions, depending on their half-lives and affinity for the receptor. Drugs of this class can produce drowsiness and impaired motor function, which may be persistent due to metabolites and subsequent hepatic and renal accumulation. Other side effects can include short-term memory loss, confusion, and shakiness. Prolonged use of benzodiazepines can lead to physical dependency; abrupt discontinuance can trigger withdrawal symptoms. Drugs in this category are all classified as controlled substances due

to having a potential for addiction in addition to the physical dependency. The newer agents in the class have fewer side effects, but caution should still be exercised when prescribing, and for optimal therapy, the drug selected should address the patient's specific sleep problem.

Interactions

Patients taking benzodiazepines must be cautious with the concomitant use of alcohol. Use of low-dose contraceptives may slightly decrease clearance of lorazepam and temazepam; the patient may need to alter the dosage or switch to oxazepam. Use of erythromycin (E-mycin) can decrease triazolam clearance by 50%; thus, prescribers must consider reducing the dosage of triazolam in patients taking both drugs concomitantly.

Benzodiazepine Receptor Agonists

This class of hypnotic was developed to improve the safety profile of the barbiturate-type and longer-acting benzodiazepine compounds. Benzodiazepine receptor agonists (BRZA) pharmacologically are similar to benzodiazepines but instead mimic the action of GABA, an inhibitory transmitter, which induces sleepiness. The difference between BZD and BRZA is which GABA-A receptor subunits are affected. BZDs act on the subunit of alpha-1, alpha-2, and alpha-3, while BZRAs are selective for alpha-1, which induces sleepiness but not anxiolysis or muscle relaxation. Initially, benzodiazepine receptor agonists (BZRA) were thought to have one of the safest profiles with little or no long-term side effects; however, with more experience, this proved not to be so. There is some evidence that long-term use of these drugs can alter sleep architecture (Mazza et al., 2014) as well as worsen Alzheimer dementia (Billioti de Gage et al., 2014). Complex sleep-related behaviors, defined as completing activities in an altered state of consciousness, also have been reported with the BZRAs. These activities include sleep walking or eating and driving a car. Some other side effects of this class include decreased motor coordination, confusion, and anterograde amnesia, which were all thought to be less than BZDs.

Eszopiclone

Eszopiclone (Lunesta) is a benzodiazepine receptor agonist indicated for the treatment of insomnia.

Mechanism of Action

While the exact mechanism of action is unknown, eszopiclone is thought to work by interacting with GABA receptors located near benzodiazepine receptors and thus shares some of the same pharmacologic properties. It is classified as a Schedule IV controlled substance.

Dosage

For nonelderly adults, eszopiclone should be started at 2 mg immediately before retiring for bed. The dose may be started or increased to 3 mg to aid in sleep maintenance. For elderly patients, the doses should be started at 1 mg to help patients fall asleep and 2 mg if sleep maintenance is the issue. Limited use of the 3-mg dose is recommended due to impairment of driving ability, coordination, and memory for over 11 hours, even if patients do not realize it (PL-Detail Document, 2014)

Time Frame for Response

The onset of action is rapid, with a peak plasma concentration occurring within 1 hour of dosing. This peak concentration can be delayed if eszopiclone is taken with or shortly after a high-fat meal.

Contraindications

There are no known contraindications to eszopiclone. However, patients should be cautioned against the concomitant use of alcohol due to the sedative effects and the potential for enhancing anterograde amnesia.

Adverse Events

Headache, dry mouth, dizziness, respiratory system infections, and unpleasant taste have occurred in patients taking 2- to 3-mg doses of eszopiclone.

Interactions

Eszopiclone is metabolized by the cytochrome P (CYP) 3A4 enzyme system. Therefore, agents that inhibit (e.g., ketoconazole) or induce (e.g., rifampin) this system will affect eszopiclone metabolism.

Zolpidem

Zolpidem tartrate (Ambien), extended-release zolpidem tartrate (Ambien CR), sublingual zolpidem tartrate (Intermezzo), and zolpidem tartrate oral solution (Zolpimist) are also benzodiazepine receptor agonist products.

Mechanism of Action

Zolpidem is also thought to modulate the GABA-A receptors, and further postulation is that it modulates the chloride channel macromolecular complex responsible for sedative, anticonvulsant, anxiolytic, and myorelaxant drug properties, therefore, causing sedation and relaxation. Zolpidem has a strong hypnotic component and improves the overall quality of sleep while producing less daytime impairment than other hypnotics. The onset of action of zolpidem is rapid; however, regular-release zolpidem peaks quickly while extended-release zolpidem has a biphasic release assisting with sleep onset and sleep maintenance. Zolpidem has no anxiolytic effects, which makes it less desirable for patients with concomitant anxiety. These drugs are also controlled substances (class IV) due to the potential for abuse.

Dosage

Starting doses of zolpidem are lower for females than males. Zolpidem is started at 5 mg for females and 10 mg for males, while extended-release zolpidem starts at 6.25 mg for females and 12.5 mg for males. Dosing can be increased but with the understanding this increases the potential for side effects. Dosing should be altered for patients with hepatic impairment but is not necessary for those who are renally impaired.

Time Frame for Response

Onset of action for zolpidem is 10 to 15 minutes of administration and last for 2 to 3 hours. Extended-release zolpidem has the same onset, but 60% is initially released with the remaining over the next 6 to 8 hours. The sublingual and oral solution products are taken immediately prior to bedtime as their onset of action is rapid.

Contraindications

Contraindications to zolpidem include anaphylactic reactions and angioedema. In addition, the FDA (1/10/2013) put forth a safety communication bulletin that patients should be cautioned about complex behaviors that include sleep-driving activities and other activities.

Adverse Events

The most common adverse events for both drugs are drowsiness, headache, and dizziness. The incidence of complex sleep behaviors can affect up to 15% of those taking zolpidem.

Interactions

Care should be exercised when prescribing zolpidem with other central nervous system drugs that have depressive effects. Other drugs that inhibit the CYP3A4 isoenzymes may increase the exposure to zolpidem.

Zaleplon

Another benzodiazepine receptor agonist is zaleplon (Sonata), which is chemically unrelated to benzodiazepines, barbiturates, and other drugs with hypnotic properties.

Mechanism of Action

Zaleplon is known to interact with the GABA-BZ omega 1 receptor, which causes sedation; however, there are no myorelaxant, anxiolytic, or anticonvulsant properties. This interaction is also hypothesized to be responsible for the pharmacologic properties of benzodiazepines. Zaleplon works well for patients who have difficulty falling asleep. It may not be the agent of choice for patients who have difficulty maintaining sleep because of its short elimination half-life. However, provided that at least 4 hours of sleep remains, this drug can be dosed a second time when patients have a nighttime awakening.

Dosage

The dose of zaleplon should be individualized and can range from 5 to 20 mg. The risk of adverse effects is dose dependent.

Time Frame for Response

The onset of action is rapid, within 1 hour after oral administration, but the medication has a short half-life of 1 hour. Zaleplon can be taken as little as 5 hours before the

scheduled wake-up time, with no lingering effects of daytime sedation.

Contraindications

Hypersensitivity and severe hepatic impairment are contraindications to use of zaleplon. Dose adjustment is not necessary for renal impairment.

Adverse Events

Headache is the most commonly reported adverse event followed by dizziness, nausea, and abdominal pain. Postmarketing reports include anaphylaxis and nightmares. Other adverse effects include depression, amnesia, and sleep-related activities.

Interactions

Zaleplon is contraindicated in concomitant use with sodium oxybate (Xyrem) and any type of fentanyl or valerian. Close monitoring is required with use of drugs that are metabolized by the CYP3A4 isoenzyme of the cytochrome P450 system.

Orexin Receptor Antagonists

Orexin receptor antagonists are a new class in the treatment of insomnia. The only agent in the class is suvorexant (Belsomra).

Mechanism of Action

The hypothalamic neuropeptide orexin system was discovered in 1998 and the influence on sleep–wake cycle (De Lecea et al., 1998; Sakurai et al., 1998). Orexin neuropeptides (orexin-A and orexin-B) are found in the hypothalamus and other areas of the brain and perform a role in arousal, appetite, metabolism, reward, stress, and autonomic function (Dubey et al., 2015). Early study of the orexin system discovered that blockage resulted in severe sleepiness, which established the role of orexin in wakefulness. Suvorexant is a selective dual orexin receptor agonist (DORA) with a binding mechanism to both orexin receptors, thus inhibiting the arousal system. Through this inhibitory action, sleep induction and maintenance are facilitated. Suvorexant has been studied for over 1 year showing favorable outcomes and lack of physical dependence and withdrawal syndrome on continuation (Michelson et al., 2014).

Dosage

The starting dose for suvorexant is 10 mg and can be increased to a maximum of 20 mg. For patients taking other drugs that inhibit the CYP3A4 isoenzyme, suvorexant should start at 5 mg and go no higher than 10 mg. Administration should occur within 30 minutes of bedtime, and patients need to have at least 7 hours of planned sleep due to potential complex sleep behaviors. Dose adjustment for hepatic and renal impairment is not

required.

Time Frame for Response

Onset of action occurs within 30 minutes of administration with peak concentrations in 2 hours. Suvorexant can last up to 6 hours.

Contraindications

Suvorexant is contraindicated with narcolepsy, alcohol use, and hypersensitivity to the class. Caution should be used with obese female patient, depression, concomitant use of other CNS depressants, and impaired respiratory function.

Adverse Events

The most common adverse reactions to suvorexant include headache, somnolence, and dizziness.

Interactions

Drugs that are CYP3A inhibitors such as ketoconazole and clarithromycin are not recommended for concomitant use. Additionally, drugs that are CPY3A inducers, carbamazepine and phenytoin, may reduce the efficacy of suvorexant.

Melatonin Receptor Agonists

Ramelteon (Rozerem) was introduced as an option to treat insomnia in 2005. There are a few drugs in this class; however, it is the only one approved by the FDA for use in the United States. To illustrate the efficacy of ramelteon, a study of 110 healthy subjects randomized to placebo versus ramelteon (Rozerem) was done; results of the study showed a significant decrease in sleep latency in the ramelteon group (Zee et al., 2010).

Mechanism of Action

Endogenous melatonin is secreted from the pineal gland and regulates the circadian sleep cycle, which is found in the suprachiasmatic nucleus (SCN) of the hypothalamus. Secretion of melatonin signals the timing of darkness via specific receptors (MT_1 and MT_2) and decreases neural firing to the SCN. Ramelteon is a synthetic derivative that has high selectivity and affinity for the MT_1 and MT_2 receptors, which block the receptors and shorten the latency to sleep onset. It does not affect other sleep neurotransmitters such as GABA, dopamine, or serotonin.

Dosage

The dose for ramelteon is 8 mg and should be administered within 30 minutes of going to bed. Avoid administration with a high-fat meal.

Time Frame for Response

Onset of action for ramelteon is within 45 minutes and half-life is 1 to 2.6 hours. There are no accumulating effects with repeated use of ramelteon due to the short half-life. Administration with a high-fat meal can increase the area under the curve (total exposure).

Contraindications

Ramelteon is contraindicated for patients with hypersensitivity to the class, severe sleep apnea, severe hepatic impairment, and angioedema. Caution should be exercised with mild to moderate hepatic impairment, depression, and severe chronic obstructive pulmonary disease.

Adverse Events

The most common adverse reactions include somnolence, dizziness, fatigue, nausea, and exacerbated insomnia.

Interactions

Ramelteon interacts with rifampin, ketoconazole, fluconazole, donepezil, doxepin, and alcohol.

Antihistamines

Antihistamines are one of the most commonly used classes of OTC sleep-inducing agents. These drugs often come in combination with analgesics such as acetaminophen and ibuprofen. One of the most commonly used agents is diphenhydramine (Benadryl). The main mechanism of diphenhydramine is to competitively inhibit histamine at the H_1 receptor with substantial sedative and anticholinergic effects. No scientific evidence exists in the literature supporting the use of diphenhydramine to relieve insomnia or prolong sleep.

Some side effects of diphenhydramine include excessive daytime drowsiness, impaired psychomotor function, and increasing tolerance to the drug. A better approach may be to use one of the sedating antidepressants before using a trial of diphenhydramine. If a patient taking diphenhydramine is stopped while driving under the influence (DUI) of antihistamines, in many states, he or she can be charged with DUI.

Another first-generation antihistamine agent used for insomnia is doxylamine succinate (Unisom). The mechanism of action is to competitively inhibit histamine at the H_1 receptor with substantial sedative and anticholinergic effects. As an OTC sedative, doxylamine succinate is stronger in the effects of sedation and anticholinergic pharmacodynamics than diphenhydramine. The only formulation of the brand Unisom that contains doxylamine succinate is Unisom SleepTabs, and all other delivery methods, gel caps, minis, liquid, and combination with analgesic, contain diphenhydramine. Precautions also include excessive drowsiness can affect coordination, therefore impairing psychomotor coordination.

Antidepressants

Sedating antidepressants also may be used in the treatment of insomnia, but only for patients with comorbid depression. The most commonly used antidepressants in this category are mirtazapine (Remeron), trazodone, and doxepin (Silenor). If the patient has comorbid panic or anxiety, some newer agents may assist with sleep. This includes trazodone, which also has some sedating as well as antianxiety effects (see Chapter 40).

Selecting the Most Appropriate Agent

As previously discussed, the goal of therapy is to improve sleep quality and quantity along with improvement of insomnia-related daytime impairments. Additionally, selection of the appropriate agent is directed by symptom pattern, treatment goals, past treatment responses, patient preference, and cost, availability of other treatments, comorbid conditions, contraindications, concurrent medication interactions, and side effects. For treatment of short-term insomnia, the suggested duration of hypnotic use is 10 to 14 days, but some patients may need a longer course. Practitioners should schedule follow-up visits to monitor the effectiveness of therapy. The time between follow-up visits can vary, but in general, they should fall between every 1 and 2 weeks. Starting the medication at the lowest possible dosage is always a good practice and should minimize side effects. The practitioner should ask the patient about the effects the drug is having on sleep and daytime functioning. Changes may exist with dreaming, learning, memory, and adaptation to stress. Having the patient complete and bring in a sleep log for review can help pinpoint initial management needs and can continue to assist with evaluation for signs of improvement (Table 42.2 and Figure 42.1). Pharmacologic therapy should be associated with patient education and cognitive therapy (Schutte-Rodin et al., 2008).

TABLE 42.2 Recommended Order of Treatment for Insomnia

Order	Agents	Comments
First line	Benzodiazepine (e.g., alprazolam, lorazepam, temazepam), benzodiazepine receptor agonists (BZRAs) (zolpidem, zaleplon, escitalopram), or ramelteon	Agent selected should match the sleep deficit
	First-generation antihistamine—doxylamine succinate	For pregnant women—Category A
Second line	Alternating short-acting BZRAs (zaleplon, eszopiclone) with ramelteon	Consider short-acting agents, especially with patients who have renal or hepatic problems.
	Sedating antidepressants (trazodone, amitriptyline, doxepin, mirtazapine)	Consider antidepressant with comorbid depression
Third line	Sedating antiepilepsy agents (gabapentin) or atypical antipsychotics (quetiapine, olanzapine)	
	Orexin receptor antagonist (suvorexant)	

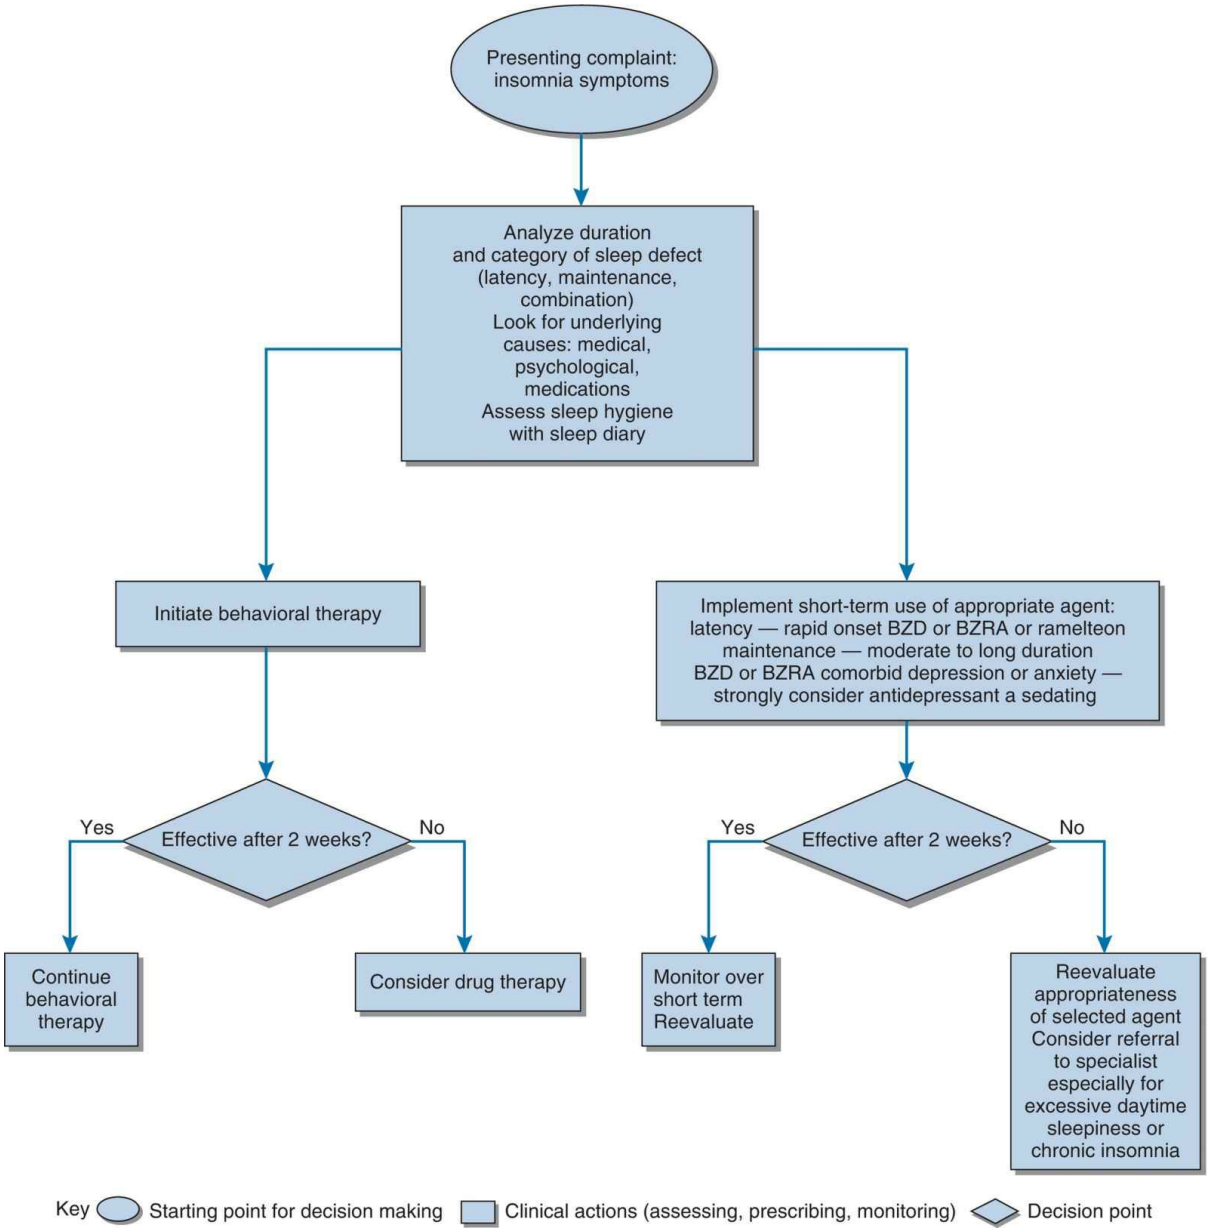

FIGURE 42.1 Treatment algorithm for insomnia. (DFA, difficulty falling asleep; DMS, difficulty maintaining sleep; EMA, early morning awakening.)

First-Line Therapy

As stated previously, the key to pharmacologic therapy is identifying the sleep defect. The practitioner should match the patient's need for an agent to both the classification of insomnia and the aspect of sleep that is altered. The recommended first-line therapy for short-term insomnia is from the benzodiazepine, benzodiazepine receptor agonist classes, or ramelteon. Examples of these medications include zolpidem, eszopiclone, zaleplon, and temazepam.

Doxylamine succinate is the only agent designated as pregnancy category A to treat any sleep defect in pregnant women. The practitioner must assess the potential side effects and

benefits for both the fetus and mother before instituting therapy.

Second-Line Therapy

If therapy is unsuccessful, as evidenced by a lack of improvement in the achievement of treatment goals, alternate short-acting BZRAs or ramelteon (Schutte-Rodin et al., 2008). If the patient has a comorbid condition such as depression, consider sedating antidepressants such as trazodone, amitriptyline, doxepin, and mirtazapine. These agents may be helpful especially with patients who have anxiety. Again, the prescriber must consider the kind of sleep defect being treated and select a drug with the appropriate onset and half-life.

Third-Line Therapy

Various combinations of therapy can be considered for third line based on lack of goal achievement. The practitioner should reassess the insomnia situation for patients who fail to respond to both first- and second-line therapies. Insomnia that has become chronic benefits most from continual evaluation and behavioral therapy. Consider other sedating agents in the antiepilepsy class such as gabapentin and atypical antipsychotics including quetiapine and olanzapine. For discussion of these agents, see Chapters 39 and 40.

Suvorexant is the newest class of hypnotic agents with a new mechanism of action but possesses pharmacodynamics similar to other known agents already on the market. Even though approved by the FDA, the preclinical trials exposed less than 2,000 patients to the drug leading to limited population exposure. The cost of suvorexant should be a consideration with prescribing.

Special Population Considerations

Pediatric

Use of barbiturates in the pediatric population is usually limited to those who have seizure disorders. In general, benzodiazepines are not indicated for children younger than age 15. Controlled studies of pharmacologic treatment in this population are lacking, and use of many drugs is off label. Caution is necessary when very young patients use antihistamines because of potential delirium or paradoxical excitation. Melatonin may be considered as treatment for a limited time (Buscemi et al., 2004; Shamseer & Vohra, 2009).

Geriatric

Older adults may report early morning awakening or general sleep disturbances. Central nervous system (CNS) changes are also thought to affect the sleep of the elderly. Frequent nighttime awakenings may result from secondary changes in circadian rhythms and loss of effective circadian regulation of sleep. Such changes can affect the quality of life. Many elderly patients exhibit daytime sleepiness, which shows that age does not diminish the need for sleep but reduces the ability to sleep.

It is important to evaluate the geriatric patient for underlying comorbidities that contribute to insomnia. Treating the underlying illnesses is important and may assist with re-establishing good sleeping patterns. Extreme caution is essential when prescribing hypnotic medications to elderly patients because these drugs can increase the potential for delirium and subsequent falls. According to the most recent Beers Criteria (American Geriatric Society, 2015), first-generation antihistamines and short- and intermediate-acting benzodiazepines should be avoided if at all possible. Prescribing must take in account the pharmacokinetic and pharmacodynamics changes in drug metabolism with the aging process (McCall, 2004). There is also an increase in falls associated with short- and long-term benzodiazepines (McCall, 2004, p. 12).

Consistent monitoring of the elderly patient can be extremely important, especially when a long-acting hypnotic is prescribed due to accumulation in the renal or hepatic system depending on the drug used. Antihistamines can cause delirium or paradoxical excitation.

Women

Pharmacokinetic differences have been noted when select BZRA agents are prescribed for women. Guidance from the FDA in 2013 lowered the dose of zolpidem to 5 mg, and in 2014 eszopiclone to no more than 2 mg. Caution is essential when prescribing all drugs to lactating women and women of childbearing age. Prescribed pharmacologic agents that treat sleep vary in pregnancy category risk designations. Only doxylamine succinate has a category A designation.

Monitoring Patient Response

Sleep can be a reliable predictor of psychological and physical health. Differences in monitoring are related to whether the insomnia is an acute or chronic problem. Brief episodes of acute insomnia can warrant treatment, with the goal of preventing it from progressing and becoming chronic. A short course (up to 4 weeks) of sedative–hypnotic therapy is the current treatment of choice. Cognitive therapy can be included to improve the chance of an optimal response.

When insomnia becomes a chronic problem, consistent interaction between the patient and health care provider is important, as is the use of behavioral techniques. With chronic insomnia, issues of drug tolerance for the older benzodiazepines and rebound insomnia usually become paramount; however, few studies have borne this out. In practice, many people take low-dose hypnotic agents for long periods with few side effects. Caution is warranted, however, if a patient requires escalation of a previously stable dosage. Careful analysis of changes in the patient's sleep patterns is necessary in this event.

Patient Education

Patient education plays a key role in the treatment of insomnia. A key side effect of most hypnotic agents is excessive drowsiness or hangover from the medication. The clinician must alert the patient to this possibility and monitor the side effects of each agent prescribed (see Tables 42.1 and 42.2).

Patient-Oriented Information Sources

Major sleep centers across the country have Web sites that are useful resources for patients and health care providers. These sites can provide information about diagnosis of sleep disorders and current research and therapies (Box 42.4).

Nutrition/Lifestyle Changes

Good sleep habits include setting a routine bedtime, getting regular exercise, using the bed for sleeping only, and getting in bed only when ready for sleep. Stimulants such as caffeine, alcohol, and excess fluids should be avoided before bedtime.

Complementary and Alternative Medications

Herbs and botanicals are often used as a "natural" way of promoting sleep. However, this is not without danger, especially if these treatments are taken in conjunction with prescription drugs. According to analysis by Clarke et al. (2015) of the National Health Statistics in 2012, 32% of adults between 18 and 44 years use some type of alternative therapy/drugs while 31% of adults over 65 years of age are likely to use CAM.

One of the most commonly used nonvitamin agents for sleep is melatonin, an endogenous hormone, synthesized by the pineal gland from tryptophan. It is mainly secreted at night and its level peaks during normal sleep hours. In 1997, Lavie discovered that endogenous melatonin opens the nocturnal sleep gate and increases nocturnal melatonin secretion. Melatonin does not induce sleep but acts as a gatekeeper in the cascade of events that enables the CNS to favor sleep over wakefulness. Most studies have examined the use of melatonin to treat sleep disorders resulting from jet lag (Choy & Salbu, 2011), but few have looked at the use of melatonin in short-term insomnia until now. A further meta-analysis of 19 studies showed that melatonin over the counter reduced time for sleep onset and increased sleep efficiency, total sleep duration, and improvement in overall quality of sleep (Ferracioli-Oda et al., 2013). There appears to be a role for use of melatonin as adjunctive therapy for treatment of insomnia; however, due to lack of safety and efficacy data, it will be important to continue to study. Valerian is a traditional sleep remedy that is derived from the perennial herb *Valeriana officinalis*. The direct physiologic activity is mediated by the active sesquiterpene components of the volatile oil. This creates a synergistic effect with neurotransmitters such as GABA and produces a direct sedative effect. Effective dosage ranges from 300 to 600 mg of the valerian root; 2 to 3 g of the dried root is soaked in a cup of hot water for 10 to 15 minutes, and the patient then drinks the tea. Administration can occur 30 minutes to 2 hours before bedtime. Significant herb or drug interactions have not been reported by the German Commission E.

As with melatonin, few studies exist regarding the safety and efficacy of valerian. Meta-analysis of those studies that exist found more *subjective* improvement of sleep rather than objective measures (Fernandez-San-Martin et al., 2010). Overall, the clinical guidelines do not support use of herbal or nutritional substance due to the lack of efficacy and safety data (Schutte-Rodin et al., 2008).

Restless Leg Syndrome/Willis-Ekbom Disease and Periodic Limb Movement Disorder

In 2011, restless leg syndrome (RLS/WED) was renamed Willis-Ekbom Disease to better reflect the neurologic process and underlying pathophysiology. Periodic limb movement disorder (PLMD) is another neurologic disorder that represents repetitive movements and may or may not be associated with RLS/WED. RLS/WED is characterized by an intense need to move the legs, but can also affect the arms and trunk, and may be accompanied by paresthesias and dysesthesias that worsen usually in the evening. Sometimes, the sensations can occur in other large muscle groups, but most often, the legs are involved. Moving around relieves the feeling, but only for a short time, as the sensation soon returns. These sensations interfere with sleep. PLMD is characterized by episodes of highly repetitive and stereotyped limb movements only during sleep.

Both disorders can interfere with sleep and contribute to sleep deprivation and decreased alertness and daytime function. Indications are that in the United States, more than 10 million adults and 1.5 million children and adolescents are affected by RLS/WED (Allen et al., 2005; Berger & Kurth, 2007). PMLD is more common in adults over 60 years of age and is rare in children. Additionally, while 80% to 90% of RLS/WED patients have PMLD, only 30% of PLMD have restless leg (Natarajan, 2010).

Causes

Generally, RLS/WED is an idiopathic disorder classified as a central neurologic disorder. Secondary causes of RLS/WED can be associated with end-stage renal disease, iron deficiency, and, sometimes, pregnancy (Natarajan, 2010). RLS/WED can also be hereditary or drug induced. A definitive link has been shown between iron deficits and RLS/WED (Allen et al., 2013a).

Pathophysiology

RLS/WED and PLMD are chronic sensory–motor disorders that are not fully understood. However, recent advances show strong evidence linking RLS/WED to low iron/transferrin, dopaminergic abnormalities, and excessive glutamate. Primary RLS/WED has a strong hereditary component, with 40% to 60% of patients having a familial association. Genome studies have linked evidence of this familial trait to six distinct different genes for RLS/WED. Onset of RLS/WED before age 45 is consistent with a familial link. Secondary RLS/WED can be associated with neuropathies from changes in axonal and small fiber neural pathways. Patients with rheumatoid arthritis and diabetes also have shown a greater prevalence of RLS/WED, again presumably from changes due to neuropathy. Parkinson disease is frequently associated with RLS/WED, pointing to a commonality in reduced dopaminergic functioning (Peeraully & Tan, 2012). A strong link has been established to the dopaminergic system by the positive response to the dopaminergic agonist classification of drugs (Earley et al., 2011).

The pathophysiology of PMLD is also uncertain, but the projection is there are changes in the descending inhibitory pathways with neuronal hyperexcitability. Dopamine transmission is also decreased, which supports use of dopaminergic therapy (Earley et al., 2011).

Diagnostic Criteria

RLS/WED is diagnosed primarily through the patient history. Clinical criteria have been established by the International Restless Legs Syndrome Study Group (Box 42.5).

BOX 42.5 Diagnostic Criteria for Restless Leg Syndrome

1. A compelling urge to move limbs associated with paresthesias/dysesthesias
2. Motor restlessness as evidenced by:

   - Floor pacing
   - Tossing and turning in bed
   - Rubbing legs

3. Symptoms worse or exclusively present at rest with variable and temporary relief by activity
4. Symptoms worse in the evening and at night

PLMD is associated more with stereotypical repetitive movements of limbs (legs alone or legs more than arms) that occur only during sleep. PLMD is generally diagnosed only through a sleep test.

The physical examination for RLS/WED and PLMD should include a full neurologic examination with emphasis on the spinal cord and peripheral nerve function. A vascular examination is also necessary to rule out vascular disorders. Secondary causes of RLS/WED should be evaluated by a serum ferritin level and serum chemistry to rule out uremia and diabetes. Polysomnography is not routinely indicated for RLS/WED but can be helpful to establish the diagnosis. Box 42.6 lists other possible diagnoses.

BOX 42.6 Differential Diagnoses for RLS/WED and PLMD

1. Nocturnal leg cramps

   - Painful, palpable involuntary muscle contractions
   - Focal with sudden onset
   - Unilateral

2. Akathisia

- Excessive movement without accompanying sensory complaints

3. Peripheral neuropathy

- Usually tingling, numbness, or pain sensations
- Not associated with motor restlessness
- Not helped by movement
- Evening or nighttime worsening

Initiating Drug Therapy

Pharmacotherapy should be tailored for each patient. Patients with relatively mild symptoms may not need medications. Nonpharmacologic therapy should be instituted, including mental alerting activities and cessation of alcohol, nicotine, and caffeine. Any medications that may precipitate or worsen RLS/WED symptoms, such as antidepressants and dopamine antagonists, should be avoided. Correction of underlying serum iron deficits may be helpful. Short-term studies have shown that drug therapy has significant benefits, but little is known about long-term treatment. A 3-year study of 70 patients by Clavadetscher et al. (2004) found that a good long-term response with drug therapy can be achieved in 80% of patients. This study helped to establish the benefit of pharmacologic therapy in RLS/WED.

Goals of Drug Therapy

The goal of drug therapy is to calm the restless legs or periodic limb movements. Some patients can be refractory to pharmacologic treatment but still achieve partial relief of their symptoms. Pharmacologic agents for RLS/WED include dopaminergic agents, dopamine agonists, opioids, benzodiazepines, anticonvulsants, and iron (see Table 42.3). Other than dopamine agonists, many of these drugs are being used in an "off-label" manner.

TABLE 42.3 Overview of Selected Drugs Used to Treat Willis-Ekbom Disease/Restless Leg Syndrome

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Dopaminergic Agents			
ropinirole (Requip) Start: 0.25 mg q pm × 2 d, then 0.5 mg × 5 d; increase by 0.5 mg weekly until at maximum. Range: 3–4 mg	Common side effects include nausea, somnolence, abdominal pain, dizziness, orthostatic hypotension	Hypersensitivity to class, caution with alcohol use, concomitant CNS depressant, renal and liver impairment	Use cautiously with elderly Extended-release form not approved to WED/RLS Augmentation is common with this class
pramipexole (Mirapex) Start: 0.125 mg/d Range: 0.125–0.5 mg Max: 0.5 mg	Same as above	Same as above	Start with lower dose for CrCl 20–60 and increase only every 14 d
rotigotine transdermal (Neupro) Start: 1 mg/24 h patch q 24 h Range: 1–3 mg/24 h Max: 3 mg/24 h	Same as above	Same as above	Same as above
Anticonvulsants: Alpha-2-Delta Ligands			
gabapentin enacarbil (Horizant)	Common side effects include somnolence, dizziness, headache, and nausea	Same as above	Monitor for baseline creatinine, depression and suicidal ideation, give with food around 5 PM, do not cut/crush/chew Only approved anticonvulsant drug for WED/RLS

Dopaminergic Agents

These drugs are dopamine precursor combinations such as ropinirole (Requip) and pramipexole (Mirapex). These drugs are the only agents of this class approved for RLS/WED. These agents are useful for intermittent RLS/WED because they have a quicker onset than dopamine agonists. This is useful for relief of sleep-onset insomnia and RLS/WED that occurs during long car or airplane journeys. Dosage of these agents is lower than used for Parkinson disease. See Chapter 45 for full discussion of these agents

Adverse Events

The carbidopa–levodopa agents may actually worsen RLS/WED symptoms in up to 80% of patients. The therapeutic effect may be reduced if taken with high-protein food. Insomnia, sleepiness, and gastrointestinal problems are other adverse events.

Dopamine Agonists

The initial dopamine agonists used for RLS/WED were bromocriptine and pergolide, which were prone to side effects. Pergolide is no longer available in the United States and has been replaced by the newer dopamine agonists. These agents include pramipexole and ropinirole, which are not ergot based; while they have fewer side effects, they can cause initial nausea and light-headedness, nasal stuffiness, edema, and rarely, daytime sleepiness. Increasing the dose slowly will help to mitigate these side effects. See Chapter 45 for full discussion of these agents.

Opioids

Research is limited with the use of opioids in RLS/WED or PMLD. Opioids are reserved for the most severe cases of RLS/WED or PLMD that are refractory to treatment with other pharmacologic agents. Opioids have been used off label without solid support of efficacy. Trenkwalder et al. (2013) led a randomized placebo-controlled trial of refractory RLS/WED patients in the United Kingdom who were treated with combination prolonged-release oxycodone–naloxone (Targiniq). The results show improvement of the quality of life indicators, which included reduction of sensory, restlessness, pain, and sleep. In 2013, the FDA approved the drug as extended release but only for the indication of severe pain and to help prevent prescription narcotic abuse (FDA News Release, 2013). Practitioners need to be judicious in the selection of patients in whom to prescribe potent narcotics. Revised guidelines for the treatment of RLS/WED support the use of careful opioid usage with careful monitoring (Silber et al., 2013). See Chapter 7 for pain management.

Benzodiazepines

Benzodiazepines (see Table 42.1) are used concomitantly with a dopamine agonist when use of a sole agent has failed. Clinical experience is particularly crucial with clonazepam and temazepam. These drugs may be helpful for patients who cannot tolerate the other medications. Caution is necessary when using these agents in the elderly, and they can cause daytime sleepiness and cognitive impairment.

Anticonvulsants

Anticonvulsants are considered when dopamine agonists have failed and in patients who describe the RLS/WED discomfort as pain. Gabapentin is helpful in patients with RLS/WED and peripheral neuropathy but is considered "off label." As with the dopamine agonists, lower dosages of gabapentin (100 to 600 mg one to three times daily) can be successful. The side effect of hypersomnia often limits the dosage. Other side effects can include nausea, sedation, and dizziness. Gabapentin enacarbil is a prodrug of gabapentin and is the only anticonvulsant drug approved for RLS/WED. The starting and continuing dose is 600 mg daily. Adverse effects of the drug are the same as gabapentin (see Table 42.2). See Chapter 39 for further discussion of other anticonvulsants.

Selecting the Most Appropriate Agent

For treatment purposes, RLS/WED can be classified as *intermittent* (not often enough to require drug therapy), *daily* (troublesome enough to require drug therapy), and *refractory* (not adequately treated by a dopamine agonist). The ideal agent will minimize or abate the symptoms of RLS/WED. No one pharmacologic agent appears to be efficacious in all patients, and often, a combination of medications is needed. The severity of RLS/WED can vary, and pharmacologic treatment needs to be individualized. See Box 42.7 for considerations when selecting a pharmacologic agent (Figure 42.2).

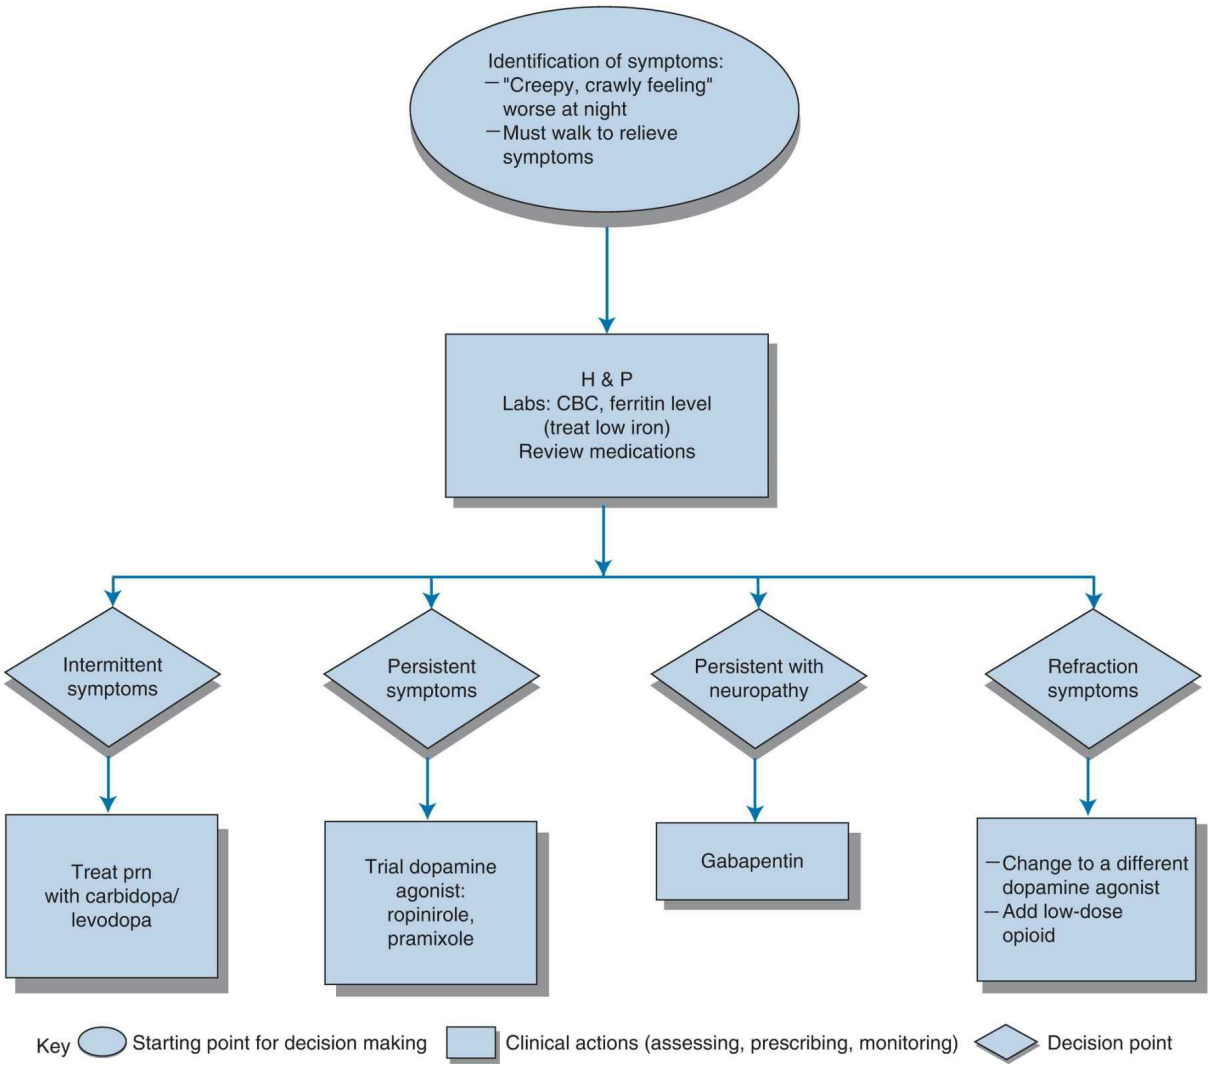

FIGURE 42.2 Algorithm for treatment for RLS/WED.

BOX 42.7 Considerations in Pharmacologic Agent Selection in RLS/WED

Age of patient	Benzodiazepines can cause cognitive impairment in elderly.
Severity of symptoms	Mild symptoms: no medication or levodopa or dopamine agonist Severe symptoms: strong opioid
Frequency/regularity of symptoms	Patients with infrequent symptoms may benefit from prn medication.
Presence of pregnancy	No safety and efficacy clinical trials on treatment of RLS/WED with medications in pregnancy
Renal failure	Need to decrease dosage if drugs are renally excreted

First-Line Therapy

Dopaminergic antagonists such as low-dose carbidopa–levodopa should be reserved for patients with intermittent RLS/WED. The first choice of therapy for daily RLS/WED is one of the dopamine agonists. Comparative analysis of all dopamine agonists (ropinirole, pramipexole, and rotigotine) showed clinically significant improvement in RLS/WED symptomatology (AHRQ, 2012). Nausea, dizziness, dyskinesia, and somnolence are potential side effects of both the dopaminergic antagonists and agonists. One problem with the dopaminergic antagonists is augmentation (worsening of RLS/WED symptoms), which can occur as early as 10 weeks of therapy. Another new first-line therapy (2015) is gabapentin enacarbil (Horizant), which is a prodrug of gabapentin. It is the only drug in the anticonvulsant category that is specifically approved for RLS/WED.

Second-Line Therapy

Pharmacologic agents approved for neuropathic pain such as gabapentin (Neurontin) or pregabalin (Lyrica) can be used alone or in conjunction with other agents, but they are also off label. It is especially helpful for patients who describe RLS/WED symptoms as painful. Other anticonvulsant agents such as carbamazepine (Tegretol) can be considered, but the older agents carry an increased risk of adverse effects such as dizziness, drowsiness, and lack of coordination. Patients also may experience nausea with these older agents. An opioid or opioid receptor agonist, tramadol (Ultram), may be added or used alone at low doses. If either the anticonvulsant or opioid fails, a repeat trial of dopamine agonists should be attempted (Silber et al., 2013).

Third-Line Therapy

Patients who continue to have symptoms may be refractory to treatment. Therapeutic doses may not have been obtained, or the patients could not tolerate the side effects of the medications. Substitution of different medications in the dopamine agonist class or adding higher-potency opioids should be considered. Consultation with a sleep specialist should be considered.

Monitoring Patient Response

Most patients will have remittance of symptoms with the first therapeutic dose of medication. This supports the theory that dopaminergic abnormality is a cause of this disorder. Another indicator of improvement is a decrease in excessive daytime sleepiness from lack of REM sleep. Patients need to be monitored for side effects of the pharmacologic agents. The long-term efficacy of these pharmacologic agents is uncertain, and monitoring for relapse of symptoms is important. It is also important to monitor for dependence when benzodiazepines or opioids are used.

Patient Education

Many patients who have RLS/WED use OTC sleep medications, and poor sleep hygiene may contribute to the lack of sleep in RLS/WED sufferers. Implementing cognitive sleep hygiene techniques may provide a modest improvement in short-term sleep symptoms (Edinger, 2003). Patients should inform all of their health care providers about their RLS/WED diagnosis, and health care providers should be aware that the patient's inability to keep his or her limbs still is not due to lack of cooperation. Improper restraint of patients with this syndrome has resulted in mortality and morbidity.

Drug Information

A higher dosage of ropinirole (Requip) is needed compared to pramipexole (Mirapex) to achieve the same therapeutic effect. This may contribute to side effects and tolerability of the drug.

Patient-Oriented Information Sources

The Willis-Ekbom Disease Foundation supports research and provides information for patients and health care providers. Extensive international research is also being conducted on this serious sleep problem (see Box 42.4).

Narcolepsy

Narcolepsy is a sleep disorder caused by poor sleep–wake cycles that can greatly impact the daily activities of those affected. Individuals with narcolepsy sleep the same amount as the average person but cannot control the timing of their sleep. The other features of narcolepsy can include excessive daytime sleepiness, cataplexy (attacks of muscle weakness), sleep paralysis, and hypnagogic hallucinations. Narcolepsy is the second leading cause of excessive daytime sleepiness and has an overall incidence in the world of 0.2 to 1.6 per thousand individuals (Leschziner, 2014). Narcolepsy can have a dramatic impact on virtually all areas of life. Unfortunately, the diagnosis of narcolepsy is often mislabeled as other chronic sleep disorders especially if cataplexy is absent.

Causes

Narcolepsy currently lacks distinct etiology and usually starts in the second or third decade of life; however, it has been identified in children as young as age 3. Excessive daytime sleepiness or cataplexy may be the first symptoms, but most often, cataplexy is delayed 2 to 3 years or may be totally absent. Cataplexy attacks are often precipitated by highly specific situations or triggers of strong emotions. Hypnagogic hallucinations can be present but are rarely the first manifestation of narcolepsy.

Pathophysiology

The pathophysiology of narcolepsy is not well understood but is evolving. Current research has focused on the loss of hypocretinergic neurons in the lateral hypothalamus. These neurons stimulate various histaminergic neurons in the basal forebrain, which increase the arousal state and involve activation of the cerebral cortex. This loss creates an instable neuronal network that is responsible for maintaining wakefulness and preventing REM sleep (Leschziner, 2014). There is also increasing knowledge about the role of genetics in narcolepsy. Demonstration of a strong genetic component is found through the human leukocyte antigen (HLA), especially when there is a first-degree relative who has narcolepsy and cataplexy.

Diagnostic Criteria

Patient presentations include complaints of excessive daytime sleepiness (EDS), cataplexy, and sleep-related hallucinations along with sleep paralysis. These criteria are commonly known as the narcoleptic triad. *The International Classification of Sleep Disorders,* third edition (2014), now classifies narcolepsy as type 1 or type 2 with subtypes. Diagnosis is based on the presence of excessive daytime sleepiness (EDS), levels of hypocretin in the cerebral spinal fluid, and multilatency sleep test (MLST) (Box 42.5).

Initiating Drug Therapy

There is no cure for narcolepsy, and pharmacologic therapy must be initiated to control the attacks (Table 42.4). Evaluation for cataplexy, sleep-related hallucinations, and sleep paralysis is important to identify the best agent for treatment. Most often, antidepressants are used to block the REM paralysis of cataplexy. The mainstay of pharmacologic therapy until now has been amphetamines and amphetamine-like drugs such as methylphenidate (Ritalin). Newer drugs on the market now focus on treating the symptoms and the neurobiologic deficit. Pharmacologic agents used in treatment of narcolepsy can be classified into psychostimulants (wake-promoting agents), amphetamines, sodium oxybate, and antidepressants.

TABLE 42.4 Overview of Selected Drugs Used to Treat Narcolepsy

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Psychostimulants			
armodafinil (Nuvigil) Start: 150–250 mg qam	*Serious:* arrhythmias, syncope, visual changes, abuse/dependency *Common:* headache, nausea/vomiting, rhinitis, diarrhea	Hypersensitivity to modafinil and armodafinil	Reduce dose in patients with severe hepatic dysfunction. Consider low doses in elderly
modafinil (Provigil) Start: 200 mg qam; maximum 400 mg daily	Same as above	Sensitivity to class, caution with coronary artery disease, mitral valve prolapse, impaired liver failure	Start at 100 mg daily in elderly
sodium oxybate (Xyrem) Start: dose 1–2.25 g at hs. Dose 2–2.25 g 2.5–4 h later Increase dose by interval 1.5 g nightly. Range: 6–9 g nightly	*Serious:* CNS and respiratory depression, abuse/dependency, depression, suicidal ideation, psychosis, paranoia, hallucinations, apnea *Common:* nausea, dizziness, vomiting, somnolence enuresis	Sensitivity to class; caution with CNS depressant use; alcohol intake; hepatic, renal, pulmonary, cardiac impairment; psychiatric disorders; drug abuse history	Black box warning for appropriate use—only distributed through Xyrem Success Program and centralized pharmacy Abuse potential due to relation to gamma-hydroxybutyrate (GHB)

Goals of Drug Therapy

Pharmacologic therapy should be titrated to promote the optimal dose of stimulation. The health care provider needs to work with the patient to identify personal treatment goals such as staying awake in a classroom or social situation or while driving. The main goal is to achieve as normal a life as possible, staying awake in situations of normal daily living.

Psychostimulants (Wake-Promoting Agents)

Modafinil and armodafinil (the R-enantiomer of modafinil) are psychostimulants with unique properties to promote wakefulness. The potential for abuse of these agents is much lower than with other stimulants, although it still needs to be monitored. The mechanism of action of modafinil and armodafinil is not well understood, but it appears to attenuate the central alpha-1 adrenergic system. The primary sites of action are the subregions of the hippocampus, the centrolateral nucleus of the thalamus, and the central nucleus of the amygdala. Modafinil can produce euphoria and psychoactive effects similar to other CNS stimulants. Absorption of the drug occurs rapidly, with peak plasma concentration in 2 to 4 hours and a half-life of 15 hours. Distribution of the drug is throughout the tissues, and it is moderately bound to plasma proteins. The drug is metabolized in the liver and excreted in the urine (see Table 42.4).

Amphetamines

Various amphetamine drugs are used to promote wakefulness in narcolepsy. The most commonly used agent is methylphenidate (Ritalin), which is approved for use in narcolepsy. The mechanism of action is generally unknown but thought to stimulate central nervous system activity and block the reuptake while increasing the release of norepinephrine with dopamine. This agent is metabolized in the liver but not through the CYP450 system. The average half-life of methylphenidate is 3.5 hours and administration can be adjusted to daily activities.

Sodium Oxybate

Sodium oxybate (Xyrem) is approved to treat two common symptoms of narcolepsy, excessive daytime sleepiness (EDS) and cataplexy. The active ingredient of sodium oxybate is gamma-hydroxybutyrate (GHB) that has potential to depress the central nervous system. The drug is only distributed through the manufacturer in a restricted risk evaluation and mitigation strategy (REMS) distribution program due to potential for abuse. While the primary care provider may not be the prescriber of this medication, it is important to have knowledge about the drug.

Antidepressants

Venlafaxine (Effexor) and duloxetine (Cymbalta) act on the serotonergic and noradrenergic systems and may be useful when cataplexy is present (see Chapter 40).

Selecting the Most Appropriate Agent

For treatment purposes, narcolepsy can be classified as *type 1N* or *type 2* (Box 42.8). The ideal agent will minimize the triad of symptoms associated with the disease. As with insomnia and RLS/WED, no one pharmacologic agent appears to help all patients, and often, a combination of medications is needed. Individualizing therapy is also important with narcolepsy. The primary care provider most likely will not prescribe these drugs initially but will continue to be part of the health care team and need knowledge about the disease and treatment.

BOX 42.8 Diagnostic Criteria for Narcolepsy

Type 1 N

Required:
Hypersomnolence daily × 3 mo
Low CSF hypocretin levels (≤110 pg/mL) **OR** cataplexy
Short sleep latency (≤8 min)
Two or more sleep-onset rapid eye movement (REM) episodes on the multiple sleep latency test (MSLT)

Subtype
Type 1 due to a medical condition
Narcolepsy without cataplexy but low hypocretin.

Type 2

Required:
Hypersomnolence daily × 3 mo
Hypocretin not measured **OR** ≥110 pg/mL
Absence of cataplexy
Short sleep latency (≤8 min)
Two or more sleep-onset REM episodes on the multiple sleep latency test (MSLT)

Subtype
Type 2 due to a medical condition

Special Populations

Pediatrics

Narcolepsy is rare and difficult to diagnose in children. There are limited drug choices, but drugs that are used in ADHD may be useful (see Chapter 43). Modafinil has not been studied in children. The alternative drug of choice would be methylphenidate.

Geriatrics

Care must be taken when prescribing modafinil to the elderly population. The oral clearance of modafinil is reduced in the elderly by 20% to 50%. Renal failure does not influence the pharmacokinetics of the drug but does increase the inactive metabolite accumulation. Liver impairment can reduce the modafinil clearance and double serum concentrations.

Monitoring Patient Response

Narcolepsy is a lifelong disease process, and patients must use the medications for their entire lives. Patient response is monitored by improvement in the disease's severity. Achieving the goals identified by the patient can help to improve compliance.

Patient Education

Patients and their families need to be aware of all available options to treat narcolepsy. Psychological distress is a consequence, not the cause, of the disease. Discussion of potential side effects of the drugs is important for compliance. Offering counseling and support groups when necessary is important.

Drug Information

Patients who are switched from amphetamine stimulants to modafinil may not experience the same euphoric effects, and this may make the switch undesirable to the patient. Amphetamines tend to produce a feeling of improved well-being and arousal, while modafinil increases arousal without a change in affect.

Patient-Oriented Sources

Health care providers and patients can find information about narcolepsy from a variety of sources. Online support groups exist (see Box 42.4).

Case Study*

S.H., age 47, reports difficulty falling asleep and staying asleep. These problems have been ongoing for many years, but she has never mentioned them to her health care provider. She has generally "lived with it" and self-treated the problem with OTC Tylenol PM. Currently, she is also experiencing perimenopausal symptoms of night sweats and mood swings. Current medical problems include hypertension controlled with medications. Past medical history includes childhood illnesses of measles, chickenpox, and mumps. Family history is positive for diabetes on the maternal side and hypertension on the paternal side. Her only medication is an angiotensin-converting enzyme inhibitor and diuretic combination for hypertension control. She generally does not like taking medication and does not take any other OTC products.

Diagnosis: Insomnia

1. List specific goals of therapy for S.H.
2. What drug therapy would you prescribe? Why?
3. What are the parameters for monitoring the success of the therapy?
4. Discuss specific patient education based on the prescribed therapy
5. List one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What would be the choice for second-line therapy?
7. What OTC and/or alternative medicines might be appropriate for this patient?
8. What dietary and lifestyle changes might you recommend?
9. Describe one or two drug–drug or drug–food interactions for the selected agent.

43 Attention Deficit Hyperactivity Disorder

Jennifer A. Reinhold

Attention deficit hyperactivity disorder (ADHD) is defined as a cluster of characteristics or behaviors that are related to several heterogeneous biopsychosocial behaviors and neurodevelopmental processes, which ultimately negatively influence one's social, occupational, or academic function (Feifel & MacDonald, 2008; Goodman et al., 2012). In children, the clinical presentation typically includes a combination of the inattentive and the hyperactivity–impulsivity components. This population tends to endorse symptoms of difficulty concentrating, failure to follow through, forgetfulness, and distractibility, the hallmarks of the inattentive symptom's domain. Many patients also endorse symptoms related to the inability to remain seated, fidgetiness, excessive running or climbing in inappropriate situations, trouble awaiting turn, and propensity to interrupt, the hallmarks of hyperactivity and impulsivity. The majority of children present with the combined subtype, that is, a combination of the inattentive and the hyperactive–impulsive subtypes.

But it is this inherent heterogeneity, particularly evident in adults, that complicates the diagnosis and contributes to the lack of uniformly recognized criteria in this population. In adults, however, clinical presentation and functional impacts vary greatly from their child and adolescent counterparts (Montano & Young, 2012). In addition to the heterogeneity with which ADHD presents, the core symptoms are arguably "normal" depending upon the age of the patient, environmental and social demands, and also the extent to which they occur. It is when the symptoms occur more frequently than is considered normal and to an extent that causes functional impairment and is inconsistent with developmental level that it is considered ADHD. For example, poor concentration in an academic setting could be considered normal in a child who is under the age of 5, particularly when the poor attention occurs sporadically. If an intervention from a parent or a teacher resolves this issue, then this would not be considered ADHD. If, however, a child of a similar age consistently does not pay attention and does so in the context of parental or teacher intervention and disciplinary action, then this may be considered maladaptive and inconsistent with developmental level.

In 2011, it was estimated that approximately 11% of children 4 to 17 years of age (6.4 million) in the United States are diagnosed with ADHD, with a CDC-estimated prevalence of 5.6% to 15.9% of children. In 2013, the worldwide prevalence of ADHD in children was estimated at 5.6%, a contrast to our domestic statistics (American Psychiatric Association, 2013). Clinically meaningful symptoms persist into adulthood in 60% to 80%

of patients, which suggests that ADHD is not exclusively a condition of childhood that resolves spontaneously but rather is a chronic illness.

Causes

A multitude of potential underlying causes of ADHD have been suggested, but none has yet to be fully validated. Secondary to the vast and diverse clinical manifestations, it is likely that the causes are multifactorial. Evidence suggests that the disorder may have a genetic component as parents and siblings of children with ADHD have a two to eight times greater chance of being diagnosed with ADHD. There have been advances in genetic studies of ADHD (Smith et al., 2009). ADHD has been associated with the dopamine transporter gene (DAT1, SLC6A3) and the dopamine 4 (D4) receptor gene (DRD4) (Franke et al., 2012). Possible nongenetic causes are neurobiological, such as perinatal stress, low birth weight, traumatic brain injury, maternal smoking during pregnancy, and severe early deprivation. Other theories involve dietary intake of certain chemicals and sugars, but the evidence is inconsistent.

Pathophysiology

The pathophysiology that underlies the clinical manifestations of ADHD involves reduced volume and functionality in the prefrontal cortex (PFC), caudate, and cerebellum. These brain regions are collectively primarily responsible for regulating attention, behavior, emotion, distraction inhibition, and executive functioning. Reduced volume or impaired function in these brain regions manifests as deficits in cognition, attention, motor planning, processing speed, and the complex behavioral complications that are consistent with ADHD. The communication among these areas is regulated by the neurochemicals dopamine and norepinephrine and a complex interaction among their multiple receptor subtypes. Dopamine governs reward, motivation, attention, and emotion, and when the available concentrations of dopamine are appropriate, there is sustained focus and on-task behavior and cognition. Norepinephrine, at appropriate levels, improves executive functioning and increases inhibition of thoughts and behavior. Functionally, norepinephrine enhances relevant signals, while dopamine suppresses irrelevant signals. Therefore, a relative balance between the two is critical for optimal function.

Both a hypoactive and a hyperactive norepinephrine and dopamine theory have been proposed, but an integration of the two may be the most realistic theory. The concentrations of available dopamine and norepinephrine relative to one another and the functionality of their receptors influence the expression of ADHD symptoms. The PFC functions optimally under conditions of moderate catecholamine release, as overstimulation results in impaired cognition as does understimulation. Acquired damage to the aforementioned brain regions produces behavioral disinhibition, distractibility, impulsivity, organizational deficits, and loss of working memory.

The symptom clusters that tend to emerge in a patient with ADHD include behavioral, cognitive, social–emotional, and deficits in executive function. The behavioral symptoms may include hyperactivity, impulsivity, disinhibition, novelty seeking, risk behaviors, and reward dependence. The cognitive features may include organizational issues, poor planning and execution skills, slower or impaired information processing, and deficits in time management. The social–emotional component may include emotional impulsivity, dysphoria, anger, anxiety, emotional lability, trouble reading social cues, and issues with making or keeping friends. Executive functioning refers to a wide range of central control processes that evolve during the process of aging and maturation. Executive function includes self-regulation, sequencing behaviors, planning and organization, working memory, and internalized speech.

Adult patients previously diagnosed and those with undiagnosed ADHD may develop and depend on compensatory mechanisms in order to overcome some of the functional impairments associated with this diagnosis (Santosh et al., 2011). Particularly, patients who are highly functioning professionals with higher than average IQs will tend to develop useful coping mechanisms to overcome symptoms or to hide them from others. Some

patients become compulsive list-makers or develop a highly structured daily routine in order to minimize forgetting details, completing tasks, or losing belongings. They may unknowingly rely on coworkers or family members to an inappropriate extent for purposes of reminders or assistance in completing tasks or fulfilling responsibilities. Though compensatory mechanisms are generally therapeutic for the patient, they may cloud the clinical picture particularly in cases where the patient does not self-suspect ADHD but rather a family member or the practitioner suspects ADHD. In any case, the use of appropriate compensatory mechanisms should also be taken into consideration when determining if a drug therapy is indicated. Some patients can adequately manage their symptoms without clinically significant functional impact by relying on compensatory mechanisms and are able to avoid drug therapy.

As patients mature and roles and responsibilities evolve, the functional impairments and symptom presentation evolve in response, thereby presenting a barrier to fulfilling diagnostic criteria (Montano & Young, 2012). Adults are exposed to a variety of social and professional situations, which may provide an opportunity for previously unnoticed symptoms to manifest (Taylor et al., 2011). Inattentive symptoms may manifest as difficulty completing tasks, poor time management, difficulty sustaining attention in work-related activities, distractibility and forgetfulness, and poor concentration. Occupational performance and professional interpersonal relationships may suffer and may ultimately result in frequent job changes, unemployment, failure to live up to one's occupational potential, and lower salaries. Perhaps, the most significant evolution of symptoms occurs in the hyperactivity–impulsivity domain. It is often assumed that these symptoms fade or resolve entirely in adults. However, in adults, these symptoms manifest as interrupting conversations, frequent job changes, irritability, quick to anger, relationship discord, dangerous driving habits, and a low frustration tolerance. Maturation results in a shift in this symptom cluster, and it evolves from behavioral to cognitive; patients will feel restless as opposed to running around and leaving their seat (Santosh et al., 2011). An overwhelming majority of adult patients, somewhere on the order of 90%, will endorse symptoms of inattention.

Diagnostic Criteria

The most contemporary multidimensional approach to a relatively objective diagnosis in children and adolescents is the DSM-5 (*Diagnostic and Statistical Manual of Mental Health Disorders*, Fifth Edition) criteria, which assess symptomatology in all three domains (American Psychiatric Association, 2013). All iterations of the DSM criteria have failed to be validated in the adult population, and therefore, up until the release of the DSM-5 in May of 2013, there was very little consideration for the assessment of adult patients, though the DSM-IV had been used for this purpose. The DSM-5 has adapted the previous set of diagnostic criteria such that they are more accurately applied to adults and adult symptom presentation. The verbiage related to the criteria and the descriptors thereof have been changed to reflect more adult-specific situations, though the use of these criteria in adults has been widely criticized. Even considering the newest iteration of the criteria, practitioners are still in a position of having to make a retrospective evaluation of the presence of ADHD in childhood in order to establish a diagnosis in adulthood. This was cited as one of the most problematic components of the criteria as many patients either could not recall the childhood symptoms or could not produce documentation that would substantiate a childhood diagnosis. As ADHD is considered a developmental disorder, the presence of current symptoms as well as a history of previous symptoms (in childhood) needs to be established. Patients with ADHD, by nature of the illness, have impaired short- and long-term memory capabilities, and therefore, recall bias may impact the accuracy of assessments (Taylor et al., 2011). The practitioner is also faced with the challenge of determining if this was an established childhood diagnosis, a missed diagnosis in childhood, or a late-onset adult ADHD.

There are a host of validated rating scales for assessing the adult patient with suspected ADHD, although each has inherent limitations. The Adult Self-Report Scale (ASRS) is an 18-item screening tool that is based on the DSM-IV criteria (Box 43.1). Patients rate the items based on the frequency and degree to which they occur. The Conners' Self-Report Scale is a multidimensional assessment scale that both the patient and an observer complete. The long version of this scale is a 66-item toll that assesses symptoms consistent with inattention and memory deficits, impulsivity and emotional lability, hyperactivity and restlessness, and problems with self-conceptualization. Having multiple perspectives is ideal in that the observer may contribute critical data that the patient may either be unaware of or not willing to disclose. One of the most significant limitations of self-report scales is that they are generally not sufficient independently for establishing a diagnosis in the absence of more objective data or documentation (Modesto-Lowe et al., 2012).

BOX 43.1 Diagnostic and Statistical Manual of Mental Health Disorders, Fifth Edition (DSM-5)

Criteria for Attention Deficit Hyperactivity Disorder

A. A persistent pattern of inattention and/or hyperactivity–impulsivity that interferes with functioning or development, as characterized by (1) and/or (2):

1. Inattention: Six (6) or more of the following symptoms have persisted for at least 6 months to a degree that is inconsistent with developmental level and that negatively impacts directly on social and academic/occupational activities.

   Note: The symptoms are not solely a manifestation of oppositional behavior, defiance, hostility, or failure to understand tasks or instructions. For older adolescents and adults (age 17 and older), at least five symptoms are required.

   a. Often fails to give close attention to details or makes careless mistakes in schoolwork, work, or during other activities (e.g., overlooks or misses details, work is inaccurate)
   b. Often has difficulty sustaining attention in tasks or play activities (e.g., has difficulty remaining focused during lectures, conversations, or lengthy reading)
   c. Often does not seem to listen when spoken to directly (e.g., mind seems elsewhere, even in the absence of any obvious distraction)
   d. Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (e.g., starts tasks but quickly loses focus and is easily sidetracked)
   e. Often has difficulty organizing tasks and activities (e.g., difficulty managing sequential tasks; difficulty keeping materials and belongings in order; messy, disorganized work; has poor time management; fails to meet deadlines)
   f. Often avoids or is reluctant to engage in tasks that require sustained mental effort (e.g., schoolwork or homework; for older adolescents and adults, preparing reports, completing forms, reviewing lengthy papers)
   g. Often loses things necessary for tasks or activities (e.g., school materials, pencils, books, tools, wallets, keys, paperwork, eyeglasses, mobile telephones)
   h. Is often easily distracted by extraneous stimuli (e.g., for older adolescents and adults, may include unrelated thoughts)
   i. Is often forgetful in daily activities (e.g., doing chores, running errands; for older adolescents and adults, returning calls, paying bills, keeping appointments)

2. Hyperactivity and impulsivity: Six (or more) of the following symptoms have persisted for at least 6 months to a degree that is inconsistent with developmental level and that negatively impacts directly on social and academic/occupational activities.

   Note: The symptoms are not solely a manifestation of oppositional behavior, defiance, hostility, or failure to understand tasks or instructions. For older adolescents and adults (age 17 and older), at least five symptoms are required.

   a. Often fidgets with or taps hands or squirms in seat

b. Often leaves seat in situations when remaining seated is expected (e.g., leaves his or her place in the classroom, in the office or other workplace, or in other situations that require remaining in place)
c. Often runs about or climbs in situations where it is inappropriate (e.g., in adolescents or adults, may be limited to feeling restless)
d. Often unable to play or engage in leisure activities quietly
e. Is often "on the go" acting as if "driven by a motor" (e.g., is unable to be or uncomfortable being still for extended time, as in restaurants, meetings; may be experienced by others as being restless or difficult to keep up with)
f. Often talks excessively
g. Often blurts out answers before questions have been completed (e.g., completes people's sentences; cannot wait for turn in conversation)
h. Often has difficulty awaiting turn (e.g., while waiting in line)
i. Often interrupts or intrudes on others (e.g., butts into conversations, games, or activities; may start using other people's things without asking or receiving permission; for adolescents and adults, may intrude into or take over what others are doing)

B. Several inattentive or hyperactive–impulsive symptoms were present prior to age 12 years.
C. Several inattentive or hyperactive–impulsive symptoms are present in two or more settings (e.g., at home, school, or work; with friends or relatives; in other activities).
D. There is clear evidence that the symptoms interfere with, or reduce the quality of, social, academic, or occupational functioning.
E. The symptoms do not occur exclusively during the course of schizophrenia or another psychotic disorder and are not better explained by another mental disorder (e.g., mood disorder, anxiety disorder, dissociative disorder, personality disorder, substance intoxication or withdrawal).

Another challenge in the evaluation of patients is the degree of *symptom overlap* between ADHD and several other psychiatric diagnoses, namely, mood and anxiety disorders. Patients tend to associate poor concentration with ADHD alone and typically would not consider that an untreated or undiagnosed anxiety disorder can produce similar levels of concentration impairment. It is recommended that practitioners include an assessment for mood and anxiety disorders in their initial evaluations of these patients in order to rule out the presence of an additional psychiatric disorder.

In addition to symptom overlap with other psychiatric illnesses, ADHD is frequently *comorbid* with other psychiatric conditions. A determination of whether ADHD is present alone or whether it is present in addition to another psychiatric diagnosis is critical, as mood or anxiety disorders may be the sole diagnosis, which is producing ADHD-like symptoms. Patients with ADHD tend to have high rates of comorbidity with anxiety,

depression, and substance abuse disorders with prevalence rates that are more than double those observed in patients without ADHD. In 2005 study, a staggering 87% of adult patients had at least one psychiatric comorbidity and 56% had two.

Substance use disorders (SUDs) are more common in patients with ADHD and the clinical course of ADHD tends to be more challenging in this patient population.

Initiating Drug Therapy

Current guidelines and practice advocate for a multimodal treatment plan, which accounts for variations in response. The Multimodal Treatment Study (MTA) reported that children receiving intensive behavioral management combined with medication fared better than those receiving intensive behavioral management alone. The core symptom clusters of ADHD (inattention, hyperactivity, and impulsivity) respond to medication, with or without the behavioral intervention. Behavioral symptoms seem to respond to environmental modification, while skills in sports, academics, and social situations may not respond to medication or behavior modification. Relationship problems usually can be treated through psychotherapy.

Nonpharmacologic aspects of a multimodal treatment plan consist of behavior modification, parent training, family therapy, social skills training, academic skills training, individual psychotherapy, cognitive behavior modification, and therapeutic recreation. These are discussed further in the Nutrition/Lifestyle section later in this chapter.

The American Association of Pediatrics (AAP) has an established guideline for the treatment of ADHD, most recently published in 2011 (Wolraich et al., 2011). There is no domestic guideline that governs the treatment of ADHD in adults at this time; however, the National Institute for Health and Clinical Excellence (NICE) guideline from the British Psychological Society and the Royal College of Psychiatrists (2009) does include adult guidance (NCCMH, 2009). The NICE guideline for adults parallels the AAP guideline for children, and clinical practice for adult patients in the United States generally aligns with the pediatric/adolescent guidelines and the European guidelines. The AAP guidelines (children 4 to 18 years old) recommend initiating behavioral therapy in children 4 to 5 years old and only initiating methylphenidate if the symptoms are severe. In children older than 5 years (and up to 18 years), the initiation of a stimulant medication +/– behavioral interventions is considered first-line therapy. Preference is not given to one stimulant over another except in the case of children <6 years of age, in which methylphenidate is recommended (due to increased availability of evidence in this age group). Second-line therapy includes the nonstimulant medications with preference given to atomoxetine, then guanfacine, and then clonidine.

The NICE guidelines include recommendations for pediatric patients, adolescents, and adults. Only in cases of moderate impairment should drug therapy be initiated in children or adolescent patients per the NICE guidelines. Preference is not given to methylphenidate, amphetamine salts (referred to as dexamphetamine in Europe), or atomoxetine. In adults, however, drug therapy is considered first-line and methylphenidate is recommended as initial therapy over the other available stimulants. Amphetamine salts and atomoxetine are considered second-line therapies in situations where patients do not respond to or are intolerant of methylphenidate. Therapy (drug and/or nondrug) should continue for as long as it remains clinically effective.

In practice, but not necessarily suggested by any guideline, practitioners tend to initiate intermediate- to long-acting stimulant medications in children, adolescents, and adults. Medication products that have an extended duration of action tend to have a positive influence on tolerability, provide convenience, and improve compliance. It is also reasonable to start therapy with a short-acting medication product to establish an effective dose and then transition to a longer-acting version of the same drug, if available. There is no guideline that governs initiation of immediate-release versus longer-acting drug products, only guidelines that recommend starting doses and titration schedules. The prescriber determines which product to initiate based upon experience, patient preference, and other patient-specific factors.

Goals of Drug Therapy

Upon initiation of drug therapy with or without nondrug therapy, the expectation is that the core symptoms of ADHD will abate and the patient will no longer experience functional deficits in social, occupational, or academic domains. This result tends to emerge relatively quickly, particularly after the initiation of medication therapy. It is not uncommon to realize this therapeutic success after the first attempt at drug therapy, and it is also not uncommon to utilize several pharmacotherapeutic modalities before the patient is adequately controlled (Table 43.1). There is a careful balance between resolving the core symptoms of ADHD and minimizing the risk of transient or serious adverse effects.

TABLE 43.1 Recommended Order of Treatment for ADHD (All Ages)

Order	Agents	Comments
First line	Stimulants	Methylphenidate or amphetamine works quickly with first dose, is available in extended release, and is easy to titrate. If treatment with one member of the class is unsuccessful, attempt subsequent drugs from this class before initiating second-line therapy.
Second line	Nonstimulants	Atomoxetine should be the next drug utilized in patients who have failed stimulants; this is also appropriate for patients who have contraindications to stimulants. Guanfacine or clonidine has less impressive efficacy but can be added on to existing stimulant or atomoxetine therapy if monotherapy is insufficient. (This could also occur in third-line treatment.)
Third line	Bupropion	Takes a few weeks to have a therapeutic effect. May worsen anxiety and lower seizure threshold.

Stimulant Medications

Psychostimulants remain the drug class of choice in treating adults and children with ADHD (Modesto-Lowe et al., 2012). Most product formulations available are derived from one of two parent molecules: methylphenidate or amphetamine. See Tables 43.2 and 43.3.

TABLE 43.2 Neurotransmitters Affected by Pharmacotherapy

	NE	DA	Comments
Methylphenidate	↑	↑	Blocks reuptake
Amphetamine	↑↑	↑	Blocks reuptake Causes release of NE
Atomoxetine	↑		Blocks reuptake of NE
Clonidine			Stimulates alpha2-adrenoceptors
Guanfacine			Stimulates alpha2-adrenoceptors
Bupropion	↑	↑	Weak blocker of NE, DA reuptake

TABLE 43.3 Overview of Agents Used to Treat ADHD

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
atomoxetine (Strattera) Start: Children and adolescents <70 kg: 0.5 mg/kg/d for 4 d, then 1 mg/kg/d for 4 d, then 1.2 mg/kg/d	Increased heart rate and blood pressure, abdominal pain, decreased appetite, nausea, sedation Urinary retention in adults	Patients on MAO inhibitors, narrow-angle glaucoma	Atomoxetine does not appear to promote the development of new tics and therefore may be a good choice for patients unable to take stimulant medications due to preexisting tics
bupropion (Wellbutrin) Children: Start: Children and adolescents <70 kg: 0.5 mg/kg/d for 4 d, then 1 mg/kg/d for 4 d, then 1.2 mg/kg/d Range: 3–6 mg/kg/d or 150–300 mg/d Adults: 100 mg bid, then 100 mg tid; max. 4.5 mg/d	Insomnia, anorexia, dizziness, anxiety, confusion, xerostomia, constipation, nausea, agitation, fever, headache, vomiting, seizures	Seizure disorders, bulimia, anorexia nervosa Within 14 d of MAO inhibitors	Monitor weight
clonidine (Catapres) Children: Start: <45 kg: 0.05 mg hs, then titrate in 0.05 mg increments bid >45 kg: 0.1 mg hs, then titrate in 0.1 mg increments bid to qid Range: 27–40.5 kg: 0.05–0.2 mg; 40.5–45 kg: 0.05–0.3 mg; >45 kg: 0.05–0.4 mg Adults: 0.1 mg bid; max 2–4 mg/d	Dizziness, drowsiness, anxiety, confusion, xerostomia, constipation, impotence, nausea, hypotension	Hypersensitivity to clonidine	Monitor blood pressure (standing and supine), respiratory rate and depth, and heart rate
Long acting: dexmethylphenidate (Focalin XR 5-, 10-, 15-, 20-, 30-, 40-mg cap) 10 mg/d; max 40 mg/d dextroamphetamine (Dexedrine Spansule 5-, 10-, 15-mg cap) 5 mg/d, titrate 5 mg/d weekly; max 40 mg/d dextroamphetamine/amphetamine (Adderall XR 5-, 10-, 15-, 20-, 25-, 30-mg cap) 10 mg/d; max 30 mg/d lisdexamfetamine (Vyvanse 20-, 30-, 40-, 50-, 60-, 70-mg cap) 30 mg qd; max 70 mg/d methylphenidate; max 60 mg/d: Concerta (18-, 27-, 36-, 54-mg cap) 10 mg/d; titrate 18 mg/d weekly Daytrana (10, 15, 20, 30 mg/9 h patch) Metadate CD (10-, 20-, 30-, 40-, 50-, 60-mg cap) 20 mg qam Ritalin LA (10-, 20-, 30-, 40-mg cap) 20 mg qam	Nervousness, insomnia, arrhythmias, dry mouth, anorexia	Cardiovascular disease, hypertension, arteriosclerosis, hyperthyroidism, glaucoma, alcohol or drug abuse	Monitor growth and CNS activity High abuse potential Not recommended for children <3 y Avoid late evening dosing
Short acting: dexmethylphenidate (Focalin 2.5, 5, 10 mg) 2.5 mg bid; max 20 mg/d dextroamphetamine (Dexedrine 5-, 10-, 15-mg cap) 5 mg/d, titrate 5 mg/d weekly; max 40 mg/d dextroamphetamine/amphetamine (Adderall 5-, 7.5-, 10-, 12.5-, 15-, 20-, 30-mg tab) 5 mg qd to bid; max 40 mg/d methylphenidate; >6 y: 5 mg bid (before breakfast and lunch), titrate 5–10 mg/d weekly; max 60 mg/d methylphenidate (5-, 10-mg tab) Methylin (5-, 10-, 20-mg tab) Ritalin (5-, 10-, 30-mg tab)	Tachycardia, nervousness, insomnia, anorexia, dizziness, drowsiness	Marked anxiety, tension, or agitation Glaucoma History of tics or Tourette syndrome in patient or family	Monitor blood pressure, weight, height, heart rate, tics, sleep habits May potentiate effects of anticoagulants and anticonvulsants Abuse potential Not recommended for children <6 y
Generic (Trade) Name and Dosage	**Selected Adverse Events**	**Contraindications**	**Special Considerations**
Intermediate acting: methylphenidate; max 60 mg/d methylphenidate CR (10-, 20-mg tab) 10 mg qam Metadate ER (20-mg tab) 10 mg qam Methylin ER (10-, 20-mg cap) 10 mg qam Ritalin SR (20-mg tab) 20–60 mg every 8 h			

bid, twice daily; cap, capsule; CBC, comprehensive metabolic panel; CR, controlled release; ER, extended release; hs, at bedtime; max, maximum; qam, every morning; qd, every day; qid, four times a day; tab, tablet; tid, three times a day; y,

year.

Clinical trials have demonstrated a 68% to 97% patient response rate for a stimulant in *either* the amphetamine or methylphenidate subclass and a 12% to 71% response rate for *both* subclasses (Hodgkins et al., 2012).

Mechanism of Action

Pharmacologically, the stimulants inhibit the reuptake of dopamine and norepinephrine, thereby increasing concentrations in the presynaptic cleft. Amphetamines also directly stimulate the release of dopamine and norepinephrine. There are about 13 products currently available in the US market, some of which are immediate-release formulations and some of which are extended-release variations.

Stimulant medications mitigate the traditional ADHD symptoms and have demonstrated utility in improving interpersonal relationships, self-esteem, cognition, as well as symptoms of comorbid anxiety disorders (Minzenberg, 2012). Prescribing stimulant medications to adults has been a clinical controversy in primary care as well as in psychiatry. This class is arguably the most efficacious in resolving symptoms of ADHD and comorbid psychopathology; however, the risk of adverse effects and abuse potential may impact the rates at which these drugs are prescribed in the adult population.

Though none of the medications within the stimulant class have demonstrated superiority over another member of the class, there are some within-class pharmacokinetic differences that may impact product selection. The immediate-release products generally have a faster onset of action (which can be palpable by the patient) and a more abrupt cessation of effect (which can also be observed by the patient). This may be advantageous for patients who only have a discrete period of time during which they require medication action (during the school day, etc.). It can also be problematic for patients who cannot tolerate the abrupt start and stop of drug action.

The intermediate- and long-acting products have a less pronounced (and therefore less abrupt) onset and offset of therapeutic effect. Extended-release products are formulated to release defined amounts of drug over a 24-hour period. Ritalin LA releases 50% of the dose in two bursts, whereas Concerta releases 22% immediately and 78% later, and Metadate CD releases 30% immediately and 70% later. In addition to their more innocuous presentation, the extended-release products also afford patients a convenience factor, only having to dose once or twice daily (as compared to multiple daily doses with some immediate-acting products). Lisdexamfetamine (Vyvanse), in particular, has a 10- to 12-hour duration of action, which necessitates once-daily dosing. In addition to the convenience factor, this drug product is formulated as a prodrug that requires enzymatic degradation in the GI tract to become active. As a result, Vyvanse is far more difficult to misuse.

The risk of abuse or misuse of stimulants is a legitimate concern, which may ultimately

impact treatment. SUDs occur comorbidly with ADHD at an odds ratio of 1.5 to 7.9 (Simon et al., 2015). Utilization of extended-release products minimizes, but does not completely negate, the risk of abuse.

Dosage

It is generally recommended that drug therapy, particularly in adults, should consist of an extended-release product in order to maximize compliance and minimize the risk of abuse. In children, many practitioners may decide to begin with a short-acting product in order to gauge response and tolerability and then switch to a longer-acting product. Initiation of drug therapy, irrespective of the nature of the release of the product, begins at the lowest dose (or the labeled starting dose) and is gradually titrated upward until the benefit is maximized and the patient is without adverse effects.

Time Frame for Response

Most patients taking a therapeutic dose of any stimulant medication will experience an effect on the day of the first dose and certainly within the first few days. If there is no appreciable improvement, then the dose should be increased, provided that it was well tolerated. As the recommended or maximum dose of the selected drug is approached and there is still an absence of effect, then either (1) the medication should be changed or (2) the diagnosis of ADHD should be re-evaluated.

Contraindications

The stimulants are contraindicated in children with certain comorbid disorders. Practitioners should not prescribe methylphenidate to patients with marked anxiety, tension, or agitation; glaucoma; or a history of tics or Tourette syndrome. Stimulants are contraindicated in patients who have existing cardiovascular disease, moderate to severe hypertension, hyperthyroidism, or history of substance abuse. In practice, the presence of a history of substance abuse may be overlooked if the risk of recurrence is determined to be low and the benefit of treatment is determined to be reasonable.

Adverse Events

The most common adverse events related to stimulant therapy tend to be cardiovascular, gastrointestinal, or neurologic in nature. Common, transient adverse effects include sleep disturbance, appetite suppression and associated weight loss, agitation, and nervousness. These are typically minimized by taking the drugs with food and using an extended-release formulation. Serious concerns exist related to the potential cardiotoxicity associated with the stimulants. Patients may experience palpitations, tachycardia, and elevations in blood pressure. Critical cardiovascular adverse effects include rhythm disturbances and cardiomyopathy, which precludes use in patients who have an existing cardiovascular abnormality.

Generally, the cardiovascular adverse effects include palpitations, tachycardia, elevated blood pressure, and potentially but uncommonly arrhythmias. Changes in appetite, nausea, vomiting, and other gastrointestinal (GI) disturbances may occur, particularly at the onset of therapy or upon a dosage increase. The neurologic adverse events range from headache and insomnia to seizure activity, particularly in patients predisposed to seizures.

In general, adverse events are manageable, results are quick and predictable with the first dose, and the medications are easy to titrate. The adverse events of the stimulants, such as headaches, dizziness, appetite suppression, tics, dyskinesias, sleep disturbances, abuse potential, and in particular growth retardation (below height or weight on normal growth charts), may be of concern, though the evidence related to growth suppression is sparse and contradictory. Determining the long-term effect of stimulants on children and adults is challenging. To minimize these effects, it is reasonable for the patient to take drug-free periods, usually over the summer. These periods also allow for reassessment of ADHD. Because children frequently seem to show symptoms in structured settings such as school, weekend "drug holidays" are also reasonable, permitting dosage adjustments and disease assessment. Rebound hyperactivity may be more prominent. No studies have been done to compare the effectiveness of weekend holidays versus summer holidays.

Other data indicate that there is less likelihood of substance abuse later in life when ADHD children take stimulant medication (NSDUH, 2013).

Nonstimulant Medications

Owing to their less impressive efficacy rates as compared to the stimulants, the nonstimulant medications tend to be prescribed less frequently among all age groups. Generally, practitioners do not initiate drug therapy with a nonstimulant unless the patient has a contraindication to stimulants (cardiac abnormalities, previous or current substance abuse) or is intolerant to or has failed the stimulant class. Currently, the nonstimulant therapeutic class includes atomoxetine (Strattera), immediate- and extended-release guanfacine (Tenex and Intuniv, respectively), clonidine and extended-release clonidine (Catapres and Kapvay, respectively), bupropion (Wellbutrin), and the tricyclic antidepressants.

Atomoxetine

Atomoxetine (Strattera) is the first nonstimulant approved by the U.S. Food and Drug Administration (FDA) for treating ADHD. It is not a controlled substance, and existing data suggest no real potential for abuse or diversion. While stimulants have greater treatment effect than atomoxetine, there are fewer adverse effects on appetite and sleep when compared to stimulants. However, there is more nausea and sedation, and it may be considered first-line therapy for ADHD treatment if the patient has an active substance abuse problem, comorbid anxiety, tics, or severe side effects to stimulants.

Atomoxetine's efficacy and safety have been demonstrated in adults and children; however, its associated rates of response are less impressive than those of the stimulants. In most clinical trials and meta-analyses, it has separated from placebo with regard to improving the core symptoms of ADHD; however, the clinical relevance of the improvements is debatable. It remains an appropriate option in patients who have contraindications to stimulants or who have a comorbid anxiety disorder, as anecdotal evidence suggests some level of anxiolytic activity.

Mechanism of Action

Atomoxetine selectively inhibits the reuptake of norepinephrine by inhibiting the presynaptic norepinephrine transporter. This translates into improved function in the PFC.

Dosage

The medication is available in 10-, 18-, 25-, 40-, 60-, 80-, and 100-mg capsules. For adolescents and adults over 70 kg, the starting dose is 40 mg; the dose is increased to an 80-mg target dose after a minimum of 3 days. The maximum recommended dose is 1.8 mg/kg/d for children and 100 mg for adolescents and adults; dosages should be adjusted only after 2 to 4 weeks of treatment at the lower dose. Since this agent undergoes significant metabolism via the CYP2D6 system, in slow metabolizers or patients taking agents with strong CYP2D6 effects (e.g., paroxetine, fluoxetine), the starting dose should be maintained for up to 4 weeks before dose adjustments are made. Patients with significant hepatic impairment should be started on a dose 50% of the usual starting dose.

Time Frame for Response

Atomoxetine is rapidly absorbed from the GI tract, leading to 63% bioavailability in extensive metabolizers and 94% bioavailability in poor metabolizers. The onset of action is quick, and dose adjustments are made in the first week. Despite the short half-life in extensive metabolizers, the duration of activity remains consistent throughout the day.

Contraindications

Atomoxetine should not be taken with MAO inhibitors because it increases synaptic norepinephrine concentrations. Further, due to the risk of angle closure, this agent should not be administered to patients with narrow-angle glaucoma.

Adverse Events

The increase in norepinephrine leads to an increase in blood pressure and heart rate; therefore, atomoxetine should be used cautiously in hypertensive patients or those with underlying cardiovascular disorders. Atomoxetine, like stimulants, should not be administered to patients with uncontrolled hypertension, structural cardiac abnormalities, cardiomyopathy, and abnormalities of the heart rhythm. In adults, there was a 3% rate of urinary retention or hesitation. Other common adverse effects include abdominal pain, vomiting, decreases in appetite, headache, irritability, and dermatitis. Atomoxetine does not appear to promote the development of new tics and therefore may be a good choice for patients who cannot take stimulant medications due to preexisting tics. Boxed warnings regarding rare hepatotoxicity and suicidal ideation in children and adolescents were issued by the FDA in 2005.

Interactions

Atomoxetine is a substrate of the CYP2D6 isoenzyme, and levels of this drug can be increased when CYP2D6 inhibitors are administered.

α-Agonists: Guanfacine and Clonidine

The α-agonists, a decades-old drug class, are traditionally used for the treatment of hypertension. For many years, they have been used off-label, particularly in children, for the adjunctive management of ADHD. Their purpose is largely limited to the treatment of behavioral manifestations, aggression, insomnia, and tics, and not for the core inattentive symptoms of ADHD. Both guanfacine and clonidine now are available in extended-release dosage forms, which are approved for the treatment of ADHD (Intuniv and Kapvay, respectively). Drugs in this therapeutic class are considered inferior to the stimulants with regard to efficacy and tolerability.

Mechanism of Action

Both guanfacine and clonidine act as postsynaptic α2-agonists, which are proposed to regulate subcortical activity in the PFC, the area of the brain responsible for emotions, attention, and behaviors. In some patients, this translates into reduced hyperactivity, impulsivity, and distractibility. Guanfacine demonstrates greater selectivity for the postsynaptic α2a receptor, which may confer improved efficacy and tolerability as compared to clonidine. Guanfacine also has a longer half-life, which is associated with less sedation and dizziness as compared to clonidine.

Dosage

Clonidine is dosed at 0.1 mg at bedtime with a 0.1 mg increase every 7 days until a therapeutic effect is realized (maximum of 0.4 mg daily; ideally dosed twice daily). Guanfacine is dosed at 1 mg daily with a weekly increase of 1 mg until clinical response is achieved (7 mg maximum daily dose). Dose adjustment for guanfacine may be necessary when administered concomitantly with strong CYP3A4 inhibitors or inducers.

Time Frame for Response

Generally, any therapeutic effects would be realized after approximately 4 weeks of treatment, but possibly after several months.

Contraindications

There are no absolute contraindications aside from hypersensitivity to the drug or any other component in the product.

Adverse Events

The adverse effects are generally mild and include fatigue, drowsiness, bradycardia, constipation, dizziness, hypotension, and headache. A gradual upward titration may minimize the emergence of these effects. It is also recommended that a downward taper be

employed when discontinuing these medications as abrupt discontinuation may potentiate a hypertensive crisis. For the aforementioned reasons, it is important to educate the patient and/or caregiver about the importance of adherence.

Interactions

Given the central nervous system depressant action of clonidine and guanfacine, other concomitant CNS depressants should be avoided.

Bupropion

Bupropion has been evaluated in a small number of studies involving children, adolescents, and adults in which its efficacy compared to placebo or to an active stimulant comparator has been established. This is not an approved indication for bupropion in any age group. Bupropion may be a therapeutic alternative in adults who have contraindications or are intolerant to stimulant medications or in patients who have a comorbid depressive illness.

Mechanism of Action

Bupropion is an aminoketone antidepressant, which is commonly used for the treatment of depressive disorders as well as smoking cessation. It inhibits the reuptake of norepinephrine and dopamine (like the stimulants) but does so less intensely via a mechanism that is not fully understood. Bupropion is not associated with dependence, abuse, or misuse, which provides a therapeutic advantage in patients who have substance abuse issues.

Dosage

An appropriate dose for the treatment of ADHD has not been established, as the treatment of ADHD is an off-label use. In practice, the antidepressant dose (150 to 450 mg daily) is generally used, though rarely do patients titrate upward to the maximum dose. Bupropion is available as an immediate-release tablet, sustained-release tablet (SR), and extended-release tablet (XL). The XL tablets are dosed once daily and the SR and immediate-release tablets are both dosed twice daily.

Time Frame for Response

The onset of response is not well documented, but it is considered to be more rapid than the α2-agonists (weeks to months) but less rapid than stimulants (same day or a few days).

Contraindications

Bupropion may lower the seizure threshold in predisposed individuals. Therefore, patients with a known seizure disorder or patients taking a medication that has additive effects on the seizure threshold (benzodiazepines, alcohol) should avoid bupropion. This would also include patients who are abruptly discontinuing alcohol or other drugs. Bupropion's labeling includes a boxed warning regarding the risk of suicidal thinking or behavior that is associated with the antidepressant drugs.

Adverse Effects

Common adverse effects include dry mouth, nausea, insomnia, dizziness, anxiety, dyspepsia, sinusitis, and tremor. Bupropion may increase the risk of seizures, particularly with higher doses and shorter-acting formulations. Consideration should be given to

patients who have a comorbid anxiety disorder, as bupropion has the potential to worsen anxiety.

Interactions

Bupropion is a major substrate and strong inhibitor of CYP2D6, and therefore, concurrent use of strong CYP2D6 substrates, inhibitors, or inducers is discouraged. Secondary to its impacts on metabolism, bupropion should not be used concomitantly with vortioxetine or the tricyclic antidepressants.

Selecting the Most Appropriate Drug

Because of the number of therapeutic options available, this section suggests only a general outline to follow. Nonpharmacologic therapy differs for children and adults and may not always be included in the treatment plan (see Table 43.1). Figure 43.1 outlines the therapeutic plan for a child, adolescent, and adult.

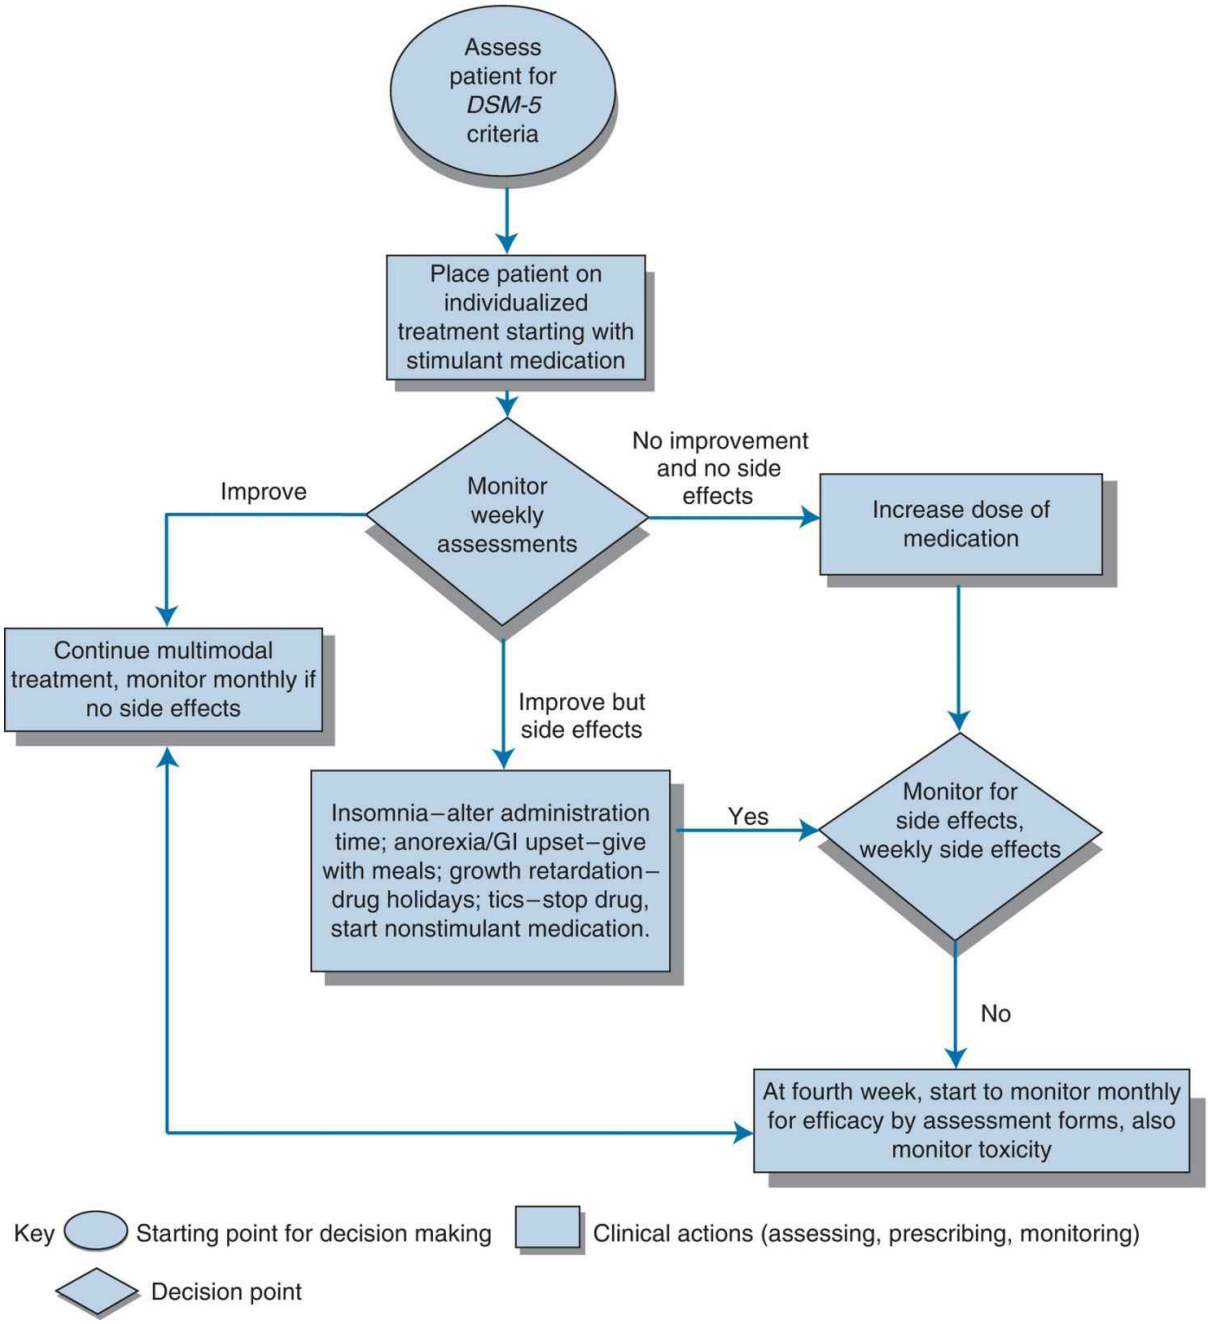

FIGURE 43.1 Treatment algorithm for attention deficit hyperactivity disorder.

Medication therapy is indicated in all patients who fulfill the diagnostic criteria and do not have contraindications to the selected medications.

First-Line Therapy

Stimulant medications are considered first-line therapy in children, adolescents, and adults without contraindications. There is no preference given to methylphenidate-type versus amphetamine-type stimulants, though methylphenidate appears to be favored in young children. There is no established difference in efficacy or tolerability among the members of this class. Product selection tends to be driven by duration of action and individual patient response (efficacy and tolerability). The longer-acting products confer improved convenience, owing to their less complex dosing regimens and possible improved compliance. Lisdexamfetamine (Vyvanse) boasts the longest duration of action and the least abuse potential secondary to its prodrug status, which requires enzymatic activation in the GI tract.

Failure of, or intolerance to, one stimulant does not necessarily mean that the entire therapeutic class is exhausted. In the event that a patient does not realize improvement or is unable to tolerate the initial drug, a different stimulant should be initiated (either from within the subclass of amphetamine-type or methylphenidate-type or from the other subclass).

Second-Line Therapy

Upon clinical failure or intolerance of the stimulants as a therapeutic class, atomoxetine is generally considered second-line therapy. Some practitioners may elect to initiate an α2-agonist at this time; however, guidelines generally recommend atomoxetine first.

Third-Line Therapy

Bupropion or the α2-agonists may be attempted after failure of, or intolerance to, the stimulants and atomoxetine. At this point, these drugs may also be considered as adjunctive therapy to a partially successfully stimulant or atomoxetine. In the past, the tricyclic antidepressants were also considered third- or fourth-line therapy but they are generally no longer used for this purpose.

After failure of several drugs (even if only the stimulants have been attempted), the diagnosis of ADHD should be re-evaluated. The response rates for stimulants exceed 90%, and therefore, a lack of efficacy is suspicious and may suggest an alternate diagnosis.

Monitoring Patient Response

To determine the efficacy of the drugs used to treat ADHD, practitioners must use the rating scales mentioned previously; no laboratory values or diagnostic tests can determine the patient's improvement. Usually, follow-up visits are scheduled monthly after initiation of a medication and until the patients have achieved a response. When the medication regimen is stable and tolerated, the follow-up visits tend to occur at longer intervals but at least every 6 to 12 months.

Treatment is indicated for as long as the patient is showing core symptoms of ADHD. Practitioners can best determine the need to continue treatment by considering the patient's response during the "drug holidays." If symptoms are no longer present, treatment may not be needed. Continued assessment of the patient even when he or she is not using medication is essential. Medication should be given at the lowest effective dosage.

Studies show that stimulants' general side effects of insomnia, decreased appetite, dizziness, stomachache, and headache are usually mild and do not necessitate discontinuation of the drug. Sleep difficulties may actually be related to the ADHD, which causes symptoms that prevent the child from sleeping. Because sleep disturbances cannot be generalized, it is reasonable to assess the patient and determine whether altered bedtimes or altered medication times are appropriate interventions.

In reviewing the complication of tics and dyskinesias, one study determined that transient tics develop in approximately 9% of children. The development of tics does not depend on prior personal or family history. Even though this study showed that tics or dyskinesias are not a contraindication, most health care professionals use stimulants cautiously in patients with prior histories.

Most of the other adverse events were discussed earlier. If any adverse event occurs that is disturbing to the patient, reasonable alternatives are to lower the dose or discontinue the medication. If the patient is using a stimulant and the outcome is poor, substituting another stimulant is reasonable before trying another medication class.

Patient Education

Medications prescribed for ADHD must be taken exactly as prescribed to get the full benefit. If any adverse events occur that are disturbing, the patient should contact the health care provider immediately. Parents and adult patients should be aware of adverse events to watch for, as previously discussed. Patients need to be evaluated on a regular basis to determine their treatment needs.

Drug Information

The FDA's Web site (www.fda.gov) is a good source of initial prescribing information. Sources such as Facts and Comparisons can also provide information about the use of these agents.

Patient-Oriented Information Sources

The National Institute of Mental Health (NIMH) has an excellent Web site related to ADHD (http://www.nimh.nih.gov/health/topics/attention-deficit-hyperactivity-disorder-adhd/index.shtml). This site provides access to booklets describing strategies for dealing with ADHD directed at parents of young children as well as adolescents. There are also links to local providers, clinical research trials, and other resources. CHADD (Children and Adults with Attention Deficit Disorder) at www.chadd.org is a great source of information and support for parents and patients with ADHD.

Nutrition/Lifestyle Changes

Dietary additives and supplements, such as dyes and preservatives, have long been implicated as a cause of ADHD symptoms. Literature is equivocal regarding whether or not removal of these from the diet in certain children is helpful. At this time, there is no recommendation to limit or exclude dyes from the diet.

Parent training involves teaching parents to recognize situations in which their child could learn or improve social skills. Parents must actively participate in the child's social life, using punishment effectively by clear instruction, positively reinforcing good behavior, ignoring some behaviors, and using negative reinforcement, such as time out, to decrease the child's stimulation. This method has been shown useful for the short term and is an alternative for parents who do not want to proceed directly to medication therapy.

As mentioned previously, the parents also may have ADHD. Family therapy can help teach all members how to negotiate and solve problems together as a unit. Because family therapy may be expensive, parent support groups can promote effective problem-solving techniques and unity.

Social skills training is based on the patient's deficits. Studies show that group training is more effective than individual training because self-observation usually is impossible for this patient population—both children and adults. Academic skills training helps to refine a child's ability to organize, take notes, improve study habits, and prioritize activities. This methodology has not been tested, but in clinical practice, it has been found useful if academic deficiencies are present. Adult patients may also benefit from reappraising their own social, academic, and occupational skill sets. Developing and adhering to a schedule, making commitments to observe deadlines, and accepting consequences when tasks or responsibilities are not successfully completed or maintained will assist in reinforcing good behaviors and minimizing bad behaviors. Adult patients may delay diagnosis by developing compensatory mechanisms and/or relying on others, actively avoiding compensatory mechanisms and not utilizing friends, family, or coworkers as a pathologic support system may also provide a therapeutic benefit.

Psychotherapy is not useful as treatment of ADHD but can help patients with moralization, self-esteem, and compliance problems. It may also be useful for patients with comorbid illnesses such as anxiety and depression. Psychotherapy may be needed only as difficulties arise.

Cognitive behavior modification teaches stepwise problem solving and self-monitoring by using the reinforcement techniques of rewarding for good behavior and removing rewards for unwanted behavior. Although initially believed to be a good strategy, cognitive behavior modification was later found not to improve outcomes when added to medication therapy.

All these techniques offer different benefits, so individual assessment and reassessment

are important to determine which techniques (if any) are making a difference for the patient. Some parents may want to try one or more of these methods before trying medication, and practitioners should permit the parents to try whatever methods they feel will be best for their child.

As with children, nonpharmacologic treatment also is beneficial for adults. "Coaching" involves daily encouragement to progress toward set goals. Educational programs help adults to identify their problem, understand it, and not blame themselves for it. Cognitive remediation also is used to teach attention enhancement, memory, problem solving, family relationships, time management, organization skills, and anger control. Medication should not be used as a substitute for treating behaviors with behavior modification. Each patient's therapeutic plan should be assessed and reassessed for success and usefulness.

Complementary and Alternative Medications

There are several herbal medications that may have an impact on a person with ADHD. Ginkgo biloba, a plant-derived medication, has shown some efficacy in improving memory and improving concentration when added to stimulant therapy in children and adolescents (Shakibaei et al., 2015). Supplementation with polyunsaturated acids has also been evaluated as a possible natural adjunctive therapy, but its efficacy has yet to be established.

Case Study*

S.B., age 8, is always interrupting his teacher, jumping out of his seat in class, fidgeting relentlessly, and butting into other children's games. At home, he runs around recklessly and is uncontrollable. His mother comes to you and wonders why he will not listen. She is concerned because his grades at school are worsening and he has had disciplinary issues with his teachers. After medical evaluation, you find nothing wrong with S.B. physically, and he is taking no other medications. Through questioning, you determine that he has trouble concentrating on his homework, often forgets he has homework, does not complete assignments when he remembers them, loses pieces of games frequently, and hates to sit and read. His mother is unsure of the time frame over which these behaviors developed, but she thinks it has been since her second child was born 4 years ago. While in your office, S.B. did not seem to be hyperactive or inattentive, but you notice he is easily distracted by people passing in the hallway because the door is slightly ajar.

Diagnosis: ADHD

1. List specific goals of treatment for S.B.
2. What would be the first-line drug therapy for S.B.? Why?
3. What monitoring parameters would you institute? S.B. parents and teachers should be aware of changes in sleep, appetite, and mood (monitoring for adverse effects) as well as improvements in organization, memory, and follow-through (monitoring for efficacy).
4. Discuss specific patient education you would provide to S.B. parents based on the prescribed therapy.
5. Describe one or two drug–drug or drug–food interactions that you would be wary of when prescribing this agent.
6. List one or two adverse reactions to the agent you selected that would cause you to change therapy.
7. If the adverse reactions you described above occurred, what would be your second-line therapy for S.B.? Why?
8. What over-the-counter and/or alternative medications would be appropriate for S.B.?
9. What dietary and lifestyle changes would you recommend to S.B. parents?

44 Alzheimer Disease

Karleen Melody Anisha B. Grover

Alzheimer disease (AD), also known as neurocognitive disorder due to Alzheimer disease, is the most common cause of dementia accounting for approximately 60% to 80% of all dementias. AD is characterized by a slow, progressive decline in cognition. Patients initially complain of short-term (recent) memory loss, forgetfulness, and a decreased ability to learn and retain new information.

Estimates suggest that approximately 5.5 million people in the United States and 35 million people worldwide have AD (Quefurth & LaFerla, 2010). The number is expected to grow to 13.2 to 16 million in the United States by 2050 as the population continues to age (Quefurth & LaFerla, 2010). A majority of individuals with AD are residing in the community, which represents a huge emotional and financial burden on the patient, friends, and family members, as well as on society as a whole. The cost of care is estimated at approximately $260 billion each year in the United States. This number does not include the cost of unpaid care given by family members or loved ones.

Early-onset AD occurs in patients younger than 65 years of age and is less common, whereas late-onset AD is more common and occurs in patients age 65 or older. Familial AD is also a less common form of AD and affects patients with genetic mutations of amyloid precursor protein (APP), presenilin-1, and presenilin-2. Familial AD may be of early or late onset (Lendon et al., 1997). Genetic causes (e.g., apolipoprotein E4 allele, presenilin-1, and presenilin-2 gene mutations) have also been linked to late-onset AD. Symptoms of AD can be divided between cognitive symptoms and noncognitive symptoms, and treatment is based on the particular domain of the symptoms. Cognitive symptoms, such as loss of short-term memory, usually present first in mild AD, whereas the noncognitive behavioral symptoms are seen in more moderate-to-severe AD. Currently, AD is incurable although pharmacologic agents have been used to modestly slow the progression of the disease. The average life span for patients with AD is reduced by as much as 70% with a mean duration of approximately 10 years from the time of diagnosis (Kua et al., 2014). In the United States, AD is the sixth leading cause of death. Women are at a slightly higher risk for developing AD than men. Prevalence increases with age, with AD affecting approximately 40% to 50% of those older than age 85. Patients with AD commonly die from causes such as cardiovascular disease, pneumonia, cancer, and diabetes (Kua et al., 2014).

Causes

Apolipoprotein E (ApoE), a protein involved in cholesterol transport, is linked to the development of AD. The E4 allele (homozygote E4/E4) is thought to increase the risk of AD, whereas the E2 allele may be protective. Advanced age and family history are the most significant risk factors for AD, and other risk factors are listed in Box 44.1.

BOX 44.1 Risk Factors and Protective Factors for Alzheimer Disease

Risk Factors
Advanced age
Apolipoprotein E (APOE) e4 gene
Family history (e.g., genetic abnormalities)
Mild cognitive impairment
Cardiovascular disease
Low education
Traumatic brain injury
Lack of social and cognitive engagement

Data from http://www.alz.org/facts/downloads/facts_figures_2015.pdf

Pathophysiology

Pathologic changes in AD include formation of neurofibrillary tangles and plaques, cortical atrophy, and neuronal (cholinergic, glutamatergic) destruction and loss. In AD patients, acetylcholine levels are decreased, and an excessive stimulation of glutamate causes neuronal toxicity. These changes affect several areas of the brain, including the hippocampus, the amygdala, the cerebral cortex, and, ultimately, the motor cortex. As a result of these changes, short- and long-term memory, learning, language, behavior, and, eventually, motor skills are impaired.

Neurofibrillary Tangles

Neurofibrillary tangles and neuritic or β-amyloid plaques are the hallmark pathologic lesions in AD. Tau protein, the principal component of neurofibrillary tangles, becomes hyperphosphorylated in AD. The abnormal phosphorylation of tau protein leads to the formation of paired helical filaments and finally neurofibrillary tangles. As a result, microtubule assembly is inhibited and critical organelles may collapse, causing abnormal intracellular transport and neuronal cell death.

Plaques

Plaques are brain lesions that contain a core of β-amyloid protein (BAP) and a shell of damaged neurites. APP is the parent protein of BAP. Proteases normally cleave APP through the BAP region, which prevents intact BAP from entering the extracellular fluid. When abnormal proteolysis occurs, leaving BAP intact, increased extracellular BAP becomes involved in plaque formation and neuronal degeneration. Plaques are also composed of neurofibrillary tangles, ApoE, and glial cells, which may be involved in the pathologic process of AD and are areas of interest to researchers. Neurofibrillary tangles and plaque density correlate with increased severity of AD.

Neuronal Destruction

The neuronal cell damage and death seen in AD result in impaired neurotransmitter function. The cholinergic and glutamatergic systems are significantly involved. Destruction of cholinergic neurons leads to decreased levels of acetylcholine, a neurotransmitter that aids in learning and memory. The symptomatic presentation of AD (memory loss and cognitive impairment) appears to be associated with acetylcholine deficiency. The cholinergic system has been the subject of a vast amount of research and pharmacologic development (e.g., acetylcholinesterase inhibitors). Overstimulation or erratic stimulation of the glutamatergic system in the synapse causes neuronal toxicity leading to neuronal death. This disruption is thought to impair learning and memory.

The autoimmune system or inflammatory mediators may be linked to late-onset AD. Glial cells, complement cascade components, and cytokines are present in plaque areas. These cells and inflammatory mediators may contribute to neuronal cell damage and loss. Their role in AD is under investigation, as is the use of intravenous immunoglobulins for the treatment of AD.

Diagnostic Criteria

The clinical diagnosis of AD can be made using the *Diagnostic and Statistical Manual of Mental Disorders* (5th ed.), known as the *DSM-5*. The diagnosis can be *confirmed* only by autopsy. Diagnostic criteria include concern for loss of memory by the patient, caregiver, or provider; insidious onset; performance below normal on standardized cognition assessments; deficits in one or more cognitive domains; and the absence of other diseases that may account for the symptoms of AD.

Patients and their caregivers should be closely involved in the diagnostic process. A complete history and physical examination that includes a neurologic and mental status evaluation is essential. The Mini Mental State Examination (MMSE) or the Montreal Cognitive Assessment (MOCA) may be used to screen for cognitive impairment. The clock drawing task (CDT) is another initial evaluation tool that is quick and can be performed by any health care professional (Figure 44.1).

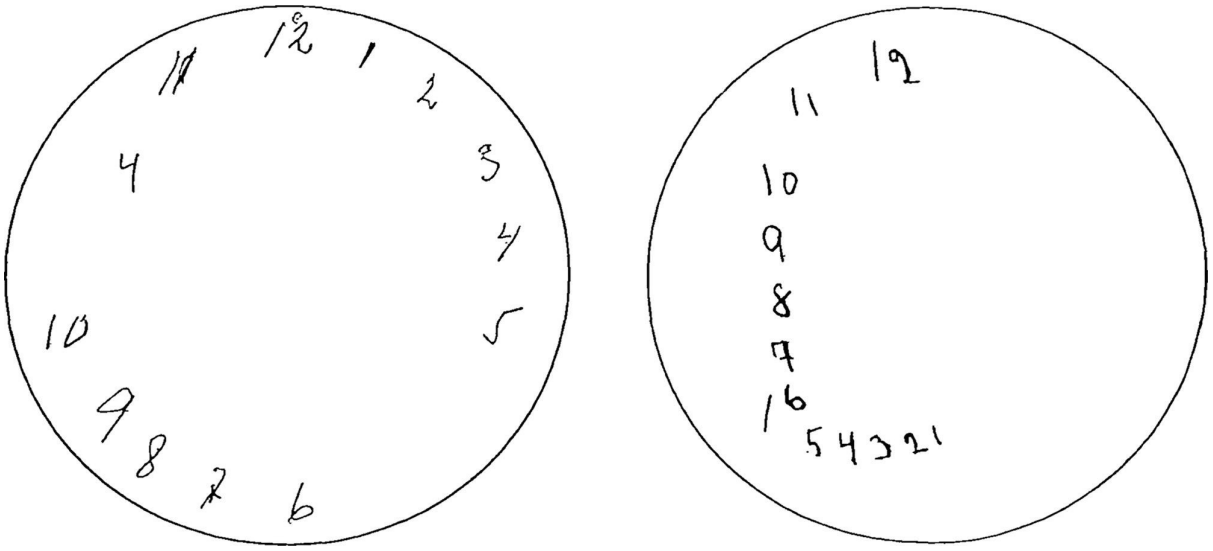

FIGURE 44.1 Clock drawing task completed by various elderly subjects. (Reproduced from Agrell, B., & Dehlin, O. (1998). The clock-drawing test. *Age and Ageing*, 27, 399–403; by permission of Oxford University Press.)

Initiating Drug Therapy

A careful assessment of baseline diagnostic findings is essential before initiating drug therapy. The patient, family, and caregiver should be informed of the severity of cognitive and functional impairment. Baseline scores on cognitive testing and functional status can help guide decisions related to drug therapy. Reversible causes of dementia must also be considered and eliminated because several medications and medical conditions may cause or aggravate dementia (Box 44.2).

BOX 44.2 Potentially Reversible Causes of Dementia

Medications
Anticholinergics (e.g., benztropine, diphenhydramine)
Antipsychotics (e.g., olanzapine, thioridazine)
Benzodiazepines (e.g., diazepam, lorazepam)
Histamine (H_2) blockers (e.g., cimetidine)

Metabolic Disorders
Dehydration
Hyperthyroidism and hypothyroidism
Hyponatremia
Hypercalcemia

Intracranial Infection or Disease
Meningitis
Neurosyphilis
Normal pressure hydrocephalus
Subdural hematoma
Tumor
Toxoplasmosis

Miscellaneous
Toxins (e.g., lead, mercury, alcohol)
Vitamin B_{12} deficiency
Depression
Psychoses

Data from Wiser, T. H. (1994). Alzheimer's disease. *US Pharmacist*, 63 and AGS 2012 Beers Criteria.

Before starting drug therapy for the cognitive symptoms of AD, the patient or family

should demonstrate a clear understanding of the efficacy and expected outcomes of treatment, as well as the potential adverse events, costs, and incurability of the disease. The choice not to initiate drug therapy is also a reasonable option as many patients only experience modest benefits from drug therapy and incur side effects and expenses from the medications.

Pharmacologic management of the noncognitive symptoms is tailored to the individual symptom. These medications are usually initiated when the patient progresses to the moderate-to-severe stages of AD. The use of both noncognitive and cognitive therapies may be necessary as the disease progresses.

Nonpharmacologic psychotherapies, such as behavior-oriented, emotion-oriented, cognition-oriented, and stimulation-oriented approaches, can be useful for some patients with AD. Other nonpharmacologic interventions include using calendars, clocks, and written notes or instructions. The caregiver should attempt to maintain a predictable routine with the patient. Drastic changes in the environment, as well as confrontation and arguments, should be avoided. Recognition of precipitants of agitation, psychosis, and anxiety can assist the caregiver and health care provider to best develop a patient-specific treatment plan.

The patient's ability to drive should be evaluated, and as AD progresses, the patient should be advised to stop driving because dementia may increase the risk of accidents. The patient's use of a stove should be evaluated because, if left on and unattended, it can be harmful. Families should be taught how to prevent falls and wandering. They should also be informed about the possibility of physical violence and caregiver stress associated with more severe disease. Capable patients may want to discuss with their families advance directives, living wills, desires for nursing home placement, and powers of attorney.

Patient and family education are the most important nonpharmacologic interventions for AD. Depending on the stage of impairment, the patient requires some or full assistance with activities of daily living (ADL), such as dressing, toileting, and, particularly, driving. Support for patients and families is vitally important at any stage of AD (Box 44.3), and anyone involved with a patient with AD should be educated on the availability of support groups to deal with the wide variety of issues associated with AD. Other resources for the caregiver include the use of respite care centers and day care centers.

Goals of Drug Therapy

The optimal goal of drug therapy is to maintain and maximize the patient's functional ability, quality of life, and independence for as long as possible while minimizing adverse events and cost (APA, 2014). A multidisciplinary approach to therapy, which includes the patient and family, a prescriber, a psychiatric or neurologic specialist, a nurse, a social worker, and a pharmacist, is the ideal. Drug therapy choices for the cognitive symptoms primarily include the cholinesterase inhibitors and memantine.

Selected Agents for Cognitive Symptoms

Cholinesterase Inhibitors

Cholinesterase inhibitors, also known as the *acetylcholinesterase inhibitors*, play a key role in the pharmacologic treatment of AD. This drug class includes donepezil (Aricept), rivastigmine (Exelon), and galantamine (Razadyne, Razadyne ER). These agents are used to slow the progression of the cognitive, functional, and behavioral domains of AD.

If no effect is seen within 3 to 6 months of treatment or the patient is experiencing an adverse effect, another agent from this class may be tried. These medications are not curative and it is unknown how long treatment with these agents should be continued. However, once a patient progresses to severe AD, these agents are no longer solely recommended or may be discontinued due to lack of benefit. Additional pharmacologic therapy may be necessary once the disease progresses into the moderate-to-severe stages. Thoughtful discussions with caregivers or families may guide the decision to discontinue therapy.

Cholinesterase inhibitors inhibit one or both types of the cholinesterase enzymes, butyrylcholinesterase or acetylcholinesterase. Butyrylcholinesterase is primarily found in the periphery, and inhibition of this enzyme leads to many of the adverse effects of the cholinesterase agents. Acetylcholinesterase is found more centrally and thus is the primary focus of inhibition for the use in AD.

Rivastigmine is a cholinesterase inhibitor with its potential advantage of being pseudoirreversible. It inhibits the enzyme for about 10 hours, making this an intermediate-acting agent. It is notable that rivastigmine is the only cholinesterase inhibitor that is approved to treat both mild-to-moderate AD as well as mild-to-moderate dementia associated with Parkinson disease. Galantamine is a cholinesterase inhibitor on the market and is indicated to treat mild-to-moderate AD. Besides inhibiting the cholinesterase enzyme, it also allosterically modulates the nicotinic receptor.

The cholinesterase inhibitors have been shown to slow the progression of AD. These medications have also had positive effects on the noncognitive or behavioral symptoms of AD. They have been shown to reduce apathy, psychosis, anxiety, depression, and agitation. Although these medications appear to improve the cognitive function of patients with AD, there is no evidence that they alter the course of the disease.

Dosage

The cholinesterase inhibitors may modestly improve cognitive function or delay decline in cognitive function. The observed delay in cognitive decline correlates with approximately a 6-month decline in patients treated with placebos. Clinical studies of these agents versus a placebo show that maximum efficacy by the maximum dose. Thus, it is recommended to titrate the cholinesterase inhibitor to the maximum tolerated dose.

Donepezil therapy is initiated at a dose of 5 mg daily. The dosage may be increased after 4 to 6 weeks to a maximum dose of 10 mg/d if tolerated. Donepezil 10 mg/d is slightly more effective than the 5-mg dose; therefore, increasing to 10 mg/d is appropriate for patients who do not respond within 6 weeks of treatment with the 5-mg dose. A 23-mg dose may be tried in moderate-to-severe patients that have been stable on 10 mg daily for at least 3 months. Donepezil is available as a tablet as well as an orally disintegrating tablet for patients who have trouble swallowing. Rivastigmine doses should be started at 1.5 mg twice a day and should increase to 3 mg twice a day after 2 weeks of treatment for the capsule and oral solution formulations. Further dose increases should be based on clinical response and can be attempted on a biweekly basis. The maximum dose is 6 mg twice a day for the capsule and oral solution formulations. If the patch formulation of rivastigmine is started, the dose should be 4.6 mg/24 hours and can be titrated to 9.5 mg/24 hours after 4 weeks and then to 13.3 mg/24 hours after another 4-week period, if tolerated. Galantamine is available as an immediate-release tablet and oral solution as well as in extended-release capsules. The immediate-release forms of galantamine are started at a dose of 4 mg twice a day and titrated up every 4 weeks as tolerated to a maximum dose of 24 mg/d (12 mg twice daily). The extended-release formulation of galantamine is started at 8 mg daily and can be titrated up to a dose of 24 mg/d in 4-week intervals.

Time Frame for Response

Cholinesterase inhibitors may slow the progression of AD, but the effects may not be immediately noticeable. Patients and families may report improvement—or lack of continued decline—within 3 to 6 weeks of beginning treatment. Response may also be seen in repeated cognitive assessment measures done in 3- to 6-month intervals.

Contraindications

Contraindications to using a CI include hypersensitivities to any of the compounds. Precautions to using the CIs include anorexia, neuroleptic malignant syndrome, bradycardia, peptic ulcer disease, conduction abnormalities, asthma or chronic obstructive pulmonary disease, and seizure disorder. Patients weighing less than 55 kg may also experience more profound GI side effects such as nausea and vomiting.

Adverse Events

The major adverse effects of the cholinesterase inhibitors are cholinergic, most commonly nausea, vomiting, and diarrhea (5% to 47%). Oral formulations of rivastigmine have been associated with the highest incidence of these gastrointestinal (GI) disturbances (19% to 47%); the patch is associated with much lower rates (6% to 20%). These effects are dose dependent and can be minimized by slowly titrating to higher doses (Table 44.1).

TABLE 44.1 Overview of Cholinesterase Inhibitors and Memantine

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
donepezil (Aricept) Start: 5 mg every day Range: 5–23 mg/d Start 5 mg every day × 4 wk, then 10 mg daily. If stable for 3 mo, may increase to 23 mg/d	*GI:* nausea, vomiting *CV:* bradycardia, syncope	Hypersensitivity to agent or piperidine derivatives	If nightmares occur, dose in the morning
rivastigmine (Exelon) Oral: Start 1.5 mg bid for 2 wk, then increase by 1.5 mg bid; max. 6 mg bid Range: 3–6 mg bid Patch: Start one patch (4.6 mg/24 h) daily × 4 wk, then increase to one patch (9.5 mg/24 h) daily × 4 wk, then increase to one patch (13.3 mg/24 h)	Nausea, vomiting, anorexia, dyspepsia, fatigue, headache, malaise	Hypersensitivity to agent or carbamate derivatives	Initial response seen within 12 wk of therapy Patches are removed and replaced every 24 h
galantamine (Razadyne, Razadyne ER) IR: Start 4 mg PO bid × 4 wk Range: 4–12 mg PO bid ER: Start 8 mg daily × 4 wk Range: 8–24 mg	Nausea, vomiting, diarrhea, anorexia, abdominal pain, dyspepsia, dizziness, sleep disturbances	Hypersensitivity to agent Severe hepatic, renal impairment	Moderate hepatic, renal impairment should not exceed a dose of 16 mg/d
memantine (Namenda, Namenda XR) IR: Start 5 mg PO daily, increase by 5 mg daily every week to a target of 20 mg PO daily XR: Start 7 mg PO daily; increase dose 7 mg each week to a maximum dose of 28 mg PO daily	Dizziness, confusion, headache, anxiety, hypertension, diarrhea	Hypersensitivity to agent	XR capsules may be opened up and sprinkled on applesauce

ER, extended release; INR, international normalized ratio; IR, immediate release; XR, extended release.

Bradycardia can occur with the use of the cholinesterase inhibitors, and they should be used with caution in patients with sick sinus syndrome. Hyperacidity can also occur with cholinesterase inhibitors, and they should be used with caution in patients with a history of peptic ulcer disease and who currently take nonsteroidal anti-inflammatory drugs (NSAIDs). Cholinesterase inhibitors should also be used cautiously in patients with a history of or current seizure disorder. Although these effects are not common, they are of concern and should be closely monitored in patients who are at risk. Donepezil is also associated with insomnia or nightmares. If these conditions occur, the dosing of donepezil before bed should be changed to a morning administration. Despite the GI effects associated with a rapid increase in dose, these agents appear to be well tolerated.

Interactions

Drug interactions with cholinesterase inhibitors include synergy with other cholinergic agents (e.g., succinylcholine). Concomitant use of any anticholinergic agents (e.g., diphenhydramine) may negate the effects of the CI and should be avoided for optimal medication benefit. Donepezil and galantamine are metabolized by the P450 enzyme system. Donepezil and galantamine are substrates for 2D6 and 3A4. A potential advantage of rivastigmine is that it is metabolized by hydrolysis and thus is not susceptible to the drug interactions associated with the P450 enzyme system. Inhibitors of these isoenzymes would cause an increased drug concentration of the cholinesterase inhibitor and thus more susceptible to cholinergic adverse effects.

Memantine (Namenda)

Memantine is an *N*-methyl-D-aspartate (NMDA) receptor antagonist. This drug was approved for the treatment of moderate-to-severe AD. It has a novel mechanism of action, which focuses on the glutamatergic system as compared to the cholinesterase inhibitors' effect on the cholinergic system. Memantine blocks the activation of the NMDA receptor during an abundance of glutamate. Thus, this blocks overstimulation of the NMDA receptor, and neuronal degeneration is inhibited. It does not interfere with the pathologic activation of the NMDA receptor during learning and memory formation.

Clinical trials have shown that memantine used alone in patients with moderate-to-severe AD has produced reduced clinical deterioration over 28 weeks. When memantine was added to donepezil therapy, it resulted in significantly better cognition and ADL compared to a placebo over 24 weeks. The immediate-release form of memantine should be started at 5 mg once daily and titrated every week, if tolerated, to a maximum dose of 10 mg twice daily. The extended-release product is started at a dose of 7 mg daily and increased by 7 mg each week to a maximum dose of 28 mg daily. Food has no effect on the onset or absorption of memantine. In general, memantine was well tolerated compared to a placebo. Memantine is minimally metabolized by the P450 enzyme system and thus not susceptible to P450 enzyme interactions. It is largely excreted renally via tubular secretion and, thus, there is the potential for decreased renal clearance with other drugs that undergo tubular secretion (e.g., amantadine, ranitidine).

Overall, clinical trials have been positive regarding the use of memantine for moderate-to-severe AD. With a different mechanism of action and indication for moderate-to-severe AD, memantine has a unique role for treatment of AD. In the past, once a cholinesterase inhibitor failed, no other viable option for therapy was available. Now, the addition of memantine to a cholinesterase inhibitor may be an option.

Selected Agents for Noncognitive Symptoms

Antipsychotic Agents

The noncognitive symptoms of AD include agitation, psychosis, anxiety, depression, and sleep disorders. Approximately one half of patients with dementia experience agitation. Many patients with AD also experience psychotic symptoms, such as delusions, hallucinations, and paranoia. Agitation and psychosis, which may be particularly frightening for families and caregivers, should be treated if the patient is causing harm to self or others.

The choice of an antipsychotic agent is based on cost and adverse events. Choosing an agent with a low degree of anticholinergic activity seems warranted in patients with AD. Atypical antipsychotics are associated with less extrapyramidal symptoms than the typical agents; thus, these agents are preferred.

Although atypical antipsychotics are preferred, none of the agents are approved to treat the noncognitive symptoms of dementia, and they all contain a black box warning alerting patients and caregivers to the fact that they are associated with an increased risk of death in patients with dementia-related psychosis. Risperidone (Risperdal) and olanzapine (Zyprexa) have also been associated with an increased risk of stroke in patients using these agents for behavioral disturbances associated with dementia. It is important for the practitioner to weigh the risks versus benefits of using these agents. Regardless of the agent chosen, the lowest effective dose should be used. The practitioner should reassess the need for these medications periodically (every 3 to 6 months).

Benzodiazepines

Benzodiazepines have been prescribed to treat behavioral problems related to dementia. Because they do not appear to be as effective as the antipsychotics for treating behavioral problems, benzodiazepines are often reserved for treating symptoms of anxiety or for episodic agitation. These agents can be used as needed in situations that precipitate acute anxiety.

If a benzodiazepine is prescribed, lorazepam (Ativan) or alprazolam (Xanax) are appropriate choices. They are inexpensive and have a short half-life, and hepatic metabolism is not significantly altered in the elderly. All benzodiazepines should be started at the lowest dose. The advantage of lorazepam is that it is available parenterally.

Adverse effects of benzodiazepines include falls, sedation, delirium, and loss of inhibition. Routine use is not recommended because of limited efficacy, adverse effects, and potential for worsening AD symptoms. The use of benzodiazepines for anxiety associated with dementia should be re-evaluated periodically.

Data on using various other agents (trazodone [Desyrel], valproate [Depakene],

carbamazepine [Tegretol], buspirone [BuSpar], SSRIs, and beta-blockers) for treating anxiety associated with AD are limited. These agents may have a role in treating agitation in patients who do not tolerate or respond to antipsychotic agents or benzodiazepines.

Antidepressants

Because there is a high incidence of depression associated with dementia, pharmacologic treatment is often necessary. Patients may not meet explicit criteria for a depressive syndrome, but it is recommended that these patients still be offered treatment. Treatment may improve cognition, mood, apathy, function, behavior, appetite, sleep, and overall quality of life. Because there is no evidence that one class of antidepressants is superior to another in treating depression, the prescriber may base the choice of an agent on the individual patient, cost, side effect profile, and potential drug interactions.

In many clinical practices, SSRIs, such as sertraline or citalopram, have become a first-line therapy for clinically significant depression in the elderly with AD (APA, 2014). Patients who experience anxiety or insomnia with this agent can be given a trial of paroxetine, which is more sedating. Citalopram, in addition to its antidepressant effects, has proved beneficial in improving certain emotional symptoms of AD (panic, bluntness, depressed mood, confusion, irritability, anxiety, and restlessness) in patients with and without depression. SSRIs in general have fewer side effects (particularly anticholinergic) than TCAs or MAO inhibitors and are better tolerated.

Selecting the Most Appropriate Agent for Cognitive Symptoms

First-Line Therapy

Once the decision has been made to initiate drug therapy, cholinesterase inhibitors may be tried. Donepezil is often considered the first choice because fewer adverse events are associated with its use and the once-daily dosing schedule is easier to follow. However, any CI dosed once per day may be tried as a first-line option. These medications may be expensive and only modestly benefit cognitive function. Patients with severe AD may be offered memantine in conjunction with a cholinesterase inhibitor (Table 44.2). The combination therapy is expensive and could only provide moderate benefit.

TABLE 44.2 Recommended Order of Treatment of the Cognitive Symptoms Associated with Alzheimer Disease

Order	Agents	Comments
First line	Cholinesterase inhibitors (CIs)	Once daily CIs will be most likely first-line agents for mild-to-moderate AD
	Memantine	Memantine is reserved for patients with moderate-to-severe AD; may be used in conjunction with a CI
Second line	CIs	A trial of second CI may be warranted
	Vitamin E	Use of vitamin E may be added to the CI or used as monotherapy in patients who cannot afford CIs

Second-Line Therapy

Second-line therapy is a trial of a different cholinesterase inhibitor. In conjunction, some providers may add vitamin E. Vitamin E has a benign side effect profile and minimal cost and may be added to acetylcholinesterase inhibitor regimens in patients with mild-to-

moderate AD.

Monitoring Patient Response

Primary care appointments involving both patients with AD and families every 3 to 6 months may be used to monitor cognitive and behavioral symptoms and to assess the patient's response to pharmacotherapy. If clinical improvement does not occur with a cholinesterase inhibitor after 3 to 6 months of treatment, the practitioner may consider switching to another cholinesterase inhibitor. The MMSE or MOCA are useful objective measures of cognitive response to therapy, but input from family and caregivers must also be recognized. Discontinuing the medication may be considered at any time during therapy if there is a perceived lack of efficacy. If a marked decline in cognitive function is noted within the first 3 to 6 weeks after discontinuing drug therapy, the practitioner may consider restarting the acetylcholinesterase inhibitor. When patients progress to severe impairment, addition of memantine may be an option.

Ability to perform ADLs, such as bathing, dressing, toileting, and feeding, and instrumental ADLs, such as transferring, housekeeping, shopping, and paying bills, should be assessed to help determine the functional status of the patient and response to treatment. Assessment of the noncognitive symptoms of AD could be a sign of disease progression.

In patients receiving antipsychotic medications, response is usually seen within the first day of therapy. If patients continue to have delusions, hallucinations, or agitation, doses can be gradually increased at 4- to 7-day interval. In contrast, response to antidepressant medications is seen within 4 to 6 weeks. Evidence of suicidal ideation should be taken seriously and immediately addressed by the practitioner.

Treatment with any of these agents may be continued until the risk of pharmacotherapy outweighs the benefit to the patient or family. Clear communication with the patient, family, and caregivers cannot be overemphasized because evaluation of pharmacotherapeutic efficacy and decisions to stop or continue treatment depend on this input.

Patient Education

Regardless of the agents chosen for AD treatment, patients, families, and caregivers must have realistic goals of drug therapy. Their goals should include increasing length of time of self-sufficiency, delaying the need for nursing home placement, and reducing the burden on the caregiver. It is important that the family and patients understand the available agents are expected to slow the disease progression. They need to understand that no currently available agents are curative and only modest improvements can be expected.

Donepezil may be taken with or without food, and patients taking donepezil should be instructed that if insomnia or nightmares occur, the drug may be given in the morning. Rivastigmine should be taken with food to have a slow dose titration to minimize the GI side effects. Galantamine can be taken without regard to food and should be slowly titrated to minimize adverse effects. Memantine appears to be well tolerated. Because vitamin E may predispose certain patients (e.g., those with vitamin K deficiency) to bleeding, patients and families should be informed to report unusual bruising, blood in urine or stool, bleeding gums, and the like immediately to their health care provider.

Patient-Oriented Information Sources

The various support resources available for patients and families of patients with AD are shown in Box 44.3.

Complementary and Alternative Medications

Vitamin E

Vitamin E, an antioxidant, may be useful in AD treatment. Due to its antioxidant effects, vitamin E can stabilize free radicals and the damage they produce. Patients with moderate AD started on vitamin E may expect approximately a 7-month delay in reaching a poor functional outcome or end point (i.e., death, institutionalization, loss of the ability to perform basic ADLs, or severe dementia; Sano et al., 1997). This difference is seen within 2 years of initiating treatment. Indefinite treatment with vitamin E is a reasonable approach.

Vitamin E may be effective because of its antioxidant effects. A starting dose of 1,000 international units given orally twice a day appears to be appropriate because this was the regimen used in the trial supporting its efficacy (Sano et al., 1997). Vitamin E, because of its benign side effect profile, minimal cost, and lack of significant drug interactions, has become a good choice for treating AD.

Minimal adverse effects are associated with vitamin E. Because vitamin E may worsen coagulation problems (causing bleeding) in patients with vitamin K deficiency or taking warfarin (Coumadin), it is suggested that these patients receive lower doses (200 to 800 international units/day). An increase in syncope and falls was also noted for vitamin E (and selegiline) in the study by Sano and colleagues (1997). Patients should be monitored for an increase in such events if they are receiving either of these agents.

Herbal Agents

Ginkgo biloba extract, thought to have antioxidant properties, has been studied in patients with mild-to-severe AD or multi-infarct dementia. Modest improvement of cognition was recorded in the results of the Alzheimer's Disease Assessment Scale. Caregivers also recognized improvement in function (Le Bars et al., 1997).

Treatment was well tolerated, with some GI side effects reported. Additional well-designed studies should be conducted before routine use is recommended. Because this product is not regulated by the FDA as a medication, its safety remains unknown, and *Ginkgo biloba* products may vary in extract concentrations and contents. Patients who choose to take this product should be cautioned that it may interact with warfarin or aspirin, increasing their risk of bleeding.

Case Study*

M.W. is a 70-year-old white woman with a medical history of hypertension, osteoarthritis, atrial fibrillation, and total hysterectomy who lives by herself in a two-story row home. She visits the primary care clinic with her daughter, who is concerned because

M.W. has “bounced” a few checks and can no longer pay her bills without assistance. M.W. admits that she has been forgetful and appears anxious as she describes an incident in which she went shopping and could not remember where she parked her car. Her daughter states that her mother’s memory has progressively worsened over the past year. M.W.’s medications include fosinopril 20 mg PO daily, metoprolol succinate ER 50 mg PO daily, warfarin 5 mg PO daily, vitamin D 1,000 IU PO daily, and acetaminophen 325 mg 2 tablets (650 mg) PO tid. A careful evaluation and workup was ordered.

Diagnosis: Mild AD with an MMSE Score OF 22

1. List specific goals of treatment for M.W.
2. What drug therapy would you prescribe for M.W.? Why?
3. What are the parameters for monitoring success of therapy?
4. Discuss specific patient education based on the prescribed therapy.
5. List one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What would be the choice for second-line therapy?
7. Would there be any over-the-counter and/or alternative agents appropriate for M.W.?
8. What lifestyle changes would you recommend to M.W.?
9. Describe one or two drug–drug or drug–food interactions for the selected agent.

45 Parkinson Disease

Karleen Melody ■ Anisha B. Grover

Parkinson disease (PD) is a neurodegenerative disorder characterized by a set of hallmark motor and nonmotor symptoms and was originally described in the "Essay on the Shaking Palsy," written by James Parkinson in 1817 (Parkinson, 1817). The mean age of onset is 65 years, with the typical age of diagnosis ranging between 55 and 65 years. The incidence is reportedly higher in males, with a male-to-female ratio of 1.5:1. The estimated prevalence among the total population is 0.3%, and the prevalence increases with age, affecting 1% of patients over the age of 60 years. Up to 1 million people live with PD in the United States (Connolly & Lang, 2014).

Causes

The underlying etiologies of PD are not well understood but likely include factors related to aging, genetic expression, and the environment.

As a preliminary step, drug-induced parkinsonism (DIP) must be considered and ruled out prior to the initiation of treatment for PD. The prevalence and incidence are difficult to determine, as it can be challenging to differentiate DIP from PD. Existing research has demonstrated that DIP may be the second most common etiology of parkinsonism (Shin & Chung, 2012). DIP is associated with agents that deplete or antagonize dopamine, such as first-generation "typical" antipsychotics or neuroleptic drugs. This drug class includes chlorpromazine, promazine, haloperidol, perphenazine, fluphenazine, and pimozide. Up to 80% of patients taking a drug from this class present with more than one kind of extrapyramidal side effect (EPS). Second-generation or "atypical" antipsychotic drugs, such as risperidone, olanzapine, and aripiprazole, were thought to carry a decreased risk than first-generation antipsychotic drugs; however, studies have shown otherwise. Of the available second-generation antipsychotics, only clozapine and quetiapine are associated with lower rates of DIP among elderly patients. Other offending agents include metoclopramide, valproic acid, methyldopa, and prochlorperazine. Amiodarone and lithium may cause tremor, which can appear similar to Parkinson-like symptoms (Shin & Chung, 2012). Management of these cases involves discontinuation of the responsible medication, as the associated parkinsonism is typically reversible. Up to 10% of patients with DIP may experience persistent symptoms, even after discontinuation of the offending drug, but this is usually explained as an unmasking of symptoms rather than a direct cause of the drug therapy. The reversibility can occur within hours or days but can take up to 2 years. These agents can also worsen symptoms in existing idiopathic PD and should be avoided when possible in diagnosed patients (Shin & Chung, 2012).

The natural aging process is likely associated with some of the neuron degeneration seen in PD. Other contributors include oxidative stress, which may be associated with increased monoamine oxidase-B (MAO-B) metabolism or decreased glutathione clearance of free radicals, mitochondrial dysfunction, inflammation, and signal-mediated apoptosis.

Approximately 15% of patients with PD have a first-degree relative with the disease. The inheritance of Mendelian genes has been linked to 10% or less of PD cases but may be associated with both familial and sporadic PD. At this point, approximately 18 loci and 8 validated genes have been identified. More recently, two causative genes may have been identified (Lesage & Brice, 2012).

Although PD is typically considered sporadic or familial, there is a broad body of epidemiologic research related to PD, which associates environmental factors, such as chronic pesticide exposure, with an increased risk for developing PD. A compound called 1-methyl-4-phenyl-1,2,3,5-tetrahydropyridine (MPTP) is converted in humans to 1-

methyl-4-phenylpyridium ion (MPP+), which is a neurotoxic agent. MPTP is structurally similar to many synthetic pesticides (Wirdefeldt et al., 2011).

Interestingly, some studies have shown an inverse association of caffeine intake with the development of PD (Liu et al., 2012). Experimental studies have shown that caffeine may protect dopaminergic neurons. The protective nature of caffeine has been identified more clearly in men, but evidence in women is conflicting. Recently, a large prospective study showed that higher caffeine intake was clearly associated with lower PD risk among women receiving hormone therapy (Ascherio et al., 2003). The same was not seen in women who had never used hormones. Some studies have also found cigarette smoking to be a protective factor; however, this factor does not have as clear of an association and needs to be evaluated separately. There are a limited number of studies that have evaluated the joint effect of caffeine and smoking status. Individuals who drink coffee are more likely to smoke cigarettes, and they often smoke more than noncoffee drinkers; however, cigarette smoking actually increases the metabolism and clearance rates of caffeine in humans, resulting in a higher plasma caffeine concentration in nonsmokers versus smokers who consume identical amounts (Liu et al., 2012). When considering the relationships between these variables, it is important to control for confounders, in order to evaluate true associations and relationships.

Pathophysiology

PD is associated with several cardinal pathologic findings within the substantia nigra pars compacta (SNpc), including the depigmentation, or degeneration, of dopaminergic neurons, autophagy dysfunction, and the formation of Lewy bodies in the residual neurons.

The extrapyramidal motor system regulates the movement of muscles. Dopamine is a neurotransmitter associated with movement control and is produced and stored in cells within the midbrain structure called the SNpc. At the point of diagnosis, patients have typically already lost at least half of the dopaminergic neurons in the SNpc. This leads to the depletion of dopamine in the corpus striatum, resulting in a breakdown of communication to the motor regulators within the brain. Additional neuronal dysfunction typically manifests in the basal ganglia, neurocortex, and spinal cord.

Autophagy describes an intracellular process in which cytoplasmic proteins and organelles are gathered in vacuoles that are transported into lysosomes, where they can be degraded and recycled. This process facilitates the elimination of damaged proteins and organelles. Dysfunction in this process may also be linked with the neurodegeneration of dopaminergic neurons, contributing to the pathogenesis of PD (Muñoz et al., 2012).

Lewy bodies, named for Frederick Lewy, are round, eosinophilic aggregates located within neuronal nuclei. These structures are made primarily of alpha-synuclein and ubiquitin and consist of a dense core, surrounded by fibrillary elements. Lewy bodies are found in a small percentage of normal older adult brains and are also found in patients with Down syndrome, Alzheimer disease, dementia, and other neurodegenerative conditions. In PD, Lewy bodies can be found within the SNpc, cerebral cortex, basal ganglia, cardiac plexus, and gastrointestinal (GI) system. The distribution and anatomical location of these protein inclusions vary among individuals with PD and are closely linked to the presentation and extent of clinical features (Halliday et al., 2012). The early stages of PD involve Lewy body formation in the medulla oblongata, locus coeruleus, raphe nuclei, and even in the olfactory bulb. This is directly associated with depression, anxiety, difficulty sleeping, and sensory impairment that may manifest initially. PD progression is marked by Lewy body presence in the SNpc, correlating with hallmark motor symptoms. In advanced cases, Lewy bodies form in the cortex, resulting in cognitive changes. Lewy body accumulation in the lateral collateral pathway within the sacral spinal dorsal horn may contribute to urinary urgency and frequency and constipation associated with PD (VanderHorst et al., 2015). Nonmotor symptoms may also result from the loss of a wide range of neurotransmitters, including dopamine, norepinephrine, serotonin, and acetylcholine, which can decrease as various regions of the brain degenerate.

Diagnostic Criteria

The clinical history of the patient, including risk factors, medical history, medication history, and review of systems, will provide the most useful information for the diagnostic process, despite technological advances in imaging and nuclear techniques (Pedrosa & Timmermann, 2013). In evaluating the patient, it is important to first exclude DIP. Patients and caregivers provide valuable information when establishing a diagnosis, including the onset of tremor, stiffness or rigidity in arms or legs, speed of movement, and description of changes in facial expressions, posture, and gait. Hallmark or cardinal motor symptoms include a slowing of movement termed bradykinesia, resting or postural tremor, cogwheel rigidity, and difficulty maintaining balance, also known as postural instability. A neurological exam includes the assessment of facial expressiveness, posture, tone, balance, tremor, and speed of extremity movements (Lyons & Pahwa, 2011). Patients should also be evaluated for any associated nonmotor symptoms or conditions, including depression, anxiety, psychosis, fatigue, sleep disturbances, urinary complaints, increased salivation, orthostatic hypotension, cognitive changes, and GI problems, such as constipation.

Functional magnetic resonance imaging (MRI) or nuclear imaging techniques may be useful in ruling out other conditions, such as essential tremor, vascular parkinsonism, multiple systems atrophy, and progressive supranuclear palsy. These tools can also help form an earlier and more precise diagnosis, preventing a delay in therapy and helping to continually improve the individualization of disease management strategies for patients with PD. Dopamine transporter (DAT) imaging, sometimes used in combination with contrast agents, can be used to assess the degree of DAT loss in patients with PD, which correlates with disease staging, severity, and duration (Eggers et al., 2012). Although patients diagnosed with PD can look similar at baseline, the clinical subtypes can be differentiated by the variances in dopaminergic degeneration. DAT imaging can be used to diagnose presynaptic parkinsonism because even in early PD, DAT uptake in the striatum is significantly decreased. Utilizing DAT imaging can help to differentiate PD from DIP, which involves drug-induced changes in postsynaptic dopaminergic receptors (Shin & Chung, 2012). It can also guide the formation of patient-specific treatment strategies. Additional studies have explored whole-brain functional connectivity.

The Movement Disorder Society–sponsored revision of the Unified Parkinson's Disease Rating Scale (MDS-UPDRS) is a tool that is not designed for diagnostic purposes, but it can be used to monitor the degree of disability and impairment (Goetz et al., 2008). This tool can be used at the time of diagnosis to establish a baseline score, so that patient progress can be measured over time. This 65-item tool has demonstrated validity and reliability and is accompanied by a detailed set of instructions to standardize the use of the tool internationally. It contains four parts, including (1) nonmotor experiences of daily living, (2) motor experiences of daily living, (3) motor examination, and (4) motor complications. The patient or caregiver completes a total of 20 questions from parts I and

II. Both rater and patient involvement are required for the remaining portions. The total rater time requirement to administer the tool is 30 minutes.

Initiating Drug Therapy

Traditionally, treatment of patients with newly diagnosed PD would be deferred until the patient developed functional disability interfering with activities of daily living (Clarke et al., 2011). This is largely driven by the lack of available disease-modifying or neuroprotective agents; however, in recent years, there is emerging evidence that points to several advantages of initiating pharmacotherapy early on in PD. Early intervention may delay or diminish both motor and nonmotor symptoms, as well as delay the initiation of levodopa (Figure 45.1). Although not conclusively proven, some trials suggest that early treatment may slow the progression of PD because the rate of disease progression is much faster in the early stages than the later stages (Murman, 2012). By the time motor symptoms present, dopamine has been depleted by 60% to 80%, further strengthening the recommendation to initiate treatment earlier rather than waiting for functional disability (Lyons & Pahwa, 2011).

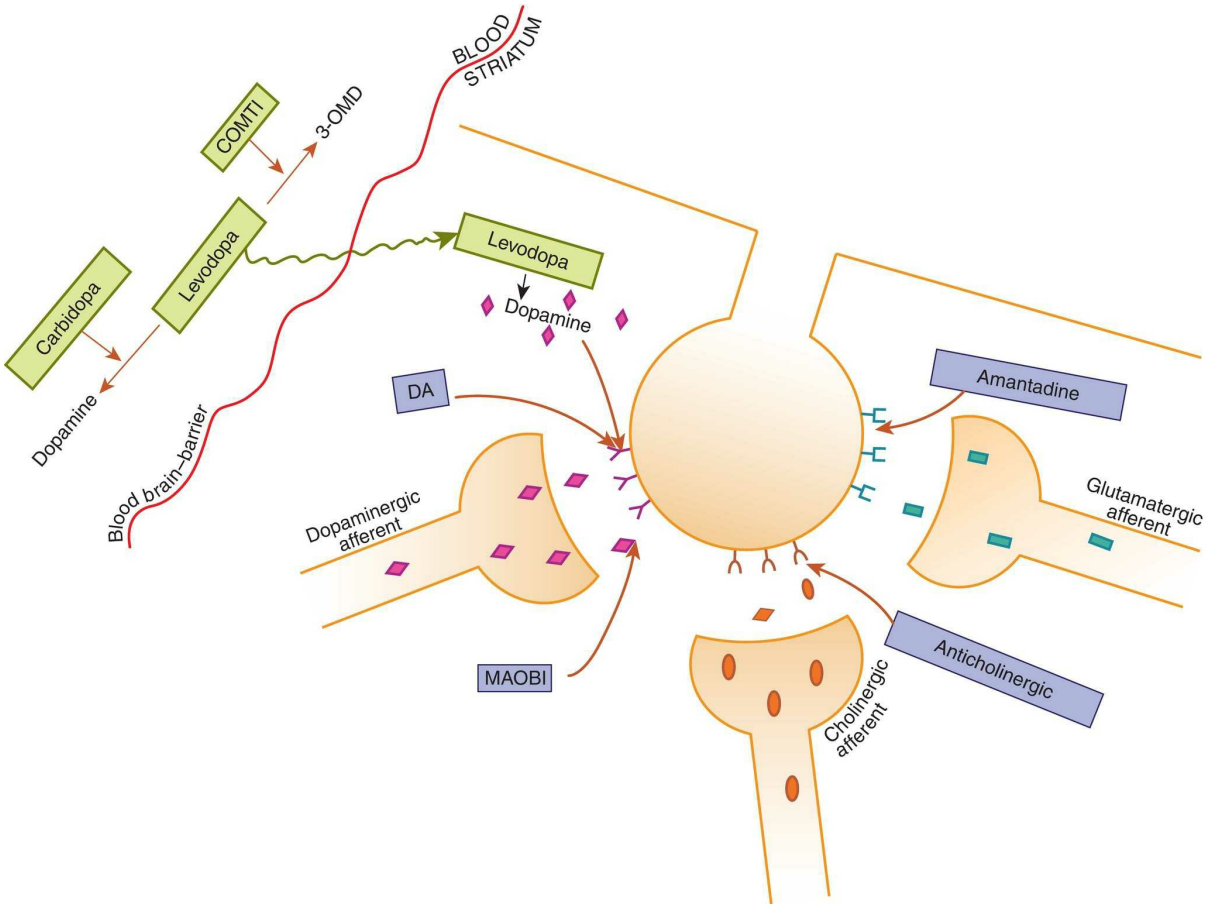

FIGURE 45.1 Sites of action of drugs used in the management of PD. PD is characterized by a deficiency in dopamine, and many drugs work to increase the activity of this neurotransmitter. In the periphery, catechol-*O*-methyltransferase inhibitors (COMTIs) block the degradation of levodopa to 3-O-methyldopa (3-OMD) and carbidopa prevents the conversion of levodopa into dopamine, increasing the amount of levodopa that can cross the blood–brain barrier. Once levodopa has entered the striatum, it undergoes central conversion to dopamine. Other drugs that act primarily in the striatum include dopamine agonists (DAs), which bind to and activate dopamine receptors, and monoamine oxidase type B inhibitors (MAOBIs), which inhibit the breakdown of dopamine. In addition to dopamine, other neurotransmitters serve as drug targets in PD. Anticholinergic drugs bind to and block acetylcholine receptors. Amantadine binds to and blocks *N*-methyl-d-aspartate (NMDA) glutamate receptors and increases the release of dopamine in other ways.

Patients with untreated or inadequately treated PD will experience significant symptomatic deterioration contributing to a reduced quality of life. Even though motor symptoms are more identifiable in PD, nonmotor symptoms have been shown to have a more negative impact on quality of life because they represent the majority of PD symptoms and tend to emerge early in PD often before motor symptoms appear. A patient presenting with significant nonmotor symptoms may warrant early treatment intervention to improve quality of life (Murman, 2012).

There are several factors that need to be considered in determining when to initiate treatment as well as which treatment option to use. These factors include age, cognitive function, psychiatric issues, comorbidities, lifestyle, symptom severity, and employment, with the latter two factors being the strongest predictors of need for dopaminergic therapy. The patient's symptom severity and levels of impairment and disability should be assessed upon diagnosis and throughout treatment using a validated scale such as the MDS-UPDRS, to objectively evaluate the motor features of PD (Lyons & Pahwa, 2011).

Goals of Drug Therapy

The ultimate goal of drug therapy for PD is to maintain quality of life by alleviating motor and nonmotor symptoms. Other desired outcomes include maintaining patient independence, preserving the ability to perform activities of daily living, and minimizing adverse drug events and treatment complications (Murman, 2012). As with any disease state, it is important to provide cost-effective therapy; involve and educate the patient, family, and caregivers when creating a patient-centered treatment plan; and connect the patient with reliable and accurate resources.

Selected Agents for Motor Symptoms (Table 45.1)

TABLE 45.1 Overview of Drugs Used in the Management of PD

Generic (Trade) Name and Initial Dosage	Dose Adjustments	Selected Adverse Events	Contraindications	Special considerations
trihexyphenidyl (Artane) 1 mg once daily; titrate by 2 mg every 3–5 d; max. 15 mg/d	None	Impaired memory, confusion, hallucinations, nausea, blurred vision, dry mouth, urinary retention, constipation	Narrow-angle glaucoma	Avoid with potassium chloride, glucagon, and other anticholinergics
benztropine (Cogentin) 1 mg once daily; titrated by 0.5 mg. Max. 6 mg/d	None	Same as trihexyphenidyl	Narrow-angle glaucoma; use in <3 y of age	Same as trihexyphenidyl
amantadine (Symmetrel) 100 mg twice daily; max. 400 mg/d	Serious concomitant illness or high doses of other PD drugs: start 100 mg once daily. CrCl 30–50 mL/min: 200 mg × 1 and 100 mg daily thereafter. CrCl 15–29 mL/min: 200 mg × 1 and 100 mg every other day thereafter. CrCl <15 mL/min or HD: 200 mg every 7 d	Hallucinations, confusion, ankle edema, livedo reticularis, blurred vision, dry mouth, constipation, insomnia	None	Caution with use with memantine or drugs that prolong the QT interval
selegiline (Eldepryl) 5 mg twice daily	None	Headache, nausea, dizziness, hallucinations, dyskinesia, insomnia	Meperidine, methadone, propoxyphene, tramadol, St. John's wort, cyclobenzaprine, dextromethorphan, other MAO-B inhibitors, carbamazepine, SSRIs, SNRIs, clomipramine, imipramine	Caution with use with other serotonergic agents, alcohol, and tyramine-containing foods
rasagiline (Azilect) 1 mg once daily; max. 1 mg/d	If used with levodopa, initial dose should be decreased to 0.5 once daily.	Headache, nausea, dizziness, hallucinations, dyskinesia, orthostatic hypotension, dyspepsia, depression, flulike symptoms, and arthralgia	Meperidine, methadone, propoxyphene, tramadol, St. John's wort, cyclobenzaprine, dextromethorphan, and other MAO-B inhibitors	Same as selegiline
pramipexole IR (Mirapex) 0.125 mg three times daily; titrated every 5–7 d	CrCl 30–50 mL/min: start 0.125 twice daily. CrCl 15–29 mL/min: start 0.125 once daily	Fatigue, nausea, constipation, orthostatic hypotension, hallucinations, lower extremity edema, ICD, sleep attacks	None	
pramipexole ER (Mirapex ER) 0.375 mg once daily; titrated by 0.75 mg every 5–7 d; max. 4.5 mg	CrCl 30–50 mL/min: start 0.375 mg every other day	Same as pramipexole IR	None	Dose should be tapered before discontinuing
ropinirole IR (Requip) 0.25 mg three times daily; titrated weekly; max 24 mg/d	HD: 0.25 mg three times daily; max. 18 mg/d	Same as pramipexole IR	None	Avoid use with CYP1A2 inhibitors and inducers
Generic (Trade) Name and Initial Dosage	**Dose Adjustments**	**Selected Adverse Events**	**Contraindications**	**Special considerations**
ropinirole ER (Requip XL) 2 mg once daily; titrated weekly by 2 mg; max 24 mg/d	HD: 2 mg once daily; max. 18 mg/d	Same as pramipexole IR	None	Dose should be tapered before discontinuing. Avoid use with CYP1A2 inhibitors and inducers
rotigotine (Neupro) 2 mg/24 h; titrated by 2 mg/24 h weekly; max. 6 mg/24 h	None	Same as pramipexole IR	None	Dose should be tapered before discontinuing
apomorphine (Apokyn) 2- or 4-mg test dose; titrated by 1 mg every few days; max 6 mg/dose	Renal impairment: start 1-mg test dose	Same as pramipexole IR	None	4-mg test dose administered 2 h after 2-mg test dose if tolerates but does not respond
carbidopa/levodopa IR (Sinemet) or ODT (Parcopa) Preferred: 25/100 mg three times daily; alternative: 10/100 mg three to four times daily; titrated by 1 tablet daily or every other day; max 8 tablets/d or 200 mg/d carbidopa or 2,000 mg/d levodopa	None	Nausea, vomiting, constipation, dizziness, headache, peripheral edema, insomnia, orthostatic hypotension, dyskinesias	Narrow-angle glaucoma	Protein consumption and constipation may reduce the absorption of levodopa, so patients should avoid meals high in protein, take levodopa 1 h before or 2 h after meals, and maintain appropriate bowel regimen
carbidopa/levodopa CR (Sinemet CR) 50/200 mg twice daily; titrated by 1 tablet every 3 d. Max. 8 tablets/d	Levodopa doses >700 mg should be divided into at least 3 daily doses	Same as carbidopa/levodopa IR	Narrow-angle glaucoma	Same as carbidopa/levodopa IR
carbidopa/levodopa ER (Rytary) 23.75/95 mg three times daily for 3 d, then 36.25/145 mg three times daily starting day 4; titrated as tolerated to max. 612.5/2,450 mg/d	None	Same as carbidopa/levodopa IR	Narrow-angle glaucoma	Same as carbidopa/levodopa IR
entacapone (Comtan) 200 mg with each dose of levodopa; max 8 doses/d	None	Dyskinesia, hypotension, nausea, diarrhea, dark-colored urine, somnolence, sleep disorders, hallucinations, headache, confusion	None	Only used adjunct to carbidopa/levodopa therapy. May be necessary to reduce dose of levodopa when adding COMTI
tolcapone (Tasmar) 100 mg three times daily	None	Same as entacapone Black box warning for hepatotoxicity	None	Same as entacapone Bioavailability is decreased by 10%–20% when taken with food

CrCl, creatinine clearance; IR, immediate release; ER, extended release; CR, controlled release; d, day; max., maximum; COMTI, catechol-*O*-methyltransferase inhibitor.

Mild-Potency Drugs

Anticholinergics

Indications/Use

The use of anticholinergics in PD is controversial. There is some evidence that they are useful in some patients with PD, particularly for symptoms of drooling and tremor (Abramowicz et al., 2013). However, other randomized controlled studies conclude that the benefits on tremor are inconclusive (Connolly & Lang, 2014). They are indicated for PD symptoms as well as drug-induced EPS.

Mechanism of Action

Anticholinergics antagonize acetylcholine receptors to decrease the release of acetylcholine, which regulates muscle movement. The resulting decrease in activity of acetylcholine muscarinic receptors can also decrease salivation, providing an explanation for its potential role for the management of drooling.

Dosage

Two anticholinergics used in PD include trihexyphenidyl and benztropine. Trihexyphenidyl, available in an oral tablet and an elixir, is initiated at 1 mg and is titrated in 2 mg increments every 3 to 5 days. A typical maintenance dose is 6 to 10 mg daily in 3 to 4 divided doses to a maximum dose of 15 mg/d. Benztropine, available in an oral tablet, injection, and solution formulation, should be started at 1 mg daily, which can be divided into 2 to 4 divided doses. Benztropine can be gradually increased every 5 to 6 days by increments of 0.5 mg to a maximum of 6 mg daily. Abrupt discontinuation of either agent can exacerbate adverse effects, so it is recommended to taper the dose.

Time Frame for Response

Anticholinergics have an onset of approximately 1 hour.

Contraindications

Both agents are contraindicated in narrow-angle glaucoma. Benztropine is also contraindicated in children less than 3 years of age.

Adverse Drug Events

Anticholinergics commonly cause impaired memory, confusion, hallucinations, nausea, blurred vision, dry mouth, urinary retention, and constipation, which often limit their use in PD.

Interactions

Potassium chloride should be avoided with anticholinergics because concurrent use

increases the risk of ulcers. The risk of GI adverse effects may also be increased in patients on anticholinergics when glucagon is administered. Due to additive side effects, other anticholinergics such as ipratropium, tiotropium, and umeclidinium should be avoided in patients on benztropine or trihexyphenidyl.

Amantadine

Indications/Uses

Amantadine is indicated for the treatment of mild PD and most frequently used in a patient experiencing dyskinesia. Evidence supporting the use of amantadine in PD is conflicting. Expert opinion supports its use as monotherapy and adjunctive therapy; however, a 2009 Cochrane review concludes that there is insufficient evidence for its use (Connolly & Lang, 2014).

Mechanism of Action

The precise mechanism of amantadine in PD is unknown, although it is hypothesized that its inhibition on *N*-methyl-d-aspartate (NMDA) receptors potentiates dopaminergic responses to reduce PD symptoms.

Dosage

Amantadine is available as an oral capsule and tablet and is typically started at a dose of 100 mg twice daily. It can be titrated to a maximum of 400 mg daily in divided doses with careful monitoring. In the presence of a serious concomitant illness, or for patients who are receiving high doses of other PD drugs, an initial dose of 100 mg daily is recommended, which can be titrated to 100 mg twice daily after 1 to 2 weeks. The dose of amantadine needs to be adjusted in patients with renal dysfunction. For patients with a creatinine clearance (CrCl) of 30 to 50 mL/min, a loading dose of 200 mg should be started, followed by 100 mg/d as a maintenance dose. For patients with a CrCl between 15 and 29 mL/min, a 200-mg loading dose should be given, followed by 100 mg every other day. Patients with a CrCl less than 15 mL/min or on hemodialysis (HD) should be given 200 mg every 7 days.

Time Frame for Response

The onset of amantadine is within 48 hours of administration.

Contraindications

There are no absolute contraindications for amantadine.

Adverse Drug Events

Adverse effects of amantadine include hallucinations, confusion, ankle edema, livedo reticularis, a blotchy, purple-colored skin condition with a net-like pattern, in addition to anticholinergic effects like blurred vision, dry mouth, and constipation. Amantadine may also affect sleep–wake cycles, causing insomnia or reduction in daytime sleepiness.

Interactions

Caution should be used when amantadine is used concurrently with memantine because of an increased risk of QT prolongation and psychosis. Other drugs that prolong the QT interval should also be used with caution in combination with amantadine.

MAO-B Inhibitors

Indications/Uses

MAO-B inhibitors are used for mild PD. When used as monotherapy in early PD, MAO-B inhibitors provide a modest improvement in motor symptoms, which may be seen as early as 1 week after initiation. In more advanced PD, MAO-B inhibitors are used as adjunctive therapy. MAO-B inhibitors also delay the need for levodopa by a few months, but they do not prevent or delay clinical progression of PD (Goetz & Pal, 2014). The MAO-B inhibitors available for the treatment of PD are selegiline and rasagiline.

Mechanism of Action

MAO-B plays a major role in the metabolism of dopamine. By inhibiting this metabolism, concentrations of dopamine are increased, allowing more dopamine to reach the brain and ultimately reducing motor symptoms of PD. Selegiline also inhibits the uptake of catecholamines and the release of catecholamine by amphetamine metabolites.

Dosage

Selegiline is available in multiple formulations, including an oral capsule, oral tablet, a patch, and an orally disintegrating tablet (ODT), whereas rasagiline is only available as an oral tablet. Of note, the patch is only indicated for depression and the ODT has insufficient efficacy for symptom improvement in PD, so these dosage forms will not be discussed further. Selegiline therapy is initiated at a dose of 5 mg twice daily with breakfast and lunch. The recommended dose of rasagiline as monotherapy or adjunctive therapy (except with levodopa) is 1 mg once daily, which is the maximum daily dose. If rasagiline is used adjunctively with levodopa, the initial dose is 0.5 mg once daily, which could be increased to 1 mg once daily based on response and tolerability.

Time Frame for Response

MAO-B inhibitors have an onset of approximately 1, with moderate improvement in motor symptoms seen within 1 week after initiation.

Contraindications

MOA-B inhibitors are contraindicated with meperidine, methadone, propoxyphene, tramadol, St. John's wort, cyclobenzaprine, dextromethorphan, and other MAO-B inhibitors. Additional contraindications with selegiline only include concomitant therapy with carbamazepine, selective serotonin reuptake inhibitors (SSRIs), serotonin–norepinephrine reuptake inhibitors (SNRIs), clomipramine, and imipramine.

Adverse Drug Events

Adverse effects seen with MOA-B inhibitors include headache, nausea, dizziness, hallucinations, or dyskinesia. Selegiline can also cause insomnia because it is metabolized to amphetamines, which is not true of rasagiline. Rasagiline may additionally cause orthostatic hypotension, dyspepsia, depression, flulike symptoms, and arthralgia.

MAO-B inhibitors have additional adverse event concerns that warrant caution with their use. The risk of developing melanoma is increased in patients with PD, although no clear association with dopaminergic drugs has been established. New or worsening mental status or behavioral changes, including impulse control disorders (ICDs), have also been noted with MAO-B inhibitor use. Somnolence, which may impair physical or mental abilities, has been reported with MAO-B inhibitor use particularly in elderly patients, patients with current sleep disorders, and patients taking concomitant sedating medications. MAO-B inhibitors may also potentiate the dopaminergic side effects of levodopa and may cause or worsen dyskinesia. Rasagiline labeling also contains a warning that it can exacerbate or precipitate hypertension. Proper screenings for the concerns listed above should be conducted regularly.

Interactions

The impact of cytochrome P450 (CYP) isoforms on the metabolism of MAO-B inhibitors is important to consider. Selegiline is metabolized primarily by CYP2B6 and to a lesser extent by CYP3A4. Selegiline does not inhibit enzymes in the CYP450 system; however, CYP3A4 inducers, such as phenytoin and carbamazepine, could reduce selegiline concentrations. Rasagiline is metabolized by CYP1A2; therefore, CYP1A2 inhibitors, such as ciprofloxacin and cimetidine, will reduce rasagiline concentrations. Rasagiline does not inhibit or induce enzymes in the P450 system. Caution should be used when MAO-B inhibitors are used concomitantly with alpha/beta agonists, stimulants, and buprenorphine. Additionally, potentially fatal serotonin syndrome has occurred when serotonergic agents are used concomitantly with MAO-B inhibitors. Alcohol- and tyramine-containing foods should also be avoided due to their increased risk of serotonin syndrome.

Moderate-Potency Drugs

Dopamine Agonists

Indications/Uses

Compared to levodopa, dopamine agonists (DAs) are less effective but cause dyskinesia or motor fluctuations less frequently (Abramowicz et al., 2013). They are classified as either ergot or nonergot derivatives. The nonergot-derived agents have superior safety profiles and are therefore the preferred choice, so they will be the focus of this section. Pramipexole, ropinirole, and rotigotine are the DAs available to treat moderate symptoms of PD. Apomorphine is an injectable DA that is only approved to treat acute intermittent hypomobility in patients with advanced PD. DAs used as monotherapy can improve UPDRS scores by 4 to 5 points (Lyons & Pahwa, 2011). When used adjunctively to levodopa, a DA has improved efficacy compared to monotherapy and can reduce "wearing-off" phenomena but has an increased risk of dyskinesia (Connolly & Lang, 2014).

Mechanism of Action

The exact mechanism of action of DAs is unknown; however, it is believed that stimulation of dopamine D2-type receptors result in improved dopaminergic transmission in the motor area of the basal ganglia.

Dosage

Pramipexole and ropinirole are available in immediate-release (IR) and extended-release (ER) oral tablet formulations. Pramipexole IR tablet is initiated at 0.125 mg three times daily and titrated every 5 to 7 days. The typical maintenance dose is 0.5 to 1.5 mg three times daily. The ER formulation of pramipexole is started at 0.375 mg daily and titrated by 0.75 mg daily every 5 to 7 days to a maximum dose of 4.5 mg once daily. Patients with renal impairment will require a dose reduction. Pramipexole IR should be initiated at 0.125 mg twice daily and 0.125 mg once daily for patients with a CrCl of 30 to 50 mL/min and CrCl of 15 to 29 mL/min, respectively. Pramipexole IR should not be used in patients with a CrCl less than 15 mL/min or in those requiring HD. For patients with a CrCl of 30 to 50 mL/min, pramipexole ER should be initiated at 0.375 mg every other day, which can be titrated to 0.375 mg daily after at least 1 week of therapy. Pramipexole ER can further be titrated by 0.375 mg every 7 days to a maximum dose of 2.25 mg daily. Patients with a CrCl less than 30 mL/min or on HD should not take pramipexole ER. To discontinue pramipexole, it is recommended to decrease the dose by 0.75 mg/d until the daily dose is 0.75 mg once daily and then to reduce the dose by 0.375 mg once daily.

The starting dose of ropinirole IR tablet is 0.25 mg three times daily. For the first month of therapy, the daily dosage should increase by 0.75 mg (divided into 3 doses) on a weekly basis. After week 4, the daily dosage may be increased by 1.5 mg/d on a weekly basis up to a dose of 9 mg/d and then by 3 mg/d on a weekly basis up to a total dose of 24 mg/d. When discontinuing ropinirole, it must be tapered over 7 days by reducing the administration to twice daily for 4 days and then once daily for the remaining 3 days. The starting dose of the ER tablet is 2 mg once daily for 1 to 2 weeks, which is then titrated by

2 mg/d on a weekly basis to a maximum of 24 mg daily. Neither formulation has been studied in patients with a CrCl less than 30 mL/min, and use of these agents should be avoided in this population. For patients requiring HD, the initial dose of ropinirole IR should be 0.25 mg three times daily and ropinirole ER should be 2 mg once daily. The maximum daily dose in patients requiring HD for both formulations is 18 mg daily.

Rotigotine is available as a transdermal patch and should be initiated at 2 mg/24 hours. The dose may be increased by 2 mg/24 hours on a weekly basis to a maximum dose of 6 mg/24 hours. If discontinuation of rotigotine is warranted, the dose should be reduced by 2 mg/24 hours every other day.

Since apomorphine is used for acute hypomobility, this medication is administered three times daily as needed. When initiating apomorphine, a test dose of 2 mg subcutaneously is administered under medical supervision. If the patient tolerates the dose, but does not respond, a second test dose of 4 mg should be administered 2 hours later. If the 4-mg dose is tolerated and the patient responds, a maintenance dose of 3 mg should be administered thereafter. If the patient tolerates and responds to either the 2- or 4-mg test dose, the maintenance dose can be titrated in 1-mg increments every few days to a maximum of 6 mg. For patients with mild to moderate renal impairment, the initial test dose and starting dose should be reduced to 1 mg as needed.

Time Frame for Response

Pramipexole and ropinirole have an onset of action within 1 hour of administration. Rogigotine has a slower onset action of 4 to 18 hours with a full treatment benefit seen within 1 week. Apomorphine has a rapid onset of action of 10 to 20 minutes.

Contrainidcations

There are no contraindications for pramipexole, ropinorole, or rotigotine. Apomorphine is contraindicated with concomitant use of 5-HT3 antagonists.

Adverse Drug Events

Adverse effects are similar among all DAs and include fatigue, nausea, constipation, orthostatic hypotension, hallucinations, and lower extremity edema. Severe side effects may include ICD, or sleep attacks. ICD may improve upon reduction or discontinuation of the DA, but switching to a different agent is not recommended as all DAs have a similar risk of ICD. Since sleep attacks can occur at any time, including while driving, eating, and talking, patients should be counseled about driving safety. Because of these significant adverse drug events, DAs are typically avoided in the elderly.

Interactions

Pramipexole and rotigotine do not have any major drug interactions, but caution should be used with antipsychotics as the efficacy of both agents can be diminished. Ropinirole is a

major substrate of CYP1A2, so its use should be avoided with any CYP1A2 inducers, such as carbamazepine and rifampin, or inhibitors, such as ciprofloxacin and cimetidine.

High-Potency Drugs

Levodopa

Indications/Uses

Nearly all patients with PD will require treatment with levodopa, as it is the most effective treatment for symptomatic relief of PD. Levodopa also has the fastest onset of action compared to other PD medications. After several years of levodopa treatment, patients can begin to experience a "wearing-off" phenomenon, which involves the return of motor and nonmotor symptoms prior to the next dose of levodopa. As PD progresses, patients may find a shortening in the length of time with a good response to the medication, also known as "on time," and a lengthening of time with a poor response, also known as "off time." As PD progresses, patients have a diminished capacity to produce dopamine and store converted levodopa for release when needed, resulting in a reappearance of symptoms. Although "wearing off" can occur with many different drugs, it is most commonly associated with levodopa. At high doses and with continued use, patients' inability to store excess dopamine can manifest in the form of motor fluctuations and dyskinesia, so it is typically reserved for severe motor symptoms of PD.

Mechanism of Action

Dopamine itself is not used to treat PD because it cannot cross the blood–brain barrier. Levodopa, a dopamine precursor, can cross the blood–brain barrier, where it is then converted via decarboxylation to dopamine. The converted dopamine is then stored in the presynaptic neurons until stimulated for release, when it will bind to dopamine receptors. Levodopa is administered in combination with carbidopa, which limits the peripheral breakdown of levodopa. This allows roughly a fourfold increase in circulating levodopa to cross the blood–brain barrier and reduces the undesirable adverse effects of nausea and vomiting caused by dopamine in the periphery.

Dosage

Carbidopa/levodopa is available in many formulations including an IR tablet, an ODT, a controlled-release (CR) tablet, a suspension, and an ER tablet and capsule. The CR formulation has a more variable absorption profile, resulting in a slower and less predictable onset of action than the IR formulation. The half-life of levodopa is only 60 to 90 minutes, so the daily dosage is divided into 3 to 6 doses.

The preferred initial dosing of the IR or ODT formulations is carbidopa 25 mg/levodopa 100 mg three times daily, although carbidopa 10 mg/levodopa 100 mg three

to four times daily may also be initiated. This can be titrated upward by 1 tablet daily or every other day as necessary to a maximum of 8 tablets of any strength or 200 mg of carbidopa and 2,000 mg of levodopa.

Patients initiating the CR formulation should start at a dose of carbidopa 50 mg/levodopa 200 mg twice daily at intervals not less than 6 hours apart. If doses of levodopa are greater than 700 mg daily, it should be divided into three or more daily doses. Intervals between doses should be 4 to 8 hours while awake, with the smaller doses given toward the end of the day, if the divided doses are not equal. This can be titrated upward by 1 tablet every 3 days to a maximum of 8 tablets daily.

For levodopa-naïve patients, ER capsule dosage should be initiated at carbidopa 23.75 mg/levodopa 95 mg three times daily for 3 days and then increased to carbidopa 36.25 mg/levodopa 145 mg three times daily on the 4th day. Since ER tablets are not interchangeable with other carbidopa/levodopa products, patients switching from other formulations to the ER formulation are dosed based on their previous total daily dose (TDD) of levodopa. If the TDD was between 400 and 549 mg, initiate 3 capsules of carbidopa 23.75 mg/levodopa 95 mg three times daily; if the TDD was between 550 and 749 mg, initiate 4 capsules of carbidopa 23.75 mg/levodopa 95 mg three times daily; if the TDD was between 750 and 949 mg, initiate 3 capsules of carbidopa 36.25 mg/levodopa 145 mg three times daily; if the TDD was between 950 and 1,249 mg, initiate 4 capsules of carbidopa 36.25 mg/levodopa 145 mg three times daily; if the TDD is ≥1,250 mg, initiate 4 capsules of carbidopa 48.75 mg/levodopa 195 mg three times daily. Titration of the ER formulations as tolerated can continue to a maximum daily dose of carbidopa 612.5 mg/levodopa 2,450 mg.

Time Frame to Response

The onset of levodopa is approximately 1 hour.

Contraindications

Carbidopa/levodopa is contraindicated in patients with narrow-angle glaucoma.

Adverse Drug Events

The most common side effects of carbidopa/levodopa include nausea, vomiting, constipation, dizziness, headache, peripheral edema, insomnia, and orthostatic hypotension. Carbidopa/levodopa can also cause motor fluctuations and dyskinesia, which are more commonly seen when initiated in younger patients.

Interactions

Carbidopa/levodopa does not have any major drug interactions, but caution should be used with antipsychotics as the efficacy of both agents can be diminished. Additionally, levodopa may enhance the effect of MAO-B inhibitors. In some cases, protein consumption may

reduce the absorption of levodopa from the intestine, so patients should avoid meals high in protein. Patients may also try taking levodopa 1 hour before or 2 hours after meals. It is important for patients to increase fluid and fiber intake, as constipation may reduce levodopa absorption, as well.

Catechol-O-Methyltransferase Inhibitors

Indications/Uses

Catechol-*O*-methyltransferase inhibitors (COMTIs) are used in combination with levodopa to decrease PD-associated disability by improving "wearing-off" phenomena; however, they can increase the risk of dyskinesia.

Mechanism of Action

COMT breaks down levodopa in the periphery. By inhibiting this action, levodopa plasma levels are increased and the half-life is prolonged.

Dosage

Two oral COMTIs, entacapone and tolcapone, are available for adjunctive therapy to carbidopa/levodopa in the treatment of patients with PD who experience "wearing-off" symptoms. Tolcapone was withdrawn from the market in Canada; however, it is still available in the United States for patients who have tried and failed entacapone. The initial dose of entacapone is 200 mg, administered with each dose of levodopa, to a maximum of 8 doses daily. Tolcapone should be initiated at 100 mg three times daily and does not have to be taken at the same times as levodopa. If no benefit is seen after 3 weeks, tolcapone should be discontinued. COMTIs can exacerbate the adverse effects of levodopa, so it may be necessary to reduce the dose of levodopa when adding a COMTI to the patient's regimen.

Time Frame to Response

The onset of COMTIs is approximately 1 hour.

Contraindications

There are no contraindications to COMTIs.

Adverse Drug Events

Common adverse effects of COMTIs include dyskinesia, hypotension, nausea, diarrhea, dark-colored urine, and central nervous system (CNS) disturbances such as somnolence, sleep disorders, hallucinations, headache, and confusion. These adverse effects are more prevalent with tolcapone. Additionally, tolcapone has a black box warning for

hepatotoxicity and requires written consent for its use as well as liver function tests every 2 to 4 weeks for the first 6 months of therapy and periodically thereafter.

Interactions

Because COMTIs commonly cause CNS disturbances, they should be used with caution with other CNS depressants. The bioavailability of tolcapone is decreased by 10% to 20% when taken with food. Therefore, it should be administered at least 1 hour before or 2 hours after meals.

Selecting the Most Appropriate Drug

There are no pharmacologic agents that provide disease-modifying or neuroprotective effects; therefore, therapy selection is based on symptoms causing the greatest disability, age, comorbidities, and side effect profile (Goetz & Pal, 2014). Patients requiring therapy for mild motor symptoms should be started first on a MAO-B inhibitor before trying a DA or levodopa due to the increased risk of major adverse drug events with the latter agents. Patients who are experiencing moderate to severe impairment will usually be initiated on a DA or levodopa. Although levodopa is more efficacious than a DA and is associated with less hallucinations, somnolence, and ICDs, DAs have a decreased risk of dyskinesia. DAs are typically chosen over levodopa in younger patients, because the onset of PD at a younger age is a risk factor for developing dyskinesia (Connolly & Lang, 2014). Careful consideration must be given to the patient's age, level of disability, treatment goals, and potential for late complications of dyskinesia and hallucinations before starting levodopa (Goetz & Pal, 2014).

The stepwise treatment approach of PD is dependent on the symptom that is causing the greatest disability. An algorithm that outlines treatment options deemed first-, second-, and third-line therapies for treating PD is shown in Figure 45.2. If symptoms are uncontrolled on an adequate trial of therapy and if there were other treatment options listed in the previous step, all of those alternative agents should be tried before moving to the next step in the algorithm. For a patient with a suboptimal benefit, defined as an improvement in symptoms yet still experiencing bothersome or disabling symptoms, the current medication dose should be increased until maximized before moving to the next step in the algorithm. If the patient is not experiencing any improvement with the medication, the agent should be discontinued and an agent listed in the next step should be initiated (Connolly & Lang, 2014).

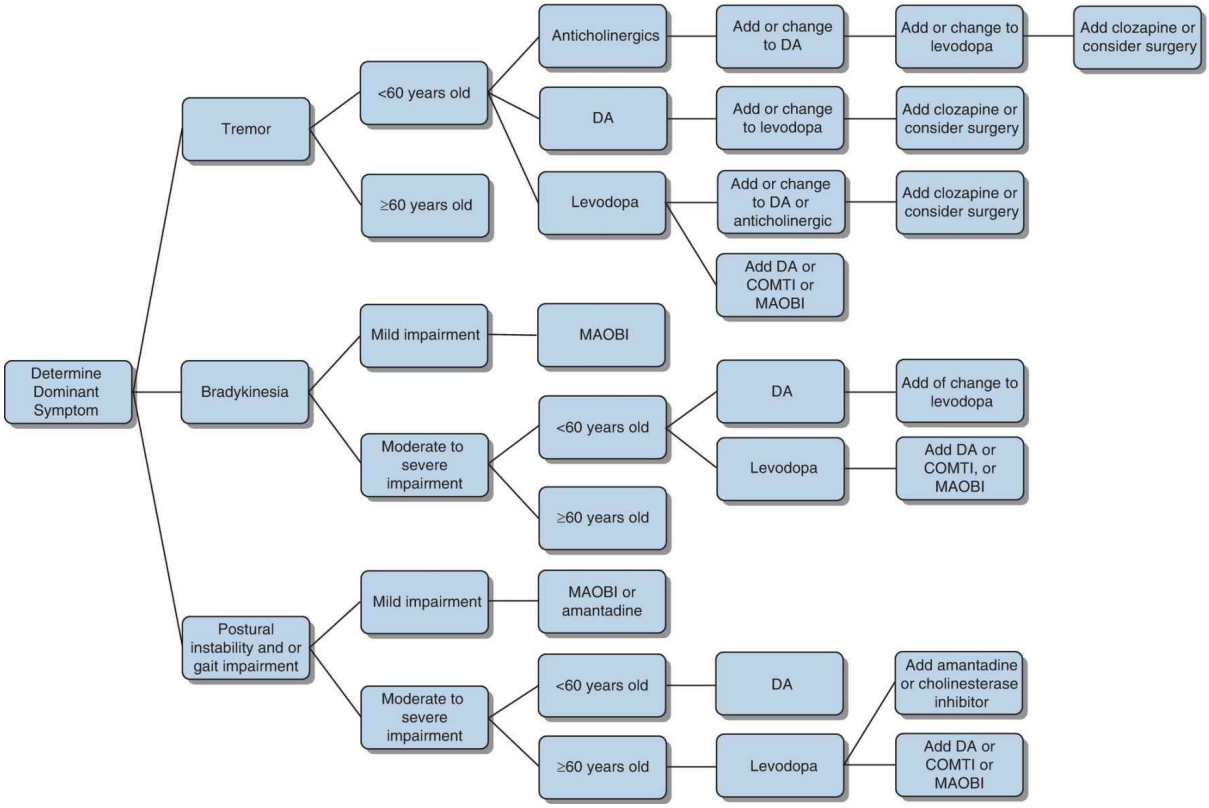

FIGURE 45.2 Treatment algorithm for PD. (MAOBI, monoamine oxidase type B inhibitors; COMTI, catechol-*O*-methyltransferase inhibitors; DA, dopamine agonists.)

Considerations with Mild- and Moderate- Potency Agents

Because of the cognitive side effects associated with anticholinergics and the conflicting evidence related to efficacy, the use of these agents is generally avoided. In younger patients presenting with tremor and fatigue, amantadine should be chosen over MAO-B inhibitors. However, MAO-B inhibitors are favored over amantadine in elderly patients and those with renal dysfunction. Selegiline may be preferred over rasagiline if cost or a positive urine test for amphetamine is a concern (Goetz & Pal, 2014).

Considerations with Moderate-Potency Agents

Cost and convenience typically direct the selection of a therapeutic option because there is no strong evidence of any agent being more effective than another in this class. Since most adverse drug effects are class effects, switching to another agent within the same class is unlikely to alleviate the problem. If adherence is an issue, selecting an ER formulation is recommended. The transdermal DA can reduce the risk of food or drug interactions within the GI system (Goetz & Pal, 2014).

Considerations with High-Potency Agents

The IR formulation is most effective particularly in early PD, since the other formulations

have a more variable absorption rate, resulting in a less predictable improvement in symptoms. Patients having difficulty with nighttime mobility may benefit from the CR formulation because the peak concentration is lower, causing less insomnia (Goetz & Pal, 2014).

Other Considerations

Mild- and even moderate-potency agents may not be the most appropriate choice for employed patients, regardless of symptom severity, since they can take several weeks to see the full effect, whereas levodopa has a rapid onset of action (Goetz & Pal, 2014).

For patients who experience the "wearing-off" phenomena, a few recommended management strategies include increasing the dose of the dopaminergic agent, adding on another dopaminergic medication, increasing the number of daily administrations, or adding a MAO-B or COMTI. Studies have compared the effectiveness of adding a MAO-B or COMTI, which has concluded that both therapeutic options similarly reduce "wearing-off" time (Connolly & Lang, 2014).

Special Considerations

Geriatric

A DA used as monotherapy can cause confusion and psychosis in the elderly and should be avoided, especially in patients with dementia. Geriatric patients, specifically those with cognitive dysfunction, are at the greatest risk for developing psychiatric adverse drug events and may benefit more from levodopa than a DA. Adverse effects of anticholinergics contribute to poor tolerability of this class of medications and it is therefore not recommended in the elderly (Connolly & Lang, 2014).

Genomics

As mentioned previously, there is a genetic link in the development of PD. Researchers have identified more than 24 genetic risk factors contributing to PD, including five "PARK" genes (Nalls et al., 2014). Because of this discovery, it is hypothesized that pharmacogenomics is going to play a huge role in emerging therapies for PD. One particular area of clinical development is using viral vectors to silence overexpressing genes that contribute to PD (Tarazi et al., 2014).

Treatment of Selected Nonmotor Symptoms

Psychological symptoms

Psychological symptoms include depression, psychosis, and dementia, which occur in about 25%, 55%, and 80% of patients, respectively (Connolly & Lang, 2014). Evidence in the literature for treating depression in PD is conflicting. Pramipexole and venlafaxine have been shown to be efficacious, while tricyclic antidepressants and dopaminergic drugs have been labeled as likely efficacious. There is unsatisfactory evidence to support the use of other agents including SSRIs, MAO-B inhibitors, omega-3 fatty acids, atomoxetine, and nefazodone. Clozapine and quetiapine have the most evidence to support their use in psychosis. Quetiapine is typically preferred, due to the agranulocytosis and frequent blood monitoring requirements associated with clozapine. Olanzapine, risperidone, and aripiprazole should not be used in PD because they do not reduce the incidence of hallucinations and actually increase the risk of motor deterioration. Donepezil, rivastigmine, and ziprasidone were also shown to be effective in reducing hallucinations. Patients with PD often develop cognitive impairment due to cholinergic dysfunction. Unfortunately, there are no published articles involving cholinesterase inhibitors in the treatment of PD-related cognitive impairment. Expert opinion concludes that although cholinesterase inhibitors provide variable and unpredictable benefit in patients with PD-related cognitive impairment, some patients experience marked improvement, and therefore, a trial is warranted (Connolly & Lang, 2014).

Sleep Problems

Insomnia, involving difficulty with initiation, duration, and/or maintenance of sleep, is the most common sleep disorder that affects patients with PD. Only the short-term treatment of insomnia in PD has been assessed with agents including carbidopa/levodopa, eszopiclone, melatonin, and modafinil. Of these agents, melatonin and the CR formulation of carbidopa/levodopa have been deemed possibly useful. Similarly, only short-term studies have evaluated the treatment of fatigue in PD with modafinil and methylphenidate, which have inconclusive efficacy (Connolly & Lang, 2014).

Autonomic or Other Problems

A patient with PD should be regularly evaluated for orthostatic hypotension, as it can be a significant issue in PD. Hypotension is not only a nonmotor symptom, but it is also an adverse effect of some PD drugs. This can complicate the treatment of hypertension in a patient with PD, so it is essential to monitor supine blood pressure in these patients. Fludrocortisone, midodrine, and indomethacin have been shown to be mildly effective at treating hypotension in patients with PD. Drooling can be an embarrassing nonmotor symptom that may affect patients with PD. Sublingual atropine drops and botulinum toxin

injections can aid in reducing drooling symptoms. Constipation is a significant problem in patients with PD. Not only can it be very uncomfortable for the patient, but over time, it can also lead to more serious complications, such as bowel obstruction, if left untreated (Connolly & Lang, 2014). To alleviate symptoms of constipation, stimulant laxatives and stool softeners can be utilized.

Monitoring Patient Response

The monitoring of patient response is multifactorial, considering the broad range of associated symptoms. The previously mentioned scales, such as MDS-UPDRS, can be used to assess disability and impairment, including motor and nonmotor symptoms, complications, and impact on daily living (Goetz et al., 2008). Monitoring plans should engage patients and caregivers, and symptom journals might help provide therapy-guiding information. It is important to establish appropriate therapy expectations early on, so that patients and caregivers understand the progressive nature of PD and which symptoms may be more likely to respond to drug therapy. Patient responses to varying medication doses, presence of dyskinesia, "on" and "off" time, dizziness, nausea, visual hallucinations, "wearing-off" effects, falls, sleep disturbances, abnormal behaviors, and mood or memory changes should be recorded and discussed. Practitioners should ensure that the patient and caregivers understand the prescribed medication regimen and administration instructions and treatment adherence should be gauged. Practitioners should evaluate and remedy adherence barriers, such as cost, adverse effects, regimen convenience, or understanding of regimen. Additionally, all health care professionals should monitor for drugs that can exacerbate parkinsonism or cognitive ability.

Patient Education

For a patient with PD, navigating a complex daily routine of medications and symptom management can be challenging. Patient needs and priorities will continue to change throughout disease progression, and it is important that patients have access to accurate, reliable information that is conveyed in understandable terms.

Drug Information

In 2011, the Movement Disorder Society released evidence-based medicine review updates for motor and nonmotor symptoms of PD (Fox et al., 2011; Seppi et al., 2011). A recent review of pharmacological treatment of PD written by Connolly et al. was published in the Journal of the American Medical Association in 2014 (Connolly & Lang, 2014). This publication contains several figures, tables, and algorithms that clarify the complex approaches to the medication management of PD. The American Academy of Neurology lists current guidelines and tools for both health care professionals and patients (AAN, 2015).

Patient-Oriented Information Sources

Organizations that provide patient-oriented information sources include the American Academy of Neurology, Parkinson's Disease Foundation, and Michael J. Fox Foundation for Parkinson's Research. The National Parkinson Foundation offers several publications, including manuals and checklists. This Web site also offers a smartphone application and allows patients to search for local chapters by indicating their state or zip code. The American Parkinson Disease Association also offers many patient-oriented publications, including books, educational supplements, and brochures. The U.S. Department of Transportation has a posting on their Web site entitled "Driving when you have Parkinson's Disease."

Nutrition/Lifestyle Changes

Nutrition and lifestyle considerations will vary based on patient-specific factors and should complement drug therapy. In more advanced stages of PD, patients may have speech or swallowing difficulties. Dysarthria is a motor speech disorder comprised of an assortment of speech characteristics. Speech therapy may show benefit with some symptoms of dysarthria, specifically with reduced vocal volume, imprecise articulation, and monotony of both pitch and loudness. Other elements of dysarthria, including hoarseness, may not improve. Speech therapy can also focus on drooling and swallowing issues, which can include slowed chewing, choking on liquids, and inability to eat food of various consistencies. The Lee Silverman Voice Treatment (LSVT) can have positive effects on voice quality, respiration, articulation, and even swallowing (Nijkrake et al., 2007). For patients with swallowing issues, a speech therapist can provide individualized dietary recommendations and recommend appropriate management strategies.

Patients may also have to manage bowel irregularities, which may develop with disease progression or as a result of medication side effects. For constipation, patients can make dietary adjustments to help alleviate this symptom. Increased fluid intake and consumption of high-fiber foods, such as fruits, vegetables, whole grains, beans, and prunes, can be helpful in maintaining bowel regularity. If dietary measures are insufficient in managing constipation, patients can use pharmacological agents, as mentioned previously.

Additional medication side effects that may require management include nausea and loss of appetite. These side effects may diminish over time, but patients can take some medications with a small snack to alleviate discomfort, initially. Other nutrition-related medication considerations involve treatment with levodopa. As mentioned previously, high-protein meals can decrease the effectiveness of levodopa. Patients should not aim to eliminate dietary protein but can instead limit protein portions to 3 to 4 ounces per meal, which is approximately the size of a bar of soap or a deck of cards. Additionally, patients should separate the administration of levodopa from meals, as described previously, and could shift protein consumption to the evening. Iron supplements may also decrease levodopa absorption, so patients should separate these by at least 2 hours. Long-term effects of altered diets should be carefully considered, along with the possible inconveniences.

Patients taking MAO-B inhibitors such as rasagiline or selegiline should avoid or limit tyramine-rich foods, as this can increase the risk of serotonin syndrome. These include aged cheeses, soybean products, red wine, tap beer, and cured, fermented, or air-dried meats or fish. Patients should work with nutritionists or dieticians when making significant dietary adjustments.

It is important for patients with PD to maintain bone density, as these individuals may be at a higher risk for developing osteoporosis and may also have an increased fall risk due to motor symptoms, which can result in fractures. Adults over 50 years of age should incorporate calcium-rich products, such as low-fat milk or yogurt or hard cheeses. Patients

should also consume vitamin D in the form of fortified dairy or juice products, egg yolks, breakfast cereal, or fatty fish, such as salmon, trout, mackerel, tuna, and eel. A 3-ounce salmon fillet contains approximately 450 IU of vitamin D. Sun exposure can increase vitamin D, although this should be balanced with the risk for skin cancer. Weight-bearing exercise can also contribute to the maintenance of bone health.

In addition to fortifying bones, high-intensity resistance exercises can improve muscle force production and mobility. A variety of exercise regimens have been studied, including progressive resistance exercise, which has a proposed impact on the mechanisms impacting bradykinesia and muscle weakness (David et al., 2012). Physical therapy is also beneficial in improving mobility and strengthening muscles for patients with PD. Benefits of physiotherapy have been described in six core areas including (1) gait; (2) transfers, such as rising from a chair or rolling over in bed; (3) balance; (4) body posture; (5) reaching and grasping; and (6) physical inactivity (Nijkrake et al., 2007).

There appears to be insufficient evidence to support or refute the use of acupuncture, biofeedback, manual therapy including chiropractic and osteopathic manipulation, or Alexander technique, which involves the development of awareness of posture in order to make improvements; however, this may result from a general lack of conducted studies (Nijkrake et al., 2007; Sucherowsky et al., 2006). These therapies are unlikely to induce harm, and patients may find them helpful in the establishment of a holistic PD management plan. Examples of other complementary therapies include tai chi to improve balance, qigong to help patients focus on breathing patterns, meditation and massage to help with relaxation, and acupuncture to help with sleep disturbances. Approximately 40% of patients with PD in the United States reportedly use at least one of these complementary therapies (Nijkrake et al., 2007). The extent of benefit may vary among patients, but patients should be encouraged to work with their health care team to individualize and optimize their PD management strategies.

Complementary and Alternative Medications

Several nonstandard pharmacologic and nonpharmacologic therapies have been explored in patients with PD. The seeds of the *Mucuna pruriens* plant contain levodopa. Although several small trials demonstrated effectiveness, the American Academy of Neurology concluded that there is currently insufficient evidence to support or refute the use of *M. pruriens* (AAN, 2015; Sucherowsky et al., 2006). Variability in standardization and preparation of this product may also lead to unreliable effects. A more recent study in primates suggested that this natural substance might act according to a different mechanism than levodopa (Lieu et al., 2012). *Vicia faba*, also known as fava beans, has also been shown to contain a minimal amount of levodopa and have been suggested for short-term benefit in PD, but evidence is lacking for the benefit of this product in PD (Sucherowsky et al., 2006).

In the early stages of PD, creatine has been explored as an option to strengthen muscles and slow the progression of PD; however, its benefit has not been demonstrated with this product. Neuroprotective effects of vitamin E at doses of 2,000 IU and coenzyme Q10 at doses ranging from 300 to 2,400 mg/d have been studied, but effectiveness has not been demonstrated for either supplement.

For patients experiencing orthostatic hypotension, increasing salt and fluid consumption, along with elevating the head of the bed, and wearing compression stockings can be beneficial. Rapid consumption of two 8-ounce glasses of cold water can also result in a prompt response.

A successful PD treatment approach, management strategy, and monitoring plan should ideally incorporate a complete team of interprofessional experts. This team may include, but is not limited to, primary care and specialist physicians, pharmacists, nurse practitioners, nurses, physician assistants, psychologists, occupational therapists, physical therapists, speech language pathologists, nutritionists, dieticians, social workers, and chaplains.

Case Study*

M.P. is a 66-year-old man with past medical history of hypertension and hyperlipidemia presenting to the clinic describing problems with balance and gait that have worsened in the past few months. A gait assessment reveals reduced arm swing while walking and a single halt hesitation when turning. During straight walking, he continues smoothly without freezing. The MDS-UPDRS reveals slight impairment related to postural instability and mild impairment related to both gait and freezing. Based on his history and physical exam, he is diagnosed with PD. Following his diagnosis, he mentions that he is considering retirement.

Diagnosis: Parkinson Disease

1. Which of the following is *not* an appropriate goal of therapy for M.P.?
   a. Maintain patient independence by alleviating motor symptoms.
   b. Preserve patient ability to perform activities of daily living.
   c. Reverse disease progression.
   d. Maintain patient quality of life by alleviating nonmotor symptoms.

2. What is the *most* appropriate initial therapy for M.P.?
   a. Amantadine 100 mg twice daily
   b. Carbidopa/levodopa IR 25 mg/100 mg three times daily
   c. Pramipexole IR 0.125 mg three times daily
   d. Benztropine 0.5 mg twice daily

3. In addition to the pharmacologic recommendation mentioned above, which of the below recommendations is *most* appropriate for M.P.?
   a. Referral to a speech therapist
   b. High-intensity resistance exercises
   c. Qigong
   d. Initiation of coenzyme Q10 300 mg daily

UNIT 10
Pharmacotherapy for Endocrine Disorders

46 Diabetes Mellitus

Lorraine Nowakowski-Grier ■ Veronica F. Wilbur

Diabetes mellitus is the term used to represent a clinically and genetically heterogeneous group of disorders characterized by abnormally high blood glucose levels (hyperglycemia) as a result of either insulin deficiency or cellular resistance to the action of insulin. Four major classifications of diabetes have been defined: type 1 diabetes mellitus (formerly known as *insulin-dependent diabetes mellitus*), type 2 diabetes mellitus (formerly known as *non–insulin-dependent diabetes mellitus*), gestational diabetes mellitus, and diabetes secondary to other conditions (e.g., hormonal abnormalities and pancreatic diseases).

According to the Centers for Disease Control and Prevention (CDC, 2014), there are more than 29.1 people with diabetes in the United States. Of this number, 90% to 95% have type 2 diabetes. Additionally, there is another 86 million who have a condition called *prediabetes* (CDC, 2014). The National Institute of Diabetes and Digestive and Kidney Diseases and the American Diabetes Association (ADA) found that diabetes was the seventh leading cause of death in the United States in 2006. Overall, the risk of death among people with diabetes is approximately twice that of people without diabetes. The annual medical costs for diabetes in the United States in 2013 were $245 billion in direct and indirect costs. This is a 41% increase in the overall dollar amount spent on all aspects of diabetes care.

Causes

Type 1 diabetes is thought to be an autoimmune disease in which pancreatic beta cells are destroyed. The beta cells are responsible for secreting insulin, a major hormone that promotes cellular uptake and use of glucose and maintains metabolic functions throughout the body. If the beta cells are destroyed, the pancreas produces no insulin, causing glucose levels in the blood to skyrocket. Onset can occur at any time, but most patients are younger than age 30.

Although type 1 diabetes is one of the most common chronic diseases in children, its etiology remains unclear. Suggested etiologies include genetic predisposition to the destruction of beta cells, infection, autoimmunity, and environmental factors. Viral agents are highly suspected in the pathogenesis of type 1 diabetes because mumps, rubella, varicella, measles, influenza, coxsackievirus, cytomegalovirus, and viral pneumonia have been reported to precede its onset. Furthermore, the incidence increases in the United States during the fall and winter, when viral infections are prevalent. Autoimmunity is evident because 80% of patients with type 1 diabetes test positive for specific human leukocyte antigen. It is likely that a combination of these factors contributes to the destruction of beta cells and the subsequent absence of insulin.

In type 2 diabetes, adipose and muscle cells become less sensitive to the actions of insulin or the pancreas produces less insulin than the body needs. In either situation, glucose levels in the blood escalate. Most patients with type 2 diabetes are older than age 30. Box 46.1 lists risk factors for type 2 diabetes; the major risk factors are obesity and family history. Both beta cell defects and insulin resistance are found in patients with type 2 diabetes.

BOX 46.1 Major Risk Factors for Type 2 Diabetes Mellitus

- Family history of diabetes (i.e., parents or siblings with diabetes)
- Obesity (i.e., 20% over desired body weight or body mass index greater than 27 kg. For Asian Americans, it is greater than 23 kg)
- Race/ethnicity (e.g., African Americans, Hispanic Americans, Native Americans, Asian Americans, Pacific Islanders have increased risk)
- Age older than 45 years
- Previously identified as having IFG (impaired fasting glucose)
- Hypertension
- High-density lipoprotein cholesterol level greater than 35 mg/dL or triglyceride level greater than 250 mg/dL
- History of gestational diabetes mellitus or delivery of babies weighing greater than 9

lb
- Sedentary lifestyle

In gestational diabetes, pregnancy causes the woman to become intolerant to glucose. The causes are not fully clear, but they appear to be related to the anti-insulin effects created by progesterone, cortisol, and human placental lactogen. Usually, once the woman has delivered her infant, blood glucose levels return to normal; however, women who have had gestational diabetes have a 20% to 50% chance of developing diabetes in the next 5 to 10 years.

Pathophysiology

In type 1 diabetes, the pancreatic beta cells are destroyed, causing a subsequent absence of insulin. In genetically susceptible people, an autoimmune attack occurs in which monocytes/macrophages and activated cytotoxic T cells infiltrate the islets. Multiple antibodies against beta cell antigens develop in the blood, and insulin reserve steadily decreases until the amount is insufficient to maintain a normal blood glucose level.

The pathogenesis of type 2 diabetes involves insulin resistance, impaired insulin secretion, elevated glucose production by the liver, or all these components. With insulin resistance, circulating insulin concentrations increase as compensation. Researchers have hypothesized that in type 2 diabetes, the ability of insulin to inhibit hepatic glucose production and to stimulate its uptake and use by adipose and muscle cells is diminished. In lean patients with type 2 diabetes, the primary defect appears to occur in the beta cells. In overweight patients, who represent most patients with type 2 diabetes, the most likely primary defect is impairment of the target cells. Although abnormal hepatic glucose metabolism plays an important role in maintaining the diabetic state, it is probably not the earliest development and most likely follows impaired insulin sensitivity in the muscle.

Insulin affects many body systems, and chronic hyperinsulinemia contributes to the pathogenesis and worsening of hypertension, dyslipidemia, and coronary heart disease. Hypertension, high plasma triglyceride levels, and low high-density lipoprotein (HDL) plasma levels correlate with hyperinsulinemia secondary to insulin resistance and a worsened cardiovascular risk profile. This collection of clinical markers or indicators associated with insulin resistance is referred to as *metabolic syndrome*.

Epidemiologic and interventional studies consistently point to the relationship between good glycemic control and the prevention or slowing of the progression of long-term complications of diabetes. The Diabetes Control and Complications Trial (DCCT) presented definitive evidence to support the hypothesis that diabetic complications are related to the degree of hyperglycemia. In this landmark study, patients with type 1 diabetes were randomized to two groups and followed for an average of 6.5 years. One group received conventional therapy (one or two daily insulin injections, daily self-monitoring of glucose, and diabetes education) to normalize blood glucose levels; the other group received intensive therapy (three or more daily administrations of insulin and glucose monitoring four times daily). The incidence of microvascular complications was 60% lower in the group that received intensive therapy than in the patients who received conventional therapy. Hence, intensive therapy delayed the onset of complications and slowed their progression. The UK Prospective Diabetes Study (UKPDS) Group answered the question as to whether the DCCT results could be extrapolated to include type 2 diabetes. In the UKPDS, patients with type 2 diabetes were randomized to intensive or conventional therapy and followed over a 10-year period. As in the DCCT, there was a significant (25%) risk reduction in microvascular end points with tight control.

Diagnostic Criteria

Patients with marked hyperglycemia present with the classic symptoms of polyuria (excessive urination), polydipsia (increased thirst), weight loss, polyphagia (increased hunger and caloric intake), and blurred vision. In type 1 diabetes, the onset of these symptoms usually is sudden and often preceded by ketoacidosis. In contrast, the course of development for type 2 diabetes is gradual, insidious, and frequently undiagnosed for years. The onset and sometimes the presence of symptoms often go unnoticed. Therefore, screening for diabetes as part of a routine medical examination is appropriate if a patient has one or more risk factors (see Box 46.1). The more risk factors that the individual has, the greater the chances are for him or her to develop or have diabetes. Because early detection and prompt treatment may reduce the impact of diabetes and its complications, screening is recommended for those at risk.

The new consensus for diagnosis includes use of hemoglobin A_{1C} (HbA_{1C}). Fasting plasma glucose (FPG) can also be used; less often, the oral glucose tolerance test (OGTT) is employed. Diagnosis can also be made on presentation with classic overt signs and symptoms of diabetes. FPG and now the HbA_{1C} are generally the easiest and least expensive diagnostic tests. Fasting is defined as no intake of food or beverage other than water for at least 8 hours before testing. The OGTT is still the preferred test for pregnant women, and it can be performed in either a one-step or two-step method. The key with pregnant women is careful risk assessment in the early stages of pregnancy regarding their risk of diabetes.

Normal glucose is defined as an FPG level of less than 100 mg/dL and a 2-hour post load glucose (PG) value in the OGTT of less than 140 mg/dL. A normal HbA_{1C} is less than 5.7 and can be obtained regardless of the last oral intake. Those who test higher than or equal to 6.5% should have repeat testing to confirm the diagnosis. An FPG level of 126 mg/dL or more or a 2-hour PG value in the OGTT of 200 mg/dL or more warrants repeat testing on a different day to confirm the diagnosis. Patients with an FPG of at least 100 mg/dL but less than 126 mg/dL have impaired fasting glucose (IFG). Patients with a 2-hour PG value of at least 140 mg/dL but less than 200 mg/dL in the OGTT are considered as having impaired glucose tolerance (IGT). Patients with IFG or IGT are now referred to as having *prediabetes*, indicating the relatively high risk of developing diabetes. Diagnostic criteria are presented in Table 46.1.

TABLE 46.1 Criteria for the Diagnosis of Diabetes Mellitus

Normoglycemia	Impaired Glucose Metabolism (Prediabetes)	Diabetes Mellitus
HbA_{1C} 4%–5.6%	5.7%–6.4%	$HbA_{1C} \geq 6.5\%$
FPG <100 mg/dL	FPG 100–125 mg/dL (IFG)	FPG ≥ 126 mg/dL
OGTT PG < 140 mg/dL	OGTT140–199 mg/dL (IGT)	≥200 mg/dL
Random plasma glucose ≥200 mg/dL and symptoms of diabetes mellitus		>200 mg/dL

FPG, fasting plasma glucose; HbA_{1C}, hemoglobin A_{1C}; IFG, impaired fasting glucose; IGT, impaired glucose tolerance; PG, plasma glucose.

Plasma glucose levels can be obtained from patients regardless of the time the patients last ate. Such levels are referred to as random plasma glucose levels. Any random plasma glucose level of 200 mg/dL or more is considered positive for diabetes and warrants additional testing, preferably by the FPG test on another day.

Many medications have adverse effect on glucose metabolism. While medications are not usually a true etiologic factor for diabetes, they can unmask less obvious glucose intolerance that had not yet been detected. Diuretics are one type of medication that is commonly blamed for "causing" diabetes. When used for hypertension therapy in people with diabetes, they may cause worsening of glucose control, probably facilitated by a loss of potassium. Often times, maintaining proper potassium replacement will eliminate some of the diuretic-induced glucose intolerance.

Initiating Drug Therapy

Effective treatment programs for diabetes mellitus require comprehensive training in self-management, ongoing support from the clinical care team, and, for many, intensive pharmacologic regimens. These programs must be individualized according to each patient's needs and should include the following features:

- Self-monitoring of blood glucose (SMBG)
- Medical nutrition therapy
- Regular exercise
- Drug therapy individualized for each patient
- Oral glucose-lowering agents for some patients with type 2 diabetes
- Instruction in the prevention and treatment of acute and chronic complications, including hypoglycemia
- Continuing patient education and support
- Periodic assessment of treatment goals

Treatment of abnormal glucose levels consists of diet and exercise. The cornerstone of therapy for all patients with diabetes is diet, but the goals of therapy differ between types 1 and 2 diabetes. In general, patients with type 1 diabetes are usually thin and present at or below ideal body weight. Therefore, the goals of diet are directed toward regulation of caloric intake and proper spacing of meals and snacks. In the presence of exogenously administrated insulin, these patients require proper timing of meals and routine activities to prevent episodes of hypoglycemia. Patients taking insulin should carry a source of simple sugar at all times in the event of hypoglycemia.

Because most patients with type 2 diabetes are overweight, the goal of treatment is directed toward weight reduction. Weight loss leads to improved glucose tolerance by enhancing the sensitivity of peripheral glucose receptors. Patients with type 2 diabetes can control the condition through diet and exercise alone. Physical activity and exercise are important in both prevention and the treatment of type 2 diabetes. Regular physical activity can prevent or delay the onset of type 2 diabetes and its complications. The Diabetes Prevention Program (DPP) was a landmark randomized clinical trial of 3,234 overweight individuals with prediabetes in the United States (2002). The DPP found lifestyle intervention to be more effective than metformin in preventing type 2 diabetes. The trial reported that intensive lifestyle intervention decreased the incidence of type 2 diabetes by 58%, compared with 31% in the group taking metformin.

If these interventions fail to achieve desirable glycemic control, practitioners should initiate drug therapy.

Goals of Drug Therapy

The major goals of drug therapy in diabetes mellitus have been established by the ADA and the American Association of Clinical Endocrinology (AACE), and while they are similar, there is some variance as follows:

Glycemic Control

American Diabetes Association

HBA_{1C} <7.0%. Individualized based on duration of disease, age/life expectancy, comorbid conditions, known CVD or advanced microvascular complications, hypoglycemia unawareness, individual patient considerations.

More (6.5%) or less (8.0%) stringent glycemic goals may be appropriate based on the above criteria.

American Association of Clinical Endocrinologist (AACE)

- HBA_{1C} ≤6.5% Individualized based on age, comorbidities, duration of disease
- Closer to normal for healthy
- Less stringent for “less healthy”

Both ADA and ACCE

- Preprandial plasma glucose level 80 to 130 mg/dL
- Postprandial plasma glucose level less than 180 mg/dL

Blood Pressure

- <140/90 mm Hg (125/75 for patients with proteinuria)

Lipids

- Low-density lipoprotein (LDL) level less than 100 mg/dL—no overt CVD
  LDL level less than 70 mg/dL—overt CVD
- Triglyceride level less than 150 mg/dL
- HDL level greater than 40 mg/dL (men)
  HDL level greater than 50 (women)

Microalbumin (Random Collection)

- <30 μg/mL creatinine

In type 1 diabetes, insulin is the mainstay of drug therapy. When diet and exercise alone do not achieve glycemic control of type 2 diabetes, drug therapy is indicated. In type 2 diabetes, oral agents with glucose-lowering effects are used. The ADA suggests that pharmacologic therapy be selected with consideration to the following factors:

- Degree of hyperglycemia and the presence or absence of symptoms
- Presence of comorbidity
- Patient motivation
- Patient preference

Sulfonylureas

Sulfonylureas are a major group of oral hypoglycemic agents used to treat type 2 diabetes (see Table 46.2). They correct derangements of carbohydrate, lipid, and protein metabolism.

TABLE 46.2 Overview of Oral Antidiabetic Agents

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Sulfonylureas			
FIRST GENERATION			
tolbutamide (Orinase) 0.25–3 g in 1 or 2 divided doses	Hypoglycemia, increased risk of cardiovascular disease	Ketoacidosis, sulfa allergy	Onset occurs within 1 h, lasts 6–12 h. Give with morning meal. Effectiveness may decrease over time. Increased hypoglycemia may occur in elderly or debilitated patients. Signs and symptoms of hypoglycemia may be masked in patients taking beta-blockers.
chlorpropamide (Diabinese) 100–750 mg qd Elderly start at 100 mg/d and others at 250 mg/d	Hypoglycemia	Same as above	Onset is 1 h, lasts 72 h. Same as above.
tolazamide (Tolinase) Initially 100–250 mg qd; increase weekly by 100–250 mg/d until desired blood glucose Maximum dose 1,000 mg/d	Hypoglycemia, increased risk of cardiovascular mortality	Same as above	Onset occurs within 4–6 h, lasts 10–14 h. Same as above.
SECOND GENERATION			
glyburide (DiaBeta, Micronase) Initially 2.5–5 mg qd; increase by 2.5 mg/wk until desired blood glucose Elderly patients start at 1.25 mg/d Maximum dose 20 mg/d	Hypoglycemia	Same as above	Onset occurs within 1.5 h, lasts 18–24 h. Same as above.
glyburide, micronized (Glynase) Initially 1.5–3 mg qd; 0.75 mg in elderly Maximum dose 12 mg/d	Same as above	Same as above	Onset occurs within 1.5 h, lasts 18–24 h. Same as above.
glipizide (Glucotrol) Initially 5 mg qd (2.5 mg in elderly); increase weekly to a maximum of 40 mg/d to desired blood glucose	Same as above	Same as above	Patients should take medication 30 min before a meal. Onset occurs within 1 h, lasts for 10–24 h. Same as above.
glimepiride (Amaryl) Initially 1–2 mg with breakfast; increase by 2 mg/wk until desired blood glucose Maximum dose 8 mg/d	Same as above	Same as above	Onset occurs within 2–4 h, lasts 24 h. Same as above.
BIGUANIDE			
metformin (Glucophage) Initially 500 mg bid; increase by 500 mg/wk until desired blood glucose	GI distress: diarrhea, nausea, bloating, flatulence Rare lactic acidosis	Renal dysfunction, CHF, metabolic acidosis, ketoacidosis, impaired hepatic function, excess alcohol consumption, pregnancy	Patients should take with meals to minimize GI side effects. Medication must be temporarily held when the patient is undergoing IV iodinated contrast study.
Generic (Trade) Name and Dosage	**Selected Adverse Events**	**Contraindications**	**Special Considerations**
Maximum dose 2,550 mg/d in divided doses			Modest synergistic effect may occur when given with sulfonylurea. Medication should be held for patients undergoing surgery.
Thiazolidinediones			
rosiglitazone (Avandia) Initially 4 mg/d in single dose; if response is inadequate after 12 wk, increase to 8 mg/d in single dose	Anemia, edema, headache, reversible increase in ALT	Children, ketoacidosis	Monitor ALT at baseline, every 2 mo for the first 12 mo and periodically thereafter. Discontinue medication if ALT is greater than three times the upper limit of normal or if jaundice occurs. Medications may increase plasma volume; caution is necessary for patients with New York Heart Association class III and IV heart failure. Monitor for increased risk of myocardial infarction. Resumption of premenopausal ovulation may occur in anovulatory women. Unintended pregnancy may result. Use restricted for patients unable to take pioglitazone or to manage their blood sugar.
pioglitazone (Actos) 15–30 mg/d Maximum 45 mg/d as monotherapy and 30 mg/d as combined therapy	Same as above	Same as above	Same as above. Increased risk of CHF but without myocardial infarction.
α-Glucosidase Inhibitors			
acarbose (Precose) Initially 25 mg tid with the first bite of a meal; increase by 25 mg at 4- to 8-wk intervals to a maximum of 300 mg in three divided doses (150 mg if weight <60 kg)	Flatulence, diarrhea, abdominal pain/distention	Renal dysfunction, ketoacidosis, inflammatory bowel disease, colonic ulceration; predisposition to intestinal obstruction; disorders of digestion	Patient should take with first bite of each meal.
miglitol (Glyset): Same as above	Same as above	Same as above	Same as above.
Meglitinide Analogs			
repaglinide (Prandin) Initially 0.5 mg with two to four meals daily if the patient has never received other treatment for diabetes; if previous treatment, 1–2 mg with two to four meals daily Double dose weekly to a maximum of 16 mg/d	Hyperglycemia, upper respiratory tract infection, headache, diarrhea, constipation, arthralgia, back or chest pain	Type 1 diabetes, ketoacidosis	As monotherapy or in conjunction with metformin, medication is to be taken within 30 min of a meal. Patient should skip a dose if he or she skips a meal and add a dose if he or she adds a meal.
nateglinide (Starlix) Initially 120 mg before each meal to a maximum dose of 360 mg/d	Same as above	Same as above	Same as above.
DIPEPTIDYL PEPTIDASE-4 INHIBITORS			
sitagliptin (Januvia) 100 mg oral daily or 50 mg oral daily	Common to both acute upper respiratory infection, urinary tract infection, headache Must adjust dosage to mild renal insufficiency Increases tendency toward hypoglycemia when combined with sulfonylureas	Type 1 diabetes	
saxagliptin (Onglyza) 2.5 or 5 mg daily	Potential for acute pancreatitis, hypersensitivity to medication	History of pancreatitis	Same as above
alogliptin (Nesina) 6.25 ng, 12.5 mg, or 25 mg daily	Same as above		
linagliptin (Tradjenta) 2.5 or 5 mg daily	Same as above		
vildagliptin (Galvus) 50 or 100 mg daily	Same as above		
Sodium–Glucose Cotransporter 2 Inhibitors			
canagliflozin (Invokana) 100 or 300 mg daily dapagliflozin (Farxiga) 5 or 10 mg daily empagliflozin (Jardiance) 10 or 25 mg daily ipragliflozin (Suglat) 25, 50, or 100 mg daily	Hyperkalemia mycotic infections, urinary tract infections, and renal insufficiency, hypotension	Type 1 diabetes or DKA, severe kidney disease (eGFR 30 mL/min/1.73), or on hemodialysis	Monitor potassium and LDL cholesterol monitoring. Check blood pressure and symptoms of mycotic infections.

Mechanism of Action

Sulfonylureas bind to specific receptors on beta cells, causing adenosine triphosphate (ATP)-dependent potassium channels to close. The calcium channels subsequently open, leading to increased cytoplasmic calcium, which stimulates the release of insulin. Theorists have hypothesized that these drugs also have extrapancreatic effects involving the liver, muscle, and adipose cells, but because these agents are ineffective in patients with type 1 diabetes, it appears that their predominant hypoglycemic action is on the beta cells. When used alone, these agents have the most significant effect on blood sugar, especially in patients who are lean and insulinopenic.

Dosage

Sulfonylureas are divided into first- and second-generation agents. All of this class should be started at the lowest dose and titrated as needed to reach target blood glucose levels. Second-generation drugs are more potent and more widely used than first-generation agents. Comparison of these drugs by potency and other pharmacologic properties is presented in Table 46.3.

TABLE 46.3 Comparison of Oral Sulfonylureas

Drug	Equivalent Therapeutic Dose (mg)	Duration of Action (h)	Doses per Day	Adverse Events (%)	Hypoglycemic Reactions (%)
First Generation					
tolbutamide	1,000	6–12	2–3	3	<1
tolazamide	250	12–24	1–2	2	<1
acetohexamide	500	12–18	2	4	<1
chlorpropamide	250	24–72	1	8	<4–6
Second Generation					
Long-acting glipizide	10	12–24	1–2	5	<2–4
Long-acting glipizide	5–10	24	1	5	<1
Long-acting glyburide	5	16–24	1–2	7	<4–6

Approximately one third of patients with type 2 diabetes fail to respond adequately to sulfonylureas, most often because of markedly impaired beta cell function, not adhering to diet, or stressful events such as infection. After 10 years of therapy, only 50% of initial responders have adequate glycemic control. For optimal response, careful patient selection should include the following criteria: duration of disease less than 5 years, no history of prior insulin therapy or good glycemic control on less than 40 units/day of insulin, close to normal body weight, and FPG less than 180 mg/dL.

Adverse Events

The most important complication of the use of sulfonylureas is hypoglycemia. In the elderly population, this risk is greatest secondary to comorbidity, polypharmacy, or poor

social situations (e.g., isolation, financial constraints). In younger patients, hypoglycemia may be associated with alcohol abuse or overexertion. Sulfonylureas are classified in pregnancy category C. However, prospective studies with glyburide (pregnancy category B) in rats and rabbits revealed no harm to the fetus, and retrospective human data suggest that glyburide may be suitable option for pregnant women unable or unwilling to use insulin. Many drugs are excreted in human milk; sulfonylureas should not be administered to nursing women. Safety and efficacy of sulfonylureas have not been established for children.

Contraindications

Long-acting agents (e.g., chlorpropamide [Diabinese]) place elderly patients with other underlying disorders at risk for prolonged and sometimes fatal hypoglycemic episodes. Drugs with active metabolites also may increase the risk of hypoglycemia in patients with impaired renal function. Hence, patient education must include recognition of symptoms as well as prevention and treatment plans for hypoglycemia. Sulfonylureas can cause weight gain of about 2 to 3 kg. They cannot be used in patients with sulfa allergies. Baseline renal and hepatic function levels should be documented prior to starting sulfonylurea therapy.

Interactions

Patients taking sulfonylureas may enhance sensitivity to sunlight, so patients should be advised to use appropriate sun protection. Certain drugs may increase the effectiveness of sulfonylureas resulting in hypoglycemia; a select list of commonly prescribed includes ciprofloxacin (especially with glyburide), clofibrate, gemfibrozil, H_2 antagonists, probenaid, sulfonamides, and tricyclic antidepressants. Drugs that may decrease the effectiveness of the sulfonylureas, resulting in hyperglycemia, include the following: beta-blockers, calcium channel blockers, cholestyramine, corticosteroids, diazoxide, estrogens, hydantoins, isoniazid, nicotinic acid, oral contraceptives, phenothiazines, rifampin, sympathomimetics, thiazide diuretics, thyroid medications, and urinary alkalinizers.

Biguanides

Biguanides are not considered hypoglycemic agents, because their major pharmacologic action does not increase insulin secretion. They can be used in conjunction with diet as first-line monotherapy or in combination with other classes of diabetic drugs, including insulin, to treat type 2 diabetes (see Table 46.2). Their mechanisms of action and side effect profiles differ from those of sulfonylureas, offering notable advantages. Biguanides do not cause hypoglycemia (when used as monotherapy) and do not promote hyperinsulinemia or weight gain.

Mechanism of Action

This class inhibits hepatic glucose production and moderately improves peripheral sensitivity to insulin. Gluconeogenesis and glycogenolysis are inhibited in the liver. Glycemic control is achieved without stimulating insulin secretion, so hypoglycemia does not develop. Metformin can also decrease intestinal absorption of glucose and improve insulin sensitivity in skeletal muscle. The oral bioavailability is 50% to 60%, and food decreases the bioavailability with a slight delay in the absorption of metformin. Metformin does not bind to liver or plasma proteins and is primarily excreted by the kidneys. Other advantages of biguanides over sulfonylureas include their tendency to induce weight loss and promote favorable effects on lipid profiles. In addition, in certain patients, biguanides can be combined effectively with sulfonylureas, thiazolidinediones (TZDs), or insulin because their mechanisms of action differ. Biguanides are the agents of choice in patients who exhibit secondary failure to sulfonylureas. In view of their many beneficial effects, biguanides appear to be a more rational choice than sulfonylureas for first-line therapy in patients with newly diagnosed type 2 diabetes. Metformin is available in over 100 combinations with other oral agents from sulfonylureas, TZDs, dipeptidyl peptidase-4 inhibitors (DPP4-i), and sodium–glucose cotransporter 2 (SGLT-2) inhibitors, refer to the discussion about cited drugs further in this chapter for review of individual agents.

Dosage

The dose of metformin is started low and increased weekly as needed to the maximum. Patients usually take the medication before meals in the morning and evening. The dose is carefully titrated in elderly patients. With metformin, the starting dose is 500 or 850 mg daily or twice daily, with increases every 1 to 2 weeks to a maximum of 2,550 mg/d. Peak action is within 2 to 2.5 hours, and the effects last for 10 to 16 hours. Steady-state levels of the drug are achieved in 24 to 48 hours. Metformin also comes in an extended-release formula. It is started at 500 mg daily with the evening meal and increased to a maximum of 2,000 to 2,550 mg daily.

Contraindications

Metformin is contraindicated in males with a serum creatinine levels of greater than 1.5 mg/dL and in females with levels greater than 1.4 mg/dL, heart failure, and pregnancy. This class also is contraindicated in children, alcoholics, binge drinkers, those over age 80, and those with dehydration. The presence of hepatic dysfunction can predispose patients receiving metformin to lactic acidosis. Metformin is classified in pregnancy category B. It is not known whether metformin is excreted in human milk. Nursing women should discontinue nursing to avoid hypoglycemia in breast-feeding infants. Patients must stop taking metformin when undergoing radiologic studies with iodinated contrast the day of and restart the metformin in 2 days when renal function has returned. Patients should also stop taking metformin, when experiencing metabolic acidosis and before surgery until they resume normal oral intake. Metformin may restore ovulation in women, who were anovulatory due to insulin resistance.

Adverse Events

The most common side effect of metformin therapy is gastrointestinal (GI) upset, which includes diarrhea, nausea, vomiting, abdominal bloating, flatulence, anorexia, and a metallic taste in the mouth. Such problems occur in approximately 30% of patients during the initiation of therapy and usually resolve with continued treatment. To minimize these adverse effects, treatment is started with a low dose and increased slowly at no less than weekly intervals. Instruct patients to take metformin with meals to reduce GI side effects.

Because GI upset is rare late in therapy, any sudden onset of severe vomiting or diarrhea at that time should alert providers to the possibility of lactic acidosis, a rare but potentially fatal complication of metformin therapy. In such cases, patients should discontinue metformin immediately until they can be evaluated and stabilized. From the data collected in Europe over 20 years, the reported worldwide incidence of metformin-induced lactic acidosis is 0.03 cases/1,000 patient-years. The risk of lactic acidosis increases with advancing age and worsening renal function. Therefore, metformin is contraindicated in patients with renal disease or dysfunction and acute or chronic metabolic acidosis. Renal dysfunction may be secondary to a variety of comorbid conditions such as cardiopulmonary insufficiency, liver disease, alcoholism, and infection. These conditions predispose patients to impaired perfusion of tissues and decreased elimination of lactate and are therefore contraindications to the use of metformin. In addition, patients should temporarily discontinue metformin during any situation in which an acute decline in renal function may occur (e.g., aggressive diuresis, dehydration from gastroenteritis, surgery).

The concomitant use of metformin with cimetidine increases the risk of hypoglycemia. The concomitant use of metformin with glucocorticoids or alcohol increases the risk of lactic acidosis.

Metformin use over the age of 80 is not contraindicated, but due to the deterioration of renal function of the elderly, glomerular filtration rate (GFR) testing should be done at the beginning of therapy and periodically thereafter.

Interactions

While metformin itself does not cause hypoglycemia, combination therapy with sulfonylureas, meglitinides, or insulin can be associated with hypoglycemia.

Thiazolidinediones

This class of antidiabetic agents (Table 46.2) reduces insulin resistance at sites of insulin action.

Mechanism of Action

TZDs bind to the nuclear steroid hormone receptor peroxisome proliferator–activated receptor gamma and increase insulin sensitivity in the skeletal muscle and fat. Clinically, they decrease peripheral insulin resistance and at higher doses may decrease hepatic glucose production. Like biguanides, they improve the action of insulin without directly stimulating insulin secretion from the pancreatic beta cells. There is an improvement of endothelial function, preservation of beta cell function, and a decrease in albumin excretion.

Dosage

Therapy is usually started at the lowest dose, with gradual increases to reach plasma glucose goals. TZDs should be taken with the main meal of the day. The dose varies according to the agent used.

TZDs are classified in pregnancy category C and are not indicated for use during pregnancy, for breast-feeding women, or children. In addition, increased risk fracture in women and macular edema has also been observed with TZD therapy.

There may be small increases in HDL-C, and LDL-C may occur with rosiglitazone.

A concern specific to pioglitazone is the possible increased risk of bladder cancer. Interim results reported an increased risk of bladder cancer with increasing cumulative dose and duration of therapy. Based on these and other data, pioglitazone was withdrawn from use in France 2011, and no new prescriptions are authorized for patient in Germany. The studies done here in the United States have not been able to reproduce this statistical significance; therefore, it is considered safe to use in the United States.

In 2011, access to rosiglitazone was restricted by the FDA due to meta-analysis from the RECORD trial findings, which suggested that rosiglitazone may increase the relative risk of myocardial infarction. Later in 2014, the FDA re-evaluated the data determining that an increased risk of myocardial infarction could not be attributed specifically to the use of rosiglitazone; therefore, restricted distribution was removed. Currently, rosiglitazone is available alone and in combination with metformin in the United States.

Adverse Events

Pioglitazone may cause reduced concentrations of combined oral contraceptives; therefore, patients using oral contraceptives should consider alternative contraception methods.

In premenopausal anovulatory women with insulin resistance, ovulation may resume

when drugs of this class are used. Thus, the patient may be at risk of unintended pregnancy, and contraception should be considered. Because of increased plasma volume from this class of drugs, TZDs are not recommended for patients with New York Heart Association class III or class IV heart failure. Another contraindication is active liver disease. TZDs can stimulate weight gain from plasma volume expansion and generation and redistribution of fats into the subcutaneous compartments.

Adverse Effects

Serum transaminase levels (AST, ALT) should be monitored prior to initiating therapy and periodically thereafter per the clinical judgment of the health care provider. Liver function studies should also be obtained in the presence of hepatic dysfunction symptoms such as abdominal pain, fatigue nausea, vomiting, or dark urine. TZD therapy should be discontinued in the presence of jaundice. Edema, shortness of breath, rapid weight gain, and other signs and symptoms of heart failure should be included in assessing TZD therapy. Hypoglycemia may develop in patients taking this class of drug with insulin or sulfonylureas because TZDs are potent sensitizers of insulin. If this occurs, the drug should be discontinued or the dose of insulin or sulfonylurea should be reduced. TZDs require several weeks to achieve the maximum benefit from a dosage level. Patients experiencing edema/swelling, shortness of breath, or muscle aches should contact their health care provider.

Interactions

As a class, TZDs are effected by other drugs that are strong CYP2C8 inhibitors, such as gemfibrozil, and other drugs that induce CYP2C8, such as rifampin. Others to be used with caution include digoxin, fexofenadine, midazolam, nifedipine, and warfarin. α-Glucosidase inhibitors

Alpha-glucosidase Inhibitors

Mechanism of Action

The enzyme α-glucosidase, found on the brush border of the intestine, is necessary for the absorption of starch and disaccharides. This class of drugs (Table 46.2) acts by slowing the absorption of carbohydrates from the intestines, minimizing the postprandial rise in blood sugar. The result of this delay is decreased levels of postprandial glucose and HbA_{1C}. The α-glucosidase inhibitors are most useful in patients with postprandial hyperglycemia and patients with very high HbA_{1C} levels and poor dietary adherence. They are useful in patients from ethnic groups with high-carbohydrate diets, such as Asians and Hispanics. Due to the limited ability of these drugs to lower HBA_{1C} and their side effect profile, they are not commonly used as monotherapy but as adjuncts to existing therapy.

Dosage

Agents from this class Acarbose (Precose) and Miglitol (Glyset), can be prescribed alone or with a sulfonylurea. Patients should take each dose with the first bite of each meal. Dosages are increased gradually (at 4- to 8-week intervals) to avoid GI side effects. The starting dose is 25 mg three times a day at the start of each meal. This regimen lasts for 4 to 8 weeks; then, the dose may be increased to 50 mg three times a day. After 3 months at 50 mg, the dose can be increased to 100 mg three times a day. Peak concentration occurs in 2 to 3 hours. Patients using alpha-glucosidase inhibitors should be encouraged to maintain physical movement, especially after a meal to limit the buildup of GI tract gas. The medication should be taken with the first bite of food.

Contraindications

Patients with inflammatory bowel disease, colonic ulceration, obstructive bowel disorders, or chronic intestinal disorders of digestion or absorption should not use these agents. Acarbose is contraindicated in patients with cirrhosis of the liver and not recommended in patients with serum creatinine levels of greater than 2.0 mg/dL or a creatinine clearance of less than 25 mL/min. Alpha-glucosidase inhibitors are classified in pregnancy category B. This drug should be used during if pregnancy only if clearly needed. These drugs should not be administered to nursing women. Elevation of serum transaminases (AST or ALT) has been observed in clinical trials in patients taking acarbose at a dose of 200 to 300 mg daily. Liver function should be periodically monitored. A 2-hour postprandial glucose measurement is useful to assess the therapeutic response during the dosage titration period. Additional monitoring should include serum aminotransferases every 3 months during the first year of therapy and periodically thereafter to monitor for liver toxicity.

Adverse Events

The most common side effects involve the GI tract. Increased fermentation secondary to the delay in carbohydrate absorption increases intestinal gas, causing flatulence, diarrhea, and abdominal distention.

Interactions

Intestinal adsorbents such as charcoal antagonize this class of drugs. The α-glucosidase inhibitors may decrease the levels of propranolol and ranitidine.

Meglitinide Analogs

Mechanism of Action

Meglitinide analogs are rapid-acting insulin secretagogues that stimulate the release of insulin from the pancreas in response to a meal (see Table 46.2). Binding at characterized sites closes the ATP-dependent potassium channels in the membranes of the beta cells. This causes a depolarization of the beta cells and an opening of calcium channels. The resulting increased influx of calcium causes insulin secretion.

Meglitinide analogs are effective in patients who become hypoglycemic while taking sulfonylureas and have acceptable FPG readings but high postprandial blood glucose levels. They also are effective for patients with irregular meal schedules because patients take them at meals. Repaglinide (Prandin) and nateglinide (Starlix) are the two drugs available in this class. They lower postprandial blood glucose concentrations without any significant effects on FPG level.

Dosage

Meglitinide analogs can be used as monotherapy or in combination with other oral agents. The starting dose of repaglinide is 0.5 mg before meals if the HbA_{1C} level is less than 8.0. If the HbA_{1C} concentration is greater than 8.0, the starting dose is 1 to 2 mg, taken 15 minutes (but no longer than 30 minutes before each meal). Patients must add a dose if they add another meal or skip a dose if they skip a meal. The dose may be doubled to 4 mg before meals to a maximum of 16 mg a day. Nateglinide is similarly administered with a starting dose of 60 to 120 mg before meals.

The peak level is achieved in 1 hour. In 96 hours, the body excretes 90% of the medication. Meglitinide analogs are contraindicated in patients with diabetic ketoacidosis. Take right before eating. Due to potential for hypoglycemia, those taking this medication should be advised to monitor blood glucose levels.

Contraindications

Type 1 diabetes, DKA, severe infection, surgery, trauma, or other severe stressors. Repaglinide and nateglinide are classified in pregnancy category C and are not indicated for use during pregnancy, for breast-feeding women, or for children. Elderly, debilitated, or malnourished patients and those with adrenal, pituitary, or hepatic insufficiency are susceptible to the hypoglycemic effects.

Adverse Events

Adverse events include hypoglycemia, GI disturbances, upper respiratory infections, headache, diarrhea, constipation, arthralgias, and back or chest pain.

Interactions

Concomitant use with beta-blockers or alcohol increases the risk of hypoglycemia. Ketoconazole, miconazole, erythromycin, and other cytochrome P-450 (CYP450) 3A4 inhibitors may potentiate the drug, as may nonsteroidal anti-inflammatory drugs, aspirin, sulfonamides, and warfarin. Drugs such as rifampin, barbiturates, thiazides, phenothiazines, phenytoin, sympathomimetics, calcium channel blockers, and isoniazid may antagonize it.

Dipeptidyl Peptidase-4 Inhibitors

Mechanism of Actions

Physiologically in response to a glucose load, two incretin hormones, glucose-dependent insulinotropic polypeptide and glucagon-like peptide 1 (GLP-1), are released from the distal bowel. These hormones account for up to 50% of the response to postprandial glucose. However, dipeptidyl peptidase-4 (DPP-4), which is a surface enzyme, inactivates GLP-1, therefore decreasing the levels of circulating GLP-1 and glucoregulatory functions. The class of agents called DPP-4 inhibitors acts to block the effect against GLP-1 and ultimately increase the amount of native active circulating incretins (see Table 46.2).

Currently, there are five DPP-4 inhibitors (DPP-4i), sitagliptin (Januvia) and saxagliptin (Onglyza), linagliptin (Tradjenta), vildagliptin (Galvus), and alogliptin (Nesina), on the market. These medications are indicated for daily administration and coadministration with other oral antidiabetic agents and insulin.

Dosage

DPP-4i drugs are administered once daily. Sitagliptin has one starting dose of 100 mg daily. Dosage should be decreased to 50 mg daily for patients with moderate renal insufficiency, defined by creatinine clearance greater than 30 mL/min but less than 50 mL/min. Sitagliptin has also been precombined with metformin. The sitagliptin dose is 50 mg with either 500 or 1,000 mg of metformin. It is also approved in combination therapy with sulfonylureas, TZDs, and insulin.

Saxagliptin has two doses, 2.5 or 5 mg, also prescribed daily. The starting dose of 2.5 mg is used for patients with mild renal insufficiency. Saxagliptin is a strong CYP3A4/5 inhibitor, which interacts with other drugs that use that pathway. Like sitagliptin, it is approved for combination therapy with sulfonylureas and TZDs but not insulin.

Contraindications

The contraindications for both medications are similar and include hypersensitivity to the agent and type 1 diabetes; caution should be used in patients with renal impairment. Only sitagliptin is contraindicated in the patient with a history of pancreatitis. All the DPP-4i inhibitors are classified in pregnancy category B. This drug category is not approved for children.

Adverse Events

The most common adverse effects are the same for sitagliptin and saxagliptin and include upper respiratory infection, urinary tract infection, and headaches when compared to placebos. Both drugs have potential for hypoglycemia when given in combination therapy

with sulfonylureas. Additional postmarketing reports for sitagliptin include hypersensitivity reactions, such as anaphylaxis, angioedema, rash, urticaria, cutaneous vasculitis, and exfoliative skin conditions including Stevens-Johnson syndrome; hepatic enzyme elevations; and potentially fatal pancreatitis.

Interactions

Sitagliptin has no pharmacokinetic drug–drug interactions, but it pharmacodynamically potentiates the action of sulfonylureas and insulin. As a potent CYP3A4/5 inhibitor, saxagliptin interacts with drugs such as ketoconazole, erythromycin, and diltiazem. When DPP-4i drugs are used on combination with sulfonylureas, doses of the sulfonylureas may be reduced to avoid hypoglycemia.

Incretins

This class is also called glucagon-like peptide 1 receptor (GLP-1R) and used as adjunctive therapy to diet and exercise in type 2 diabetes.

Mechanism of Action

The mechanism of action is to stimulate glucose-dependent secretion of insulin from pancreatic beta cells while suppressing the inappropriate release of glucagon from alpha cells. It slows gastric emptying, therefore increasing satiety. Fasting and postprandial glucose are reduced with the use of incretins. As euglycemia is approached, insulin secretion subsides, therefore avoiding hypoglycemia by the response of glucagon. Incretins are not a substitute for insulin, but augment the natural physiologic responses to elevated blood sugar levels. There are presently five GLP-1R agonists available: exenatide (Byetta, Bydureon), liraglutide (Victoza), albiglutide (Tanzeum), and dulaglutide (Trulicity).

Dosage

Exenatide (Byetta) is only available as an injectable and can be used as monotherapy or in conjunction with other oral agents, metformin, sulfonylureas, TZDs, and insulin. The starting dose is 5 mcg, administered within the 60 minutes before morning and evening meals or prior to the largest meals of the day and spaced more than 6 hours apart. Based on response, in 1 month, the dose can be increased to 10 mcg twice a day. If a dose is missed, the treatment should be restarted at the next scheduled dose time.

Liraglutide may be administered once daily at any time. The initial dose of 0.6 mg/d is not effective for glycemic control, but should be administered for 1 week to reduce GI symptoms; once initial dose is tolerated, it should be increased to 1.2 mg daily; if glycemic goals are still not met after 2 to 4 weeks, the dose may be increased to the maximum 1.8 mg/d.

The extended release of exenatide (Bydureon) is dosed once weekly, and timing of the injection may be performed without regard to meals.

Albiglutide (Tanzeum) is a long-acting GLP-1R agonists; it can be given once a week. Its fusion with albumin extends its half-life. The initial dose is 30 mg once weekly. It can be increased to 50 mg with or without food. There is no adjustment of renal impairment. There are less GI effects with this GLP-1R.

Dulaglutide (Trulicity) may be administered once weekly. What makes this unique is it has a hidden needle and requires not reconstitution. When used with a hypoglycemic agent, GLP-1R agonists may cause hypoglycemia; therefore, patients should be cautioned to monitor blood glucose levels carefully.

Contraindications

Contraindications to GLP-1R agonists include type 1 diabetes, ketoacidosis, and allergy. GLP-1R agonists should be avoided in patients with severe GI disorders, including gastroparesis. GLP-1R is classified in pregnancy category C, and nursing women should either discontinue the drug or discontinue nursing. Both exenatide and liraglutide may delay and reduce the peak concentration of digoxin, lisinopril, lovastatin, and acetaminophen. Exenatide is associated with acute pancreatitis, including fatal and nonfatal, and hemorrhagic or necrotizing pancreatitis based on postmarketing data.

Liraglutide causes thyroid C-cell tumors in both male and female mice and rats; it is unknown whether liraglutide causes thyroid C-cell tumors in humans.

Patients with a personal or family history of medullary thyroid carcinoma or multiple endocrine neoplasia syndrome type 2 should not take liraglutide. Alternative therapy should be considered.

Adverse Events

The most common adverse reactions to exenatide are GI related, including nausea, vomiting, diarrhea, and dyspepsia. Hypoglycemia is also a concern when exenatide is prescribed in combination with a sulfonylurea. Caution should be exercised with any dose increase to monitor for signs and symptoms of pancreatitis, especially severe abdominal pain with or without vomiting. Exenatide should be stopped immediately with any of these signs.

Interactions

Due to the decrease in gastric emptying, exenatide should not be administered close to drugs that have a narrow therapeutic window. Caution should be exercised when patients are taking warfarin, and the international normalized ratio should be monitored closely with drug initiation and dose changes. Exenatide can possibly decrease in the ethinyl estradiol component of oral contraceptives; therefore, exenatide and oral contraceptives should not be administered within 1 hour of each other.

After initiation of therapy or dose increases with GLP-1R agonists, patients should be monitored for signs and symptoms of pancreatitis.

Dopamine Receptor Agonists

Dopamine receptor agonists are used as monotherapy in type 2 diabetes or secondary diabetes with substantial capacity for insulin production. The mechanism by which dopamine receptor agonists improve glycemic control is unknown. Following morning administration of bromocriptine mesylate (Cycloset), postprandial glucose levels are improved without increasing plasma insulin concentrations.

Dosage

The dose of bromocriptine mesylate is 0.8 mg taken 2 hours after waking with the first meal of the day. The dose may be increased by 0.8 mg each week until the maximal tolerated daily dose of 1.6 to 4.8 mg is achieved. Bromocriptine mesylate should be taken 2 hours after waking with the first meal of the day. Patients should notify their health care provider regarding symptoms of orthostatic hypotension such as dizziness, nausea, or diaphoresis.

Contraindications

Bromocriptine mesylate is classified in pregnancy category B. It also inhibits lactation and should not be administered to nursing women. Additionally, there may be an increased risk of hypotension and syncope with bromocriptine upon increase in dose. Exacerbation of psychotic disorders or reduction in the effectiveness of drug that treat psychosis may occur when bromocriptine is coadministered.

Concomitant use of bromocriptine mesylate with other dopamine receptor agonists indicated for the treatment of Parkinson disease, restless leg syndrome, acromegaly, and other disorders is not recommended. Bromocriptine mesylate is highly bound to serum proteins and may increase unbound fraction of other highly protein-bound drugs (e.g., salicylates, sulfonamides, chloramphenicol, and probenecid), resulting in altered effectiveness.

Adverse Events

The most common side effects include somnolence, nausea, fatigue, dizziness, vomiting, and headache. Monitoring blood glucose monitoring should include some premeal and postmeal readings to assess the effectiveness of the medication. Patients should also be assessed for signs and symptoms of orthostatic hypotension.

Interactions

Bromocriptine mesylate is highly bound to serum proteins; therefore, it may increase the unbound fraction of other concomitantly used highly protein-bound therapies (e.g., salicylates, sulfonamides, chloramphenicol, and probenecid), which may alter their

effectiveness and risk for side effects.

Amylin Analog

A recombinant form of amylin is pramlintide (Symlin). This is an injectable agent that is a synthetic of the pancreatic neurohormone amylin, which is cosecreted with insulin from beta cells in response to food. Pramlintide has three actions as an amylinomimetic agent. First, it helps to delay gastric emptying into the small intestine, which delays the rise in postprandial glucose release. This effect lasts for approximately 3 hours and does not alter nutrient absorption. Second, pramlintide alters the release of additional inappropriate glucagon by pancreatic alpha cells, which is abnormal in diabetes. Finally, there is an increase in satiety, which decreases the total calorie intake and promotes weight loss. Pramlintide can be used to treat type 1 or type 2 diabetes. It is also approved for use with insulin.

Dosage

The initiation and dosage of pramlintide differs for type 1 and type 2 diabetes; however, the management of changes in dosage, side effects, and monitoring blood sugar levels is the same for both. The starting dose for those with type 1 diabetes is 15 mcg just prior to any major meal. If tolerated, pramlintide is titrated by 15 mcg increments to a total dose of 30 to 60 mcg. Patients with type 2 diabetes also administer pramlintide just prior to any major meal at 60 mcg per injection. The dose is increased to 120 mcg in 3 to 7 days if there is no nausea. Both patients with type 1 and type 2 diabetes must reduce their current insulin regimen by 50%. The titration of pramlintide is based on blood glucose levels and the presence or absence of nausea. Close monitoring of blood glucose levels is very important to detect hypoglycemia. If significant nausea occurs, the dosage should be decreased until the drug is tolerated. If nausea persists even at the lowest dose, pramlintide should be discontinued.

Contraindications

Few physiologic contraindications exist for those whom pramlintide is appropriate; however, it is critical to select appropriate patients. Those with poor adherence to diabetic care regimens, those with HbA_{1C} greater than 9%, those taking drugs that increase gastric motility gastroparesis, and pediatric patients should not take pramlintide. Additional precaution exists for anyone with known hypersensitivity to the product. Studies have shown no effects on the drug in those with renal or liver disease and are approved as safe. Pramlintide is categorized in pregnancy category C. The major concern is the risk of hypoglycemia. This effect is not actually due to the pramlintide, but rather secondary to making the insulin more effective.

Adverse Events

Nausea is the most common side effect. Gradual titration to the recommended dose

reduces this reaction. Other side effects include nausea, vomiting, headache, and anorexia.

Interactions

Pramlintide must not be mixed together with regular, NPH, or 70/30 insulin in the same syringe and must be administered as separate injections. It also has the potential to delay the absorption of concomitantly administered oral medications such as analgesics, antibiotics, and oral contraceptives. Patients who are taking drugs that alter gastric motility such as anticholinergics should not take pramlintide or alpha-glucosidase inhibitors. Interaction can also occur with oral antidiabetic products, ACE inhibitors, and fibrates, fluoxetine, and sulfonamide antibiotics.

Sodium-Glucose Co-transporter 2 (SGLT2) Inhibitors

This category of medication functions to induce glycosuria through the kidneys independent of insulin secretion by inhibiting the SGLT-2 system. Normally, 90% of filtered glucose is reabsorbed through SGLT-2 transport system in the proximal tubule of the kidney. A normal glucose load in the tubules is approximately 120 mg/min, and due to reabsorption there is almost no glucose excretion in the urine. To promote blood sugar control, SGLT-2 inhibitors will cause an approximately 60% excretion of glucose in the urine. The SGLT-2 inhibitors include empagliflozin (Jardiance), canagliflozin (Invokana), and dapagliflozin (Farxiga).

Mechanism of Action

All drugs in this class block the action of SGLT—resulting in increased excretion of glucose in the urine. The reduced ability to reabsorb tubular glucose results in lower plasma glucose and potentially excess calorie in fat accumulation. Using canagliflozin (Invokana), one study showed a weight loss of ≥5% from baseline occurred for the 100-mg dose and the 300-mg dose (Cefalu et al., 2015). Glucose control is enhanced by allowing increased insulin sensitivity and uptake of glucose in the muscle cells, decreased gluconeogenesis, and improved first-phase insulin release from the beta cells.

Dosage

Empagliflozin is started at 10 mg po in the morning and can be titrated up to 25 mg. The medication should be discontinued for persistent estimated glomerular filtration rate (eGFR) less than 45. The initial dose of canagliflozin is 100 mg before the first meal for the day. The dose can be increased to 300 mg daily in patients with normal kidney function, defined as eGFR greater than 60 mL/min/1.73 m. The dose should remain at 100 mg daily for patients with impaired kidney function (eGFR between 45 mL/min/1.73 m and 60 mL/min/1.73 m). The initial dose for dapagliflozin is 5 mg with or without food. The dose can be increased to 10 mg. Do not initiate or discontinue dapagliflozin if eGFR less than 60 mL/min/1.73 m.

Contraindications

SGLT-2 inhibitors should not be used to treat type 1 diabetes or diabetes ketoacidosis (DKA). Patients with severe kidney disease (eGFR, 30 mL/min/1.73) or on hemodialysis should not use SGLT-2 inhibitors.

Adverse Events

This class of drug can cause hyperkalemia, mycotic infections, urinary tract infections, and

renal insufficiency. SGLT-2 inhibitors are classified in pregnancy category C and should not be administered to nursing women or children. Risk of hypotension may be increased in patients with low volume status, which can be found in patients taking diuretics, angiotensin-converting enzyme inhibitors, or angiotensin receptor blockers. These patients should be carefully monitored and have fluid status corrected before starting an SGLT-2. The increased glucose excretion is associated with increased urinary frequency. The high urinary glucose concentration also predisposes patients to genital mycotic infections and urinary tract infections. SGLT-2 inhibitors may cause hyperkalemia, especially in patients with decreased kidney function; therefore, careful monitoring of potassium is indicated. Increases in LDL cholesterol have also been observed. Routine HBA_{1C} monitoring should be accompanied by potassium and LDL cholesterol monitoring. Check blood pressure and symptoms of mycotic infections.

Interactions

Some of the commonly prescribed drugs that need to be monitored with this class include sulfonylureas, amlodipine, carvedilol, and cortisone. See Table 46.2 for further information.

Combination Oral Medication for Type 2 Diabetes

There are many fixed-dose combination products of two or three different drug classes available to treat type 2 diabetes. Many patients find it easier to take a single medication as opposed to two separate medications, therefore improving overall drug adherence. Fixed-dose combinations are generally tried after a patient has failed to reach reduction of their hyperglycemic goals based on one drug alone. The drawback of using these combination medications is the cost. In some cases, the combinations cost more than each drug separately. In addition, starting combination therapy in drug-naive patients can create problems determining the specific cause of drug-induced side effects or allergic reactions.

Insulin

Insulin is the only drug therapy of choice for all patients with type 1 diabetes and for those patients with type 2 diabetes who cannot control their condition with diet and exercise alone or in whom oral therapy fails. Other clinical situations in which insulin therapy is appropriate include newly diagnosed cases of type 2 diabetes presenting with severe, symptomatic hyperglycemia, pregnancy, and surgery.

Just like the insulin normally produced by the pancreas, insulin as drug therapy regulates glucose metabolism in the muscle and other tissues (except the brain). It causes the rapid transport of glucose and amino acids intracellularly, promotes anabolism, and inhibits protein catabolism. In the liver, it promotes the uptake and storage of glucose in the form of glycogen, inhibits gluconeogenesis, and promotes the conversion of excess glucose into fat.

The major characteristics of insulin preparations are onset of action and duration of action (Table 46.4). Semisynthetic insulin, which is produced by recombinant deoxyribonucleic acid technology, has the identical amino acid composition as human endogenous insulin and is therefore referred to as *human insulin*. Human insulin preparations lower the risk of local reactions. An insulin analog, lispro insulin, is a two amino acid modification of regular human insulin. Aggregates do not form when lispro insulin is injected subcutaneously, allowing for a more rapid onset and shorter duration than regular insulin and minimizing the postprandial rise in blood sugar and the risk of late hypoglycemia. Another human insulin analog is insulin glargine.

TABLE 46.4 Insulins

Preparation	Brand	Onset (h)	Peak (h)	Duration (h)
Very Rapid Acting				
Insulin analog	Humalog	<0.5	0.5–3	3–5
	NovoLog	<0.5	1–3	3–5
	Glulisine	<0.5	1	2–4
Short Acting				
Insulin injection				
	Humulin R	0.5	2–4	6–8
Regular (R)	Novolin R	Same	Same	Same
Intermediate Acting				
NPH	Humulin N	1–4	4–12	14–26
	Novolin N			
Long Acting				
Insulin extended zinc suspension (U)	Humulin U	4–6	8–20	24–36
Insulin glargine	Lantus	1–2	None	24
	Toujeo	3–4	None	>24
Insulin detemir	Levemir	1	None	24
Combination				
Fixed combination	70/30 (NPH/regular ratio)	30–60 min	Dual	10–16 h
	50/50 (NPH/regular ratio)	5–15 min	Dual	10–16 h
	75/25 (NPL/lispro ratio)	5–15 min	Dual	10–16 h
	70/30 (NPA/aspart ratio)	5–15 min	Dual	10–16 h

Insulins are categorized as basal (NPH, glargine, and detemir) or bolus (regular, lispro, and aspart). Initial insulin doses should be individualized in patients previously untreated with insulin. The preferred method of insulin therapy administration is through a basal insulin plus a bolus insulin 15 minutes before the start of each meal.

Insulin harvested from animal sources is no longer manufactured. Human insulin is less antigenic than beef insulin and slightly less antigenic than pork insulin. Insulin analogs and U-500 insulin all require a prescription.

The concentrations of insulin currently available in the United States are U-100 and U-500, indicating 100 units/mL and 500 units/mL. U-500 insulin is available for patients with extreme insulin resistance. A goal of insulin therapy is to mimic, as nearly as possible, the physiologic profile of insulin secretion (basal/bolus). The evolution of insulin management has moved from a single daily injection therapy to multiple injections with multiple insulin products. This pattern allows the opportunity to adjust the prandial insulin (rapid-acting or regular) doses based on the results of the blood glucose checks and food quantity consumed while targeting specific glucose levels. Most programs are very similar in terms of the prandial insulin (see Figure 46.1).

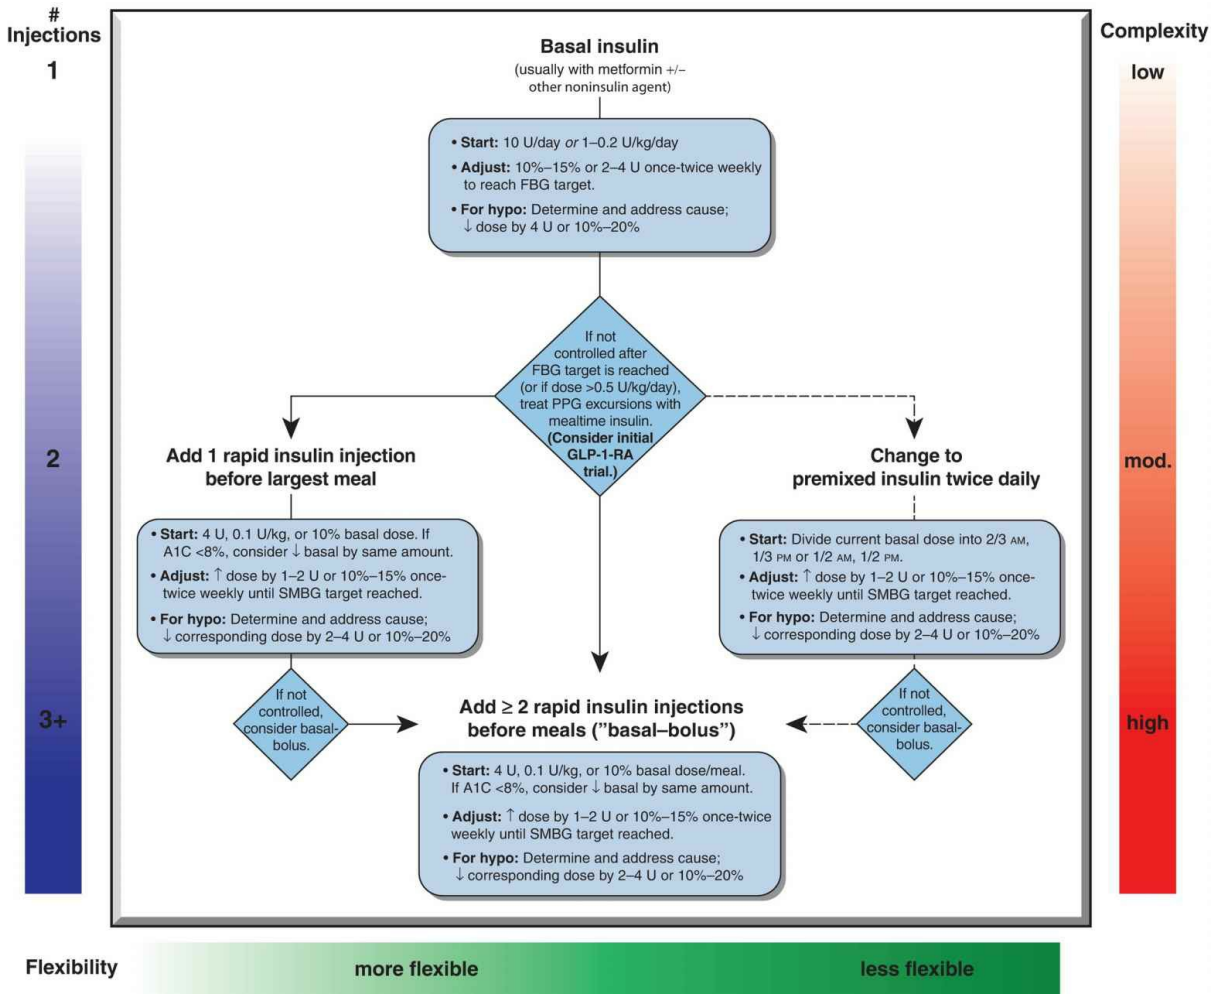

FIGURE 46.1 Algorithm for pharmacotherapy for insulin management. (Reprinted with permission from American Diabetes Association. (2015). Approaches to glycemic treatment. Diabetes care. *Diabetes Care*, 38(Suppl. 1), S41–S48. doi: 10.2337/dc15-S010. Copyright © 2015, American Diabetes Association.)

There are various ways to providing the basal insulin. One common regimen for programs using insulin injections is providing a basal insulin that is long acting and peakless such as glargine or detemir, then adding short-acting insulin for meals. Another method of administration is to utilize an insulin pump with only short-acting insulin. The pump provides continuous insulin subcutaneously as an infusion in very small doses. Basal insulin and boluses are administered through the pump to cover for ingestion of carbohydrates and blood sugars out of range from normal. The goal is to normalize the blood sugars with insulin administration as much as possible

In the past, multiple doses of an intermediate insulin, neutral protamine hagedorn (NPH), have provided basal insulin before the availability of peakless basal insulins. While NPH can still work well as a basal insulin for some people, the ease of the new peak less basal insulins has led to best practice and predominance of usage.

Premixed insulins that contain both basal and prandial (biphasic) insulins are

commercially available as 70/30, 50/50, or 75/25. This insulin regimen may be appropriate for patients who have difficulty mixing their own insulins or for those in whom these ratios are effective. However, for intensive insulin regimens, these insulins are usually not recommended.

Dosage

When staring insulin therapy, take the total daily amount of insulin that can be determined based on this general calculation: 0.55 × Total Weight in Kilograms. For example, total daily insulin dose = 0.55 × 70 kg = 38.5 units of insulin/day. For type 2 diabetes, there are two ways to start insulin. First, insulin may be supplemental or as an additional agent added to one or more oral agents. Typically, single daily injections are used, commonly starting between 10 and 20 units depending on the size of the person and the degree of hyperglycemia.

Secondly, type 2 diabetes can also be treated with insulin as the sole pharmacologic agent requiring at least two or more injections per day. In two injection regimens, insulin is administered in the morning before breakfast and before the evening meal or at bedtime. This regimen may include only intermediate-acting insulin; doses of regular or rapid acting can be added. Insulins mixed with long-acting or intermediate-acting insulin, or premixed formulations (i.e., mixtures such as Humalog Mix 75/25 or NovoLog Mix 70/30), are dosed twice a day. One injection before breakfast and one injection before dinner. Rapid-acting or regular insulin doses are adjusted based on glucose levels in the targeted range of about 100 to 150 mg/dL. Algorithmic adjustments can be up or down by amount such as 1 or more units for every 50 to 100 mg/dL glucose increment:

- 2 units if FBG greater than 120 mg/dL
- 4 units if FBG greater than 140 mg/dL
- 6 units if FBG greater than 180 mg/dL

Insulin doses should be individualized and closely monitored. In lieu of empiric estimations, however, the following guidelines can be used for total daily dosage:

- Children and adults: 0.5 to 0.6 units/kg/d
- Adults during illness or adolescents: 0.5 to 0.75 units/kg/d
- Adolescents during a growth spurt: 1.25 to 1.5 units/kg/d
- Pregnancy: 0.7 units/kg/d

If two doses are given a day, it is recommended that two thirds of the total daily dose be given in the morning with a 2:1 ratio of intermediate- to short-acting insulin and one third of the total daily dose be given before dinner with a 1:1 ratio of short-acting insulin and intermediate-acting insulin.

Doses should be adjusted based on the patient's clinical response, as evidenced by blood glucose levels. Adjustments are made in 1 to 2 unit increments. Insulin must be

decreased with hypoglycemia and increased with hyperglycemia. Table 46.5 provides some suggestions on when dosages need adjusting. For information on time frame for response, see Table 46.4. Insulin glargine and detemir is given at bedtime and cannot be mixed with other insulins. The advantage of using the basal insulins includes:

TABLE 46.5 Adjusting Insulin Dosages Based on Clinical Response

Problem	Time Experienced	Possible Solutions
Hyperglycemia	Fasting	If the patient is receiving a single dose of an intermediate-acting insulin, split into two doses: ⅔ of total dose before breakfast, ⅓ of total dose before supper. If the patient is receiving split-dose insulin, increase presupper dose or move to later in the evening.
	Midmorning	Add Regular to morning dose to achieve a ratio of 2:1 (intermediate to Regular).
	Midafternoon	Increase morning NPH or Lente dose. Add Regular at lunch.
	Bedtime	Add or increase Regular with presupper dose.
	Early morning (2:00–3:00 AM)	Give the presupper dose later in the evening. Give Regular at bedtime.
Hypoglycemia	Fasting	Decrease evening insulin dose.
	Midmorning	Decrease or omit prebreakfast dose of Regular.
	Midafternoon	Decrease morning NPH or Lente.
	Bedtime	Add a bedtime snack. Decrease presupper dose of Regular.
	Early morning (2:00–3:00 AM)	Consider Somogyi effect—decrease evening NPH.

- Provides a smooth basal effect than patterns using multiple injections for intermediate insulin
- Provides moderate flexibility in timing of meals
- Very effective in mimicking normal physiologic acting patterns
- Very effective in controlling the fasting glucose without increasing nocturnal hypoglycemia
- Less weight gain than NPH-based regimens

The 1,500 rule can be used to determine the change needed in the insulin dose. The insulin sensitivity factor (ISF) is determined by dividing a constant (1,500) by the total daily dose (TDD) of insulin. This determines the change in blood glucose from 1 unit of insulin. The formula is as follows: ISF = 1,500/TDD. For example, if the patient takes 50 units of insulin in 24 hours, the ISF is 1,500/50 = 30.

Therefore, each unit of insulin lowers the blood glucose level of 30 mg/dL. If the SMBG at noon is 170, an addition of 2 units in the morning should lower the blood glucose level to 110 mg/dL.

Adverse Events

Hypoglycemia, hypokalemia, lipodystrophy, and local or systemic allergic reaction can occur with insulin. The dawn phenomenon, so-called for worsening hyperglycemia that occurs in the early morning hours, is caused by growth hormone surges that occur during sleep. The Somogyi effect, which also may be mistaken for inadequate control, is a rebound

of hyperglycemia that occurs after an early morning episode of insulin-induced hypoglycemia. The hypoglycemia goes unnoticed because it happens while the patient is sleeping, at approximately 3:00 AM. Signs and symptoms include night sweats, nightmares, sleep disturbances, and early morning headaches. Monitoring of blood glucose when hypoglycemia is thought to be occurring helps make the diagnosis.

Interactions

There are many drugs that can interact with insulin either causing hypoglycemia or hyperglycemia. The following are the most common drug interactions associated with the use of insulin:

Salicylates, beta-blockers, monoamine oxidase inhibitors, alcohol, and sulfa drugs potentiate insulin. Corticosteroids, isoniazid, niacin, estrogens, thyroid hormones, thiazides, phenothiazines, and sympathomimetics antagonize it.

Continuous Glucose Monitoring

Glucose monitoring has come a long way from dipstick measurements of urine glucose, to glucose meters and strips, to the present era in continuous glucose monitoring or "CGM." CGM uses a disposable sensor that measures interstitial glucose every few minutes, 24 hours a day. The patient inserts the sensor subcutaneously just underneath the skin, replacing it every 3 to 7 days. The sensor transmits glucose readings to a separate receiver or insulin pump. These glucose readings can provide both the patient and clinician a "video" perspective on the overall glucose patterns throughout the day and night. The blood sugars can then be correlated with factors such as food intake or activity and can assist with achieving glycemic control. Indications for CGM include frequent hypoglycemia, hypoglycemia unawareness, and elevated HBA_{1C} despite multiple adjustments in treat plan.

Special Considerations

Pediatric/Adolescent

Until the mid-1990s, type 1 diabetes was the prevalent type of diabetes in children and adolescents. Type 2 diabetes for children is on the rise worldwide, and the mean age is approximately 13.5 years (Rosenbloom et al., 2009). The greatest risk factors are childhood obesity and inactivity. Diabetes is often discovered with glycosuria on a random urinalysis. A red flag for type 2 diabetes in adolescents is acanthosis nigricans, dark pigmentation in skin creases and flexural area. This is a sign of insulin resistance and is present in 60% to 90% of adolescents with type 2 diabetes. It is often easier to see on a physical exam of non-Caucasians, due to having more skin pigmentation. Hypertension is present in 20% to 30% of adolescents with type 2 diabetes. In type 1 diabetes, children present with inappropriate polyuria, dehydration, poor weight gain, and ketonuria.

Treatment for type 1 diabetes in children is insulin therapy. Doses are:

- 0.7 mg/kg before puberty
- 1.0 mg/kg midpuberty
- 1.2 mg/kg after puberty

These children should be treated by a specialist.

Treatment for type 2 diabetes is weight loss, medical nutritional therapy, exercise, and, in many cases, medication. The only drugs approved for adolescents are insulin and metformin.

Geriatric

Diabetes in the elderly is often complicated by coexisting conditions. Complications develop at an accelerated rate probably because poor glycemic control has been long standing. Also, the elderly usually have a decrease in renal function. Exercise programs for the elderly have to be started carefully with comorbid conditions in mind.

Pregnancy

There are two types of diabetes during pregnancy. One is pregestational diabetes, present before the pregnancy. This is treated by a specialist during pregnancy and is considered very high risk. The most common is gestational diabetes, which is glucose intolerance detected during pregnancy and associated with probable resolution after pregnancy. Experts now believe that high-risk women found to have diabetes at pregnancy should be diagnosed with overt diabetes, not just gestational diabetes.

During pregnancy, human placental lactogen plays a pivotal role in triggering glucose intolerance. It has an anti-insulin and lipolytic effect. Peripheral insulin sensitivity decreases

to 50% of the first trimester while during the third trimester, while basal hepatic glucose output increases by 30%.

Screening is recommended between weeks 24 and 48. There are two choices for screening. Women can have a two-step test, with a 50-g one-hour glucose load, followed by a 3-hour glucose tolerance test if necessary. A second alternative is a one-step test, with a 75-g two-hour test.

In the gestational diabetic, multiple daily SMBG is required, and it can often be controlled by diet and medical nutritional therapy. If this does not control glucose levels, insulin is required.

Potential neonatal complications include shoulder dystocia, hypoglycemia, polycythemia, and respiratory distress.

Selecting the Most Appropriate Agent

Insulin is necessary in all cases of type 1 diabetes. In patients with type 2 diabetes, various oral agents as monotherapy or in combination therapy can be prescribed, because the oral agents act in different ways. Table 46.6 lists the potential decrease in HbA_{1C} with each agent. Table 46.7 shows first- and second-line agents for patients with type 1 diabetes. Table 46.8 shows first-, second-, and third-line therapy for patients with type 2 diabetes (Figure 46.2). The ultimate goal of controlling glycemia is to avoid hyperosmotic symptoms of hyperglycemia, instability of blood sugar over time, and prevent or delay complications from diabetes.

TABLE 46.6 Capacity to Decrease HbA_{1C} by Agent/Class of Drugs

Agent	Decrease in HbA_{1c}
insulin	>2%
sulfonylurea	1%–2%
biguanide	1.5%–2%
TZD	0.5%–1.8%
α-glucosidase inhibitor	0.5%–1%
meglitinide	0.6%–1.8%
sitagliptin	1%
sitagliptin with biguanide	1.8%
saxagliptin	0.1%–0.3%
GLP-1 agonists	0.4%–0.9%
SGLT-2 inhibitors	0.5%–0.9%

TABLE 46.7 Recommended Order of Treatment for Type 1 Diabetes Mellitus

Order	Agents	Comments
First line	Four-injection regimen, a long-acting insulin such as insulin glargine once a day and a rapid-acting or short-acting insulin administered at mealtimes or a combination of intermediate and short acting; dose is 0.5–0.6 units/kg/d	Several schedules are used to administer insulin (see **Table 46.5**). The most commonly used regimen is four injections a day. This regimen best duplicates normal physiologic insulin. The second regimen would be two injections a day, one in the morning and one in the evening. This promotes glycemic control both during the day and while sleeping. The insulin dose required is divided into ⅔ of the dose in the morning and ⅓ of the dose in the evening. The morning dose is divided into ⅔ intermediate insulin and ⅓ short- or rapid-acting insulin. The evening dose is ½ intermediate insulin and ½ short- or rapid-acting insulin.
Second line	Insulin dose is gradually increased	Adjustments are made at 1 to 2 units at a time over 3 d. Adjustments are based on SMBG records.

TABLE 46.8 Recommended Order of Treatment for Type 2 Diabetes Mellitus

Order	Agents	Comments
Entry HBA_{1c} <7.5		
First line	Monotherapy with an oral agent: biguanides, GLP-1, DPP4-i, and AG-i	The rule for initiating therapy with any of these agents is to start slowly and increase the dose every 1–2 wk as needed. The patient can be switched to another drug or class after 1 mo if the therapy is not effective in achieving glycemic control. Biguanides are the drugs of choice in the patient with metabolic syndrome X and when the blood glucose levels are <250 mg/dL. The α-glucosidase inhibitors are most effective in patients with postprandial hyperglycemia but only mild fasting glucose elevations.
Second line	SGLT-2, TZD, and SU/GLN	Sulfonylureas are the best choice if the patient is thin, older than age 40, has had diabetes for <5 y, and has a blood glucose >250 mg/dL. Glyburide is most effective in patients with fasting hypoglycemia, and glipizide is most effective in patients with postprandial hyperglycemia. Start with a single timed dose of 10 units of insulin with dose adjusted weekly (2 units if FPG >120 mg/dL; 4 units if FPG >140 mg/dL; 6 units if FPG >180 mg/dL).
Entry HBA_{1c} >7.5		
First line Second line	Metformin or another first-line agent, combinations of sulfonylureas and biguanides, TZDs, or α-glucosidase inhibitors are effective. Also, metformin can be combined with a meglitinide or TZD for effective control	Again, the dose is started at the lowest level and increased every 1–2 wk as needed.
Entry HBA_{1c} >9.0%		
First line	Consider starting insulin therapy and slowing wean back Triple oral therapy and consider additional basal insulin and short-acting boluses	Oral medications at the same dose.

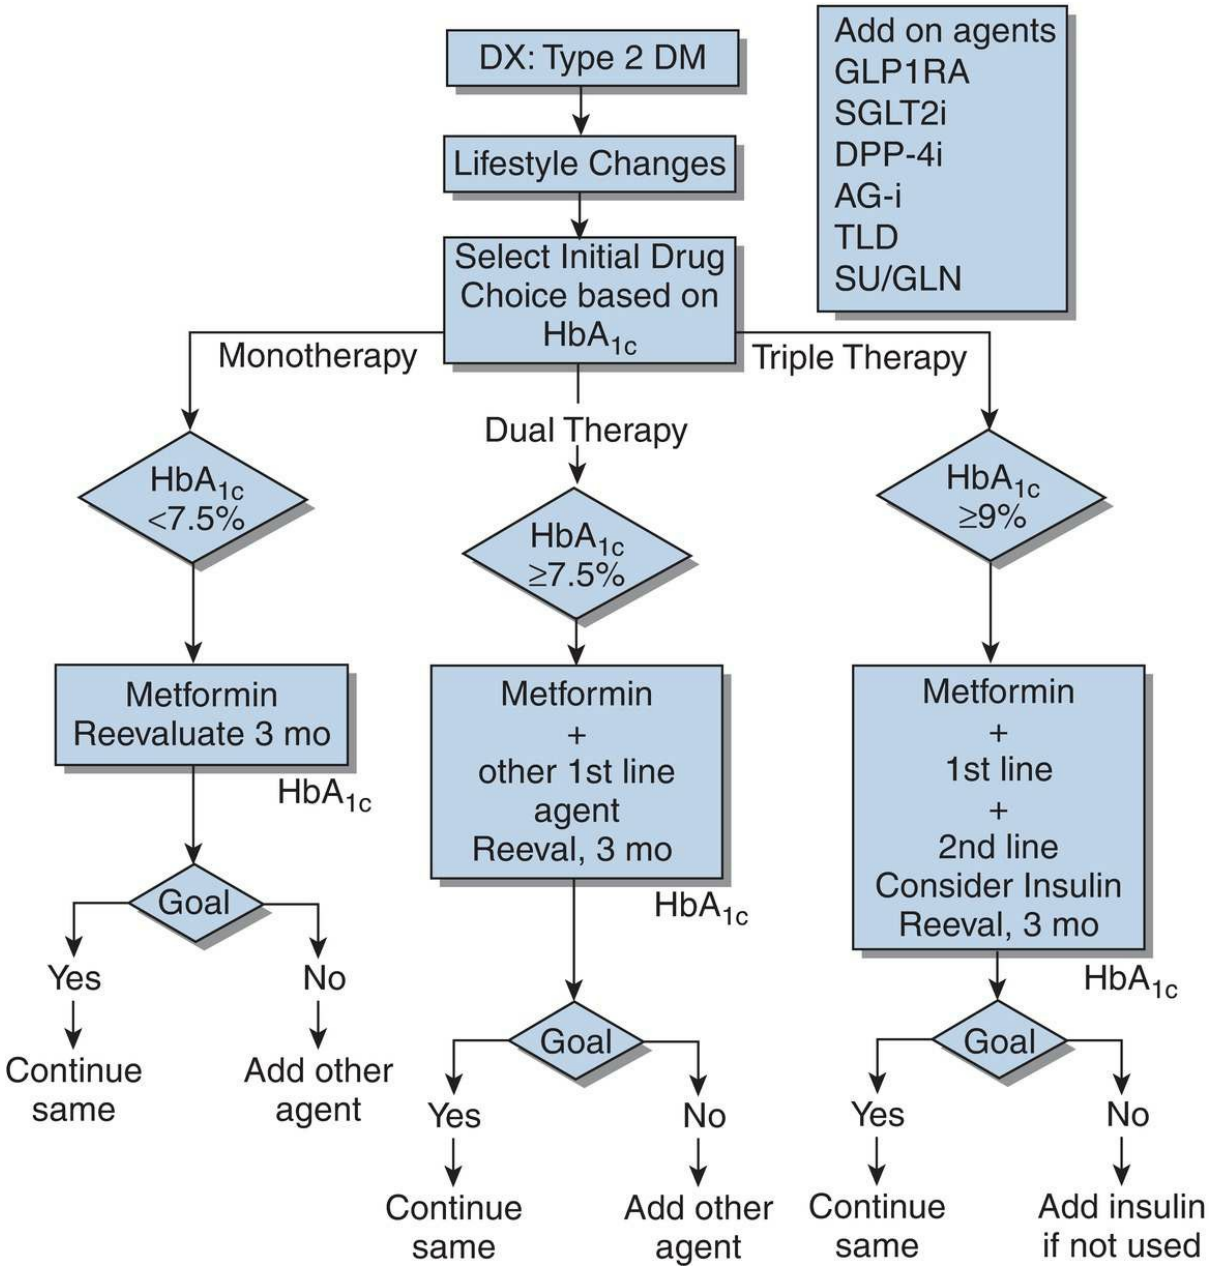

FIGURE 46.2 Algorithm for type 2 oral therapy management.

First-Line Therapy

In type 1 diabetes, insulin is the only first-line therapy due to absolute insulin deficiency. There are several schedules that can be used for administering acting insulin (see Table 46.9). The most common regimen is a program that provides basal insulin coverage, using a peakless basal insulin and a rapid-acting insulin before breakfast, lunch, and dinner (see Figure 46.1). The dosage is 0.5 to 0.6 units/kg/d. This promotes glycemic control during the day and while the patient sleeps. Approximately 25% to 50% of daily total as basal insulin is given once a day. Premeal (prandial) insulin (rapid acting or regular insulin) is distributed as 40% before breakfast, 30% before lunch, and 30% before dinner. A second

regime is a combination of intermediate- and short-acting insulin. This consist of two injections a day, one in the morning and one in the evening (see Table 46.9). The morning dose is divided into two-thirds intermediate-acting insulin and one-third short- or rapid-acting insulin. The evening dose is one-half intermediate-acting insulin and one-half short- or rapid-acting insulin.

TABLE 46.9 Various Insulin Regimens

No. of Daily Injections	How Administered	Comments
2	Two thirds of insulin 15–30 min before breakfast and ⅓ 15–30 min before the evening meal In AM, ⅔ intermediate, ⅓ short or rapid acting In PM, ½ intermediate, ½ rapid or short acting	This regimen is the most commonly prescribed. It is the most desirable to patients. There may be too little coverage at noon and too much insulin during the night. There is less dawn phenomenon and Somogyi effect.
3	40% intermediate and 15% short or rapid acting 15–30 min before breakfast 15% short or rapid acting before dinner 30% intermediate acting at bedtime	There is too little coverage at noon.
4	20%–25% of daily dose with rapid or short acting before each meal 25%–40% intermediate or long acting at bedtime	Use of insulin glargine or detemir provides most predictable basal control.

First-line therapy for type 2 diabetes with HBA_{1C} ≥6.5% is monotherapy with metformin if not contraindicated and tolerated. The goal is to achieve or maintain a targeted HBA_{1C} of less than 7.0%. If the HBA_{1C} in patients with markedly elevated blood sugars consider starting insulin therapy. Other agents used for first-line therapy and have few adverse events include GLP-1RA, DPP4-i, and α-glucosidase inhibitors. Meglitinides, SGLT-2i inhibitors, sulfonylureas, and TZDs are used with caution. The rule for initiating therapy with any of these agents is to start slowly and increase the dose every 1 to 2 weeks as needed. If intensification of treatment is required to meet goals (i.e., HbA_{1C} <7.0%), the addition of another drug from a different class is recommended.

Biguanides and TZDs are the drugs of choice in patients with metabolic syndrome. The α-glucosidase inhibitors are most effective in patients with postprandial hyperglycemia but only mild fasting glucose elevations.

Second-Line Therapy

With failure to achieve optimal blood glucose levels in type 1 diabetes, practitioners must gradually increase the insulin dose, making adjustments 1 to 2 units at a time over 3 days. They must base their adjustments on SMBG records. Figure 46.1 and Table 46.9 list how to determine adjustments.

Failure to achieve optimal blood glucose levels in type 2 diabetes with an HBA_{1C} greater than 7.5 necessitates the addition of another oral agent. Combinations of sulfonylureas and biguanides, TZDs, or α-glucosidase inhibitors may be added. SGLT-2 inhibitors, DPP-4 inhibitors, and GLP1 agonist may also be considered as therapy.

Third-Line Therapy

In patients with type 2 diabetes, and an HBA_{1C} greater than 9.0 with no symptoms, a third agent can be added. If the goal of decreasing the HBA1C is not achieved in 3 months, proceed to insulin therapy. An intermediate or basal insulin at bedtime added to the daytime oral regimen can be very effective in treating those with type 2 diabetes. Patients with type 1 diabetes may be appropriate candidates for an insulin pump.

Combination Therapy

Many combination products of two different drug classes are available to treat type 2 diabetes. The following are some of the most common combinations:

- A sulfonylurea and a biguanide combination produces mealtime stimulation of endogenous insulin with the sulfonylurea and gluconeogenesis with the biguanide. This is recommended for an HbA_{1C} level above 8%.
- A sulfonylurea and a TZD combination improves insulin resistance and may enable a decrease in the sulfonylurea dose.
- A biguanide and a TZD combination provides a synergistic effect on glycemic reduction. Liver and renal function must be monitored with this regimen.
- A DPP-4i and a biguanide combination improves insulin resistance and helps to lower postprandial blood sugars, which are best used with an elevated postprandial blood glucose level.
- Meglitinide and a TZD or biguanide combination promotes a stimulation of insulin release and a decrease in peripheral insulin resistance and fasting hyperglycemia.

The provider must weigh the risks and benefits of using combinations medications. In some cases, the combination products cost more.

Monitoring Patient Response

Prolonged hyperglycemia of diabetes gives rise to long-term complications that involve lesions of the small (microvascular) and large (macrovascular) blood vessels. Microvascular complications include retinopathy, nephropathy, and neuropathy.

Control is measured using the patient's levels of blood glucose and HbA_{1C}. Patients use SMBG to keep a daily record of blood glucose. HbA_{1C} measures blood glucose over 3 months. Table 46.10 lists the desired levels and levels that require changes in drug regimen.

TABLE 46.10 Measures of Control of Fasting Blood Glucose

Measure of Glucose	Goal	Levels When Adjustment to Regimen Is Indicated
Fasting glucose	80–130 mg/dL	<80 or >140 mg/dL
Bedtime glucose	110–150 mg/dL	<110 or >160 mg/dL
HbA_{1C}	<7	≥7

Patient Education

Drug Information

Education is a hallmark of diabetes therapy. SMBG is essential for monitoring therapeutic response. Practitioners must educate patients about the signs and symptoms of hypoglycemia and instruct them to carry a source of glucose with them at all times. Possible sources are hard candy (not sugarless) or 4 oz. of orange juice. All patients with diabetes should have medical identification in the form of a Medic Alert bracelet or necklace.

In patients taking insulin, meals are to be eaten on a regular basis. If a rapid-acting insulin is used, it is taken immediately before eating. The α-glucosidase inhibitors are only taken if a meal is eaten.

Here are some patient-oriented sources for information and Apps that can be downloaded to a smartphone:

- www.diabetes.org is the site from the ADA with information for managing the diabetic's life.
- www.niddk.nih.gov/health/diabetes.htm is a site from National Institutes of Health that serves as an information clearinghouse.
- www.diabetes.com provides information for the diabetic individual.
- CDC national Web site for diabetes

Diabetes Apps

- Glucose Buddy
- Diabetes In Check
- Calorie King Food Search
- My Fitness Pal

Nutritional and Lifestyle Changes

Diabetes management includes medical nutrition therapy, exercise, and, in most cases, drug therapy. Foods high in processed sugar and fat are to be avoided, as is alcohol. Regular daily exercise helps to control blood sugar levels.

Patients with diabetes must follow "sick day guidelines" for the treatment of their condition when dealing with other illnesses. In general, practitioners should instruct people with diabetes not to stop their medication when they are ill. Infection, stress, and other variables increase plasma glucose levels, even though oral intake may be reduced. Practitioners should instruct patients to increase their fluid intake to approximately 8 oz of water or sugar-free beverage every hour, especially if they have a fever. Patients should monitor blood glucose levels at home more frequently, as often as every 4 hours. Urine also requires testing for ketones. If the blood glucose concentration is greater than 300 mg/dL on two consecutive readings, fever is persistently high, and symptoms of severe dehydration and ketonuria develop, the patient requires formal evaluation. Sick day plans should be developed with patients before illness occurs.

Complementary and Alternative Medicine

Many people with diabetes combine alternative and traditional medicine. Some of the most common forms of alternative dietary supplements is cinnamon. The use of cinnamon is a popular dietary supplement by many people with diabetes to help lower blood glucose levels. Cinnamon is thought to enhance insulin sensitivity and reduce postprandial glucose levels. In a recent study conducted at the U.S. Department of Agriculture, cinnamon reduced serum glucose levels and improved lipid profiles in patients with type 2 diabetes. Patients were randomized into six groups that received 1, 2, or 3 g of cinnamon or a placebo. All groups receiving cinnamon had a decrease of 18% to 30% in fasting serum glucose values and a reduction of 23% to 30% in triglycerides and 7% to 27% reduction in LDL levels. Total cholesterol level declined from 12% to 26%. Doses used have ranged from 1 to 6 g. Overall cinnamon used as a food is safe.

Case Study*

R.S. is a 55-year-old moderately obese Hispanic woman (body mass index is 29). She was referred to you when her gynecologist noted glucose on a routine urinalysis. She subsequently has an FPG of 190 and 200 mg/dL on two separate occasions. She is thirstier than usual and has more frequent urination. She also complains of decreased energy over the last several months and numbness and tingling in her left lower extremity.

- Family history: sister, mother, and maternal grandmother have diabetes
    - Social history: nonsmoker, drinks alcohol socially (1 drink about three times a month), and does not exercise
    - Review of systems: 20 lb weight gain over the past 2 years, has some blurred vision, has had two urinary tract infections in the past year, and has frequent vaginal yeast infections
        - Gestational diabetes in last two pregnancies
    - Physical exam: unremarkable except blood pressure of 150/90
        - Height: 5.2 inches
        - Weight: 200 lb
    - Laboratory results: FPG 200 mg/dL, HbA_{1C} 10%, LDL 160 mg/dL, HDL 35 mg/dL, and triglycerides 266 mg/dL

Diagnosis: Type 2 Diabetes Mellitus

1. List specific goals for the treatment for R.S.
2. What dietary and lifestyle changes would you recommend for R.S.?
3. What drug therapy would you prescribe? Why?
4. What is the goal for the FPG? Postprandial glucose? HbA_{1C}?
5. Discuss specific education for R.S. based on the prescribed therapy.
6. List one or two adverse reactions for the therapy selected that would cause you to change the therapy.
7. If the HbA_{1C} after 3 months on the prescribed therapy is 8.8%, what would be the next line of therapy?
8. What over-the-counter or herbal medicines might be appropriate for R.S.?
9. Describe one or two drug–drug or drug–food interactions for the selected agent.

* Answers can be found online.

47 Thyroid Disorders

Louis R. Petrone

Diseases of the thyroid gland are common clinical conditions, accounting for many office visits each year. Population-based studies have found that hypothyroidism exists to some degree in 4.6% to 9.5% of individuals, with higher rates occurring in the elderly (Canaris et al., 2000; Hollowell et al., 2002; Rodondi et al., 2010); prevalence also varies according to the availability of iodine in individual communities. These studies and others found a 1.2% to 2.2% rate of hyperthyroidism. Both hypothyroidism and hyperthyroidism have been associated with adverse cardiovascular outcomes (Hak et al., 2000; Iervasi et al., 2007; Rodondi et al., 2010). If these conditions are not treated properly, their morbidity can be high. Thyroid nodules are common, occurring clinically in approximately 5% of patients but found using ultrasound studies in 22% of patients and in autopsy studies in 50% of patients. Although most thyroid nodules are nonmalignant and most thyroid cancers are not very aggressive, approximately 298,000 new cases are diagnosed worldwide annually (Ferley et al., 2012), and 1,900 deaths per year are attributed to thyroid malignancy in the United States (American Cancer Society, 2014). Therefore, clinicians should understand the therapeutic options for these conditions.

To diagnose and treat thyroid disease, a basic understanding of thyroid anatomy and physiology is necessary (Figures 47.1 and 47.2). The gland is divided into two lobes that are separated by an isthmus. Histologically, the thyroid is composed of follicles that are made of cells that are cuboidal at rest but column shaped when activated by thyroid-stimulating hormone (TSH). These follicular cells encircle a mass of colloid that contains thyroglobulin, a glycoprotein that the follicular cells secrete. Iodine, which is consumed in the diet, is reduced to iodide in the gastrointestinal (GI) tract and readily absorbed. Iodide is then carried to the thyroid, where it is taken up by the follicular cells. In these cells, iodide is oxidized and incorporated into tyrosine residues of thyroglobulin to form monoiodothyronine (MIT). Two MITs are paired to make diiodothyronine (DIT), and combinations of MIT with DIT produce triiodothyronine (T_3) and thyroxine (T_4).

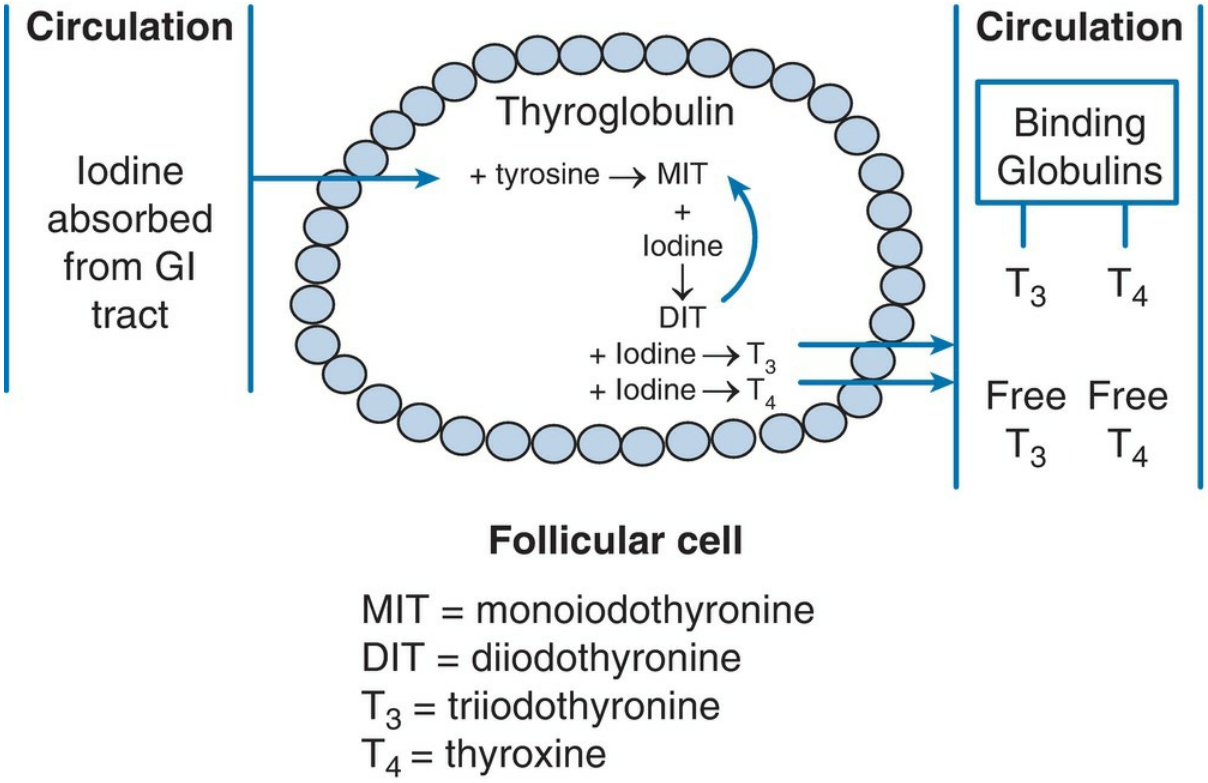

FIGURE 47.1 Thyroid hormone synthesis.

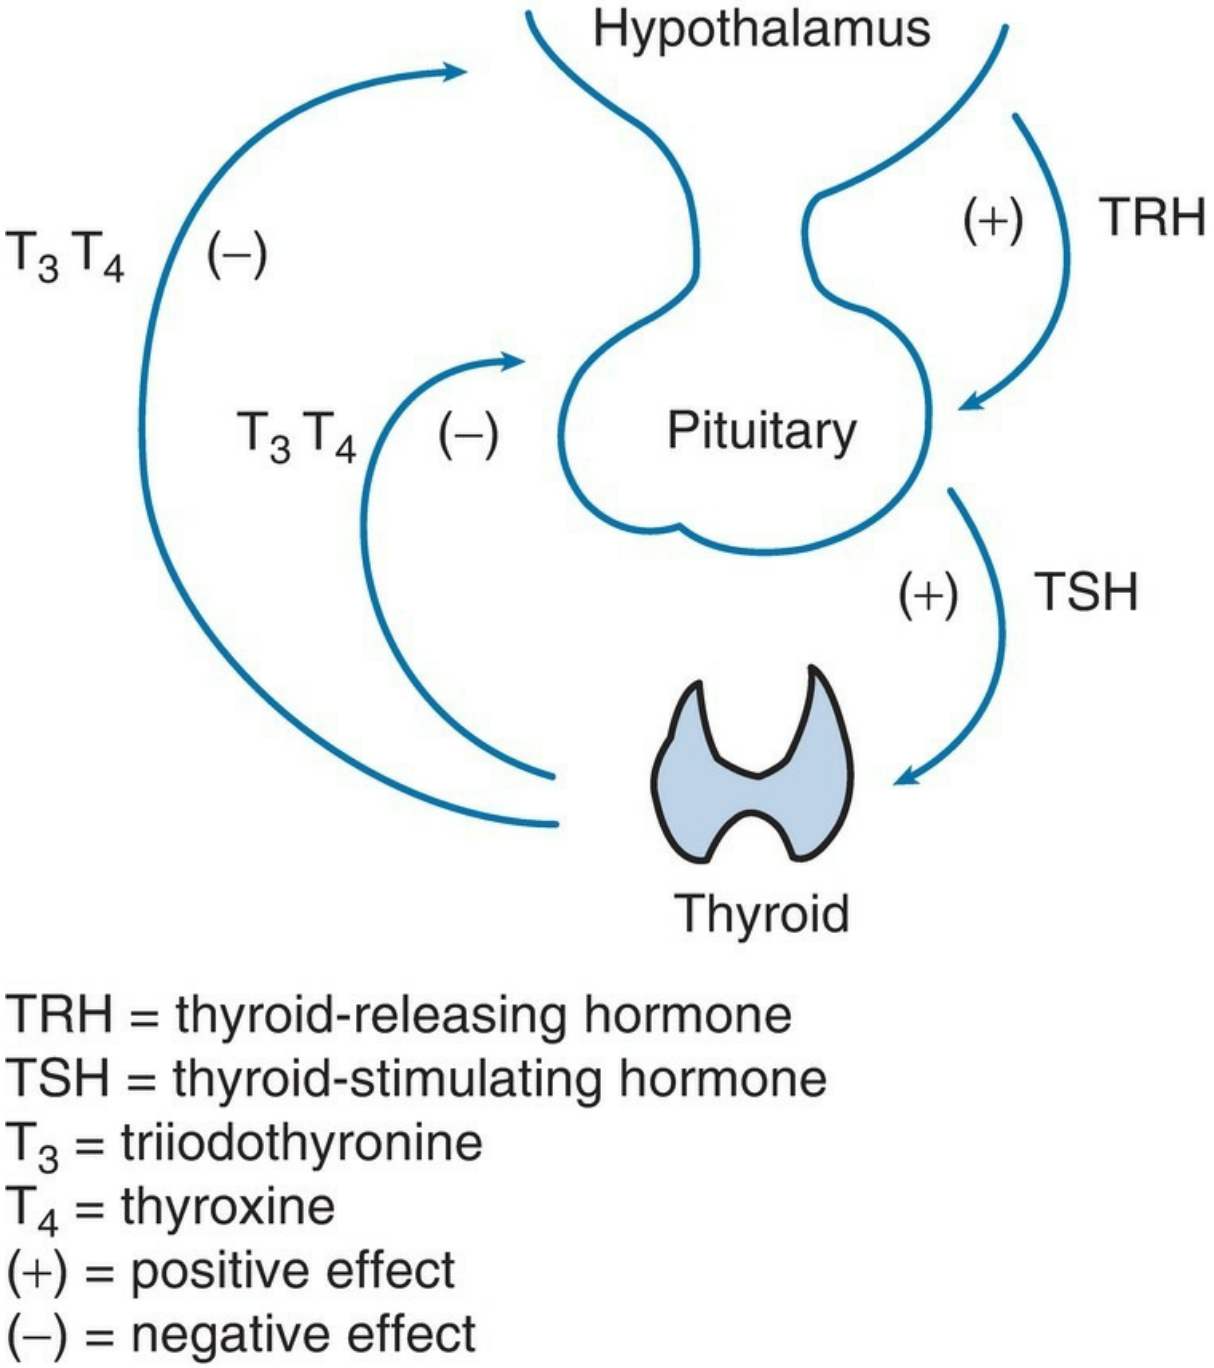

FIGURE 47.2 Hypothalamic–pituitary–thyroid axis.

The pituitary gland secretes TSH, which controls the rate of release of T_3 and T_4. The hypothalamus secretes thyrotropin-releasing hormone (TRH), which modulates the release of TSH. All of these hormones work in a negative feedback system, in which low levels of thyroid hormones in the blood cause increased secretion of TRH, TSH, and, subsequently, T_3 and T_4.

Once T_3 and T_4 are secreted into the bloodstream, proteins known as *thyroid-binding globulins* (TBGs), which are synthesized by the liver, bind most of these hormones. Only a

small amount of T_3 and T_4 is in the "free" or unbound state; the hormones in this state are the clinically significant ones. Free T_3 and free T_4 act at the cellular level to regulate metabolism by binding to nuclear receptors and affecting gene expression and protein synthesis. Any condition that can affect TBGs also can affect the level of free T_3 and free T_4. The thyroid produces only approximately 20% of circulating T_3, whereas monodeiodination of T_4 in the periphery produces the remainder.

Clinically, measurement of serum TSH and free T_4 are used most commonly to assess thyroid function. Given the availability of the free T_4 assay, total T_4 is used less frequently because actual thyroid function depends on the level of free T_4 rather than total T_4. Table 47.1 depicts relative levels of TSH and free T_4 in disorders of thyroid function.

TABLE 47.1 Thyroid Function Testing in Common Thyroid Disorders

	TSH	Free T_4
Primary hypothyroidism	Increased	Decreased
Secondary or tertiary hypothyroidism	Decreased	Decreased
Mild thyroid failure	Increased	Normal
Hyperthyroidism	Decreased	Increased (or normal in T_3 thyrotoxicosis)
Subclinical hyperthyroidism	Decreased	Normal

Hypothyroidism

Hypothyroidism is a relatively common clinical entity, occurring in up to 5.9% of women and 0.2% of men. Patients may complain of symptoms of fatigue, constipation, weight gain, or change in menstrual periods, among others. Physical examination may reveal thyromegaly, bradycardia, or peripheral edema (Box 47.1). Total cholesterol and low-density lipoprotein (LDL) levels may be elevated in 90% to 95% of patients.

BOX 47.1 Symptoms and Signs of Hypothyroidism

- Fatigue
- Constipation
- Menorrhagia
- Weight gain
- Hair loss
- Cold intolerance
- Hoarseness
- Depression
- Dry skin
- Infertility
- Difficulty with memory and concentration
- Bradycardia
- Delayed deep tendon reflexes
- Hyperlipidemia
- Goiter
- Hypothermia
- Periorbital swelling
- Jaundice
- Ataxia
- Edema
- Myalgias

Causes

Hypothyroidism has several causes (Box 47.2). In the United States and other developed countries, hypothyroidism nearly always results from a problem with the production or release (or both) of thyroid hormones. Worldwide, iodine deficiency is most commonly the cause. Hashimoto (or autoimmune) thyroiditis is the most common precipitant of hypothyroidism in the United States. It results from the infiltration of the thyroid gland by lymphocytes, which results in progressive fibrosis and decreased function of the gland. Patients may present with goiter and be euthyroid or hypothyroid initially; antithyroid antibodies are often positive in high titers.

BOX 47.2 Causes of Hypothyroidism

Primary Hypothyroidism

- Thyroid dysgenesis
- Destruction of thyroid tissue
- Chronic autoimmune thyroiditis—atrophic and goitrous forms
- Radiation—^{131}I therapy for thyrotoxicosis, Graves disease; external radiotherapy to the head and neck for nonthyroid malignant disease
- Subtotal and total thyroidectomy
- Infiltrative diseases of the thyroid (amyloidosis, scleroderma)
- Defective thyroid hormone biosynthesis
- Congenital defects in thyroid hormone biosynthesis
- Iodine deficiency
- Drugs with antithyroid actions—lithium, iodine, and iodine-containing drugs and radiographic contrast agents

Central Hypothyroidism

- Pituitary disease
- Hypothalamic disease

Transient Hypothyroidism

- Silent (painless) thyroiditis including postpartum thyroiditis
- Subacute thyroiditis
- After withdrawal of thyroid hormone therapy in euthyroid patients/inadequate thyroid hormone replacement

Reprinted with permission from Braverman, L. E., & Cooper, D. S. (2013). *Introduction to hypothyroidism. Werner & Ingbar's the thyroid; A fundamental and clinical text* (10th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Posttherapeutic (after treatment for hyperthyroidism) hypothyroidism is another common cause, whereas other entities such as subacute thyroiditis or postpartum thyroiditis can produce brief periods of hypothyroidism. Subacute and postpartum thyroiditis are discussed at the end of this chapter.

Many drugs may interfere with thyroid function and induce hypothyroidism (Box 47.3). These include amiodarone (Cordarone) and lithium (Eskalith). If patients discontinue these drugs, thyroid function should return to normal; however, many patients taking these drugs have serious coexisting conditions and cannot stop using them. Therefore, clinicians should monitor these patients regularly for hypothyroidism and treat them with thyroid replacement if appropriate.

BOX 47.3 Drugs that May Alter the Levothyroxine Dose Required by a Patient by Affecting T4 Metabolism or Transport

	Drugs That Alter T_4 Transport	
Drugs That Alter T_4 Metabolism	**Increased TBG**	**Decreased TBG**
Phenobarbital	Estrogen	Androgens
Phenytoin	Tamoxifen	Anabolic steroids
Carbamazepine	Raloxifene	Glucocorticoids
Rifampin	Clofibrate	
Sertraline	Opioids	
Imatinib	Mitotane	
Amiodarone	Fluorouracil	
	Capecitabine

Pathophysiology

Hypothyroidism results from a relative deficit of thyroid hormones, usually free T_4. The deficit may result from failure of the thyroid gland itself (primary hypothyroidism) or, less commonly, from failure of the pituitary gland or hypothalamus (secondary or tertiary hypothyroidism, respectively). Presenting symptoms of thyroid hormone deficiency are similar in all types of hypothyroidism.

Diagnostic Criteria

Primary hypothyroidism is confirmed, in the appropriate clinical setting, by the finding of an elevated TSH and a low free T_4 level. Secondary hypothyroidism, as a result of pituitary dysfunction, results in low free T_4 and low TSH levels. Tertiary hypothyroidism results from decreased production of TRH by the hypothalamus. Secondary hypothyroidism can be distinguished from tertiary hypothyroidism by imaging of the pituitary and hypothalamus. There is a TRH stimulation test in which exogenous TRH is administered and serum TSH response is measured, but this test is of limited value. Secondary hypothyroidism and tertiary hypothyroidism are not very common.

Initiating Drug Therapy

The only course of treatment for hypothyroidism is replacement with thyroid hormone. Figure 47.3 shows an algorithm for the evaluation and treatment of hypothyroidism.

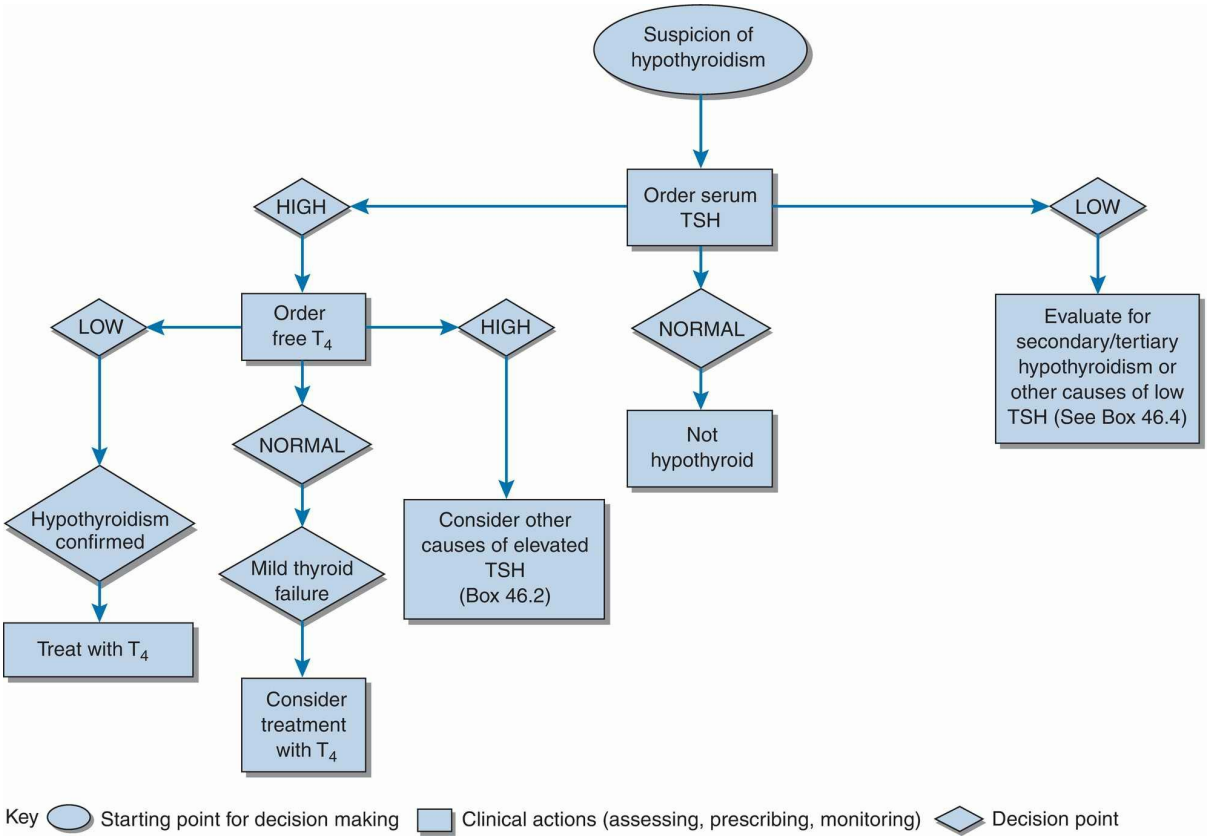

FIGURE 47.3 Treatment algorithm for hypothyroidism.

Goals of Drug Therapy

The goal of therapy is to return the patient to the euthyroid state with a TSH in the range of 0.5 to 4.0 mIU/mL. However, there is some debate regarding the optimal range of TSH; some organizations favor a top normal level of 2.5. Also, there is a natural rise of TSH levels in the elderly, which must be considered when treating and monitoring this group of patients (Cappola et al., 2015). Clinicians should exercise caution not to overtreat hypothyroidism by suppressing the TSH to lower than normal levels because such overtreatment will put the patient at risk for hyperthyroidism and its attendant morbidities. Treatment of most cases of hypothyroidism usually is lifelong; exceptions include those cases that occur transiently in patients with postpartum or subacute thyroiditis (discussed later in this chapter).

Thyroid Hormone

Once they have made a diagnosis of hypothyroidism, practitioners should initiate treatment with thyroid hormone replacement in the form of levothyroxine (T_4). Table 47.2 lists the various preparations available. Natural thyroid extract is derived from porcine thyroid glands and is a combination of T_3 and T_4. This preparation is not used much because of variability in the amount of T_3. T_3 replacement alone is available (liothyronine [Cytomel]) but also is not prescribed frequently because of its association with an increased risk of iatrogenic hyperthyroidism. It is sometimes given for short-term use before radioactive iodine scanning and as augmentation therapy in treatment-resistant depression. A combination product of T_3 and T_4 (liotrix [Thyrolar]) exists but offers no advantage over T_4 alone. Furthermore, this product increases serum T_3 above physiologic levels within several hours, leading to palpitations.

TABLE 47.2 Overview of Drugs Used for Treatment of Hypothyroidism

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
levothyroxine (Synthroid, others) Start: 12.5–100 mcg/d Maintenance: 75–150 mcg/d	Only with excessive dosing: arrhythmias, palpitations, nervousness, tremor, weight loss	Untreated thyrotoxicosis, hypersensitivity to thyroid hormones, uncorrected adrenal cortical insufficiency	Goal TSH 0.5–4.0 milliunits/L
liothyronine (Cytomel) Start: 25 mcg/d Maintenance: 25–75 mcg/d	Only with excessive dosing	Same as above	Goal TSH 0.5–4.0 milliunits/L
liotrix (Thyrolar) (liothyronine and levothyroxine) Start: levothyroxine 50 mcg/d + liothyronine 12.5 mcg/d Maintenance: levothyroxine 100 mcg/d + liothyronine 25 mcg/d	Only with excessive dosing	Same as above	Goal TSH 0.5–4.0 milliunits/L
thyroid, desiccated (Armour) (liothyronine and levothyroxine) Start: 60 mcg/d Maintenance: 60–120 mcg/d	Only with excessive dosing	Same as above	Goal TSH 0.5–4.0 milliunits/L; not used much because of variability of T_3 content

Several branded preparations of T_4 are available, any one of which may be used. Historically, authorities have recommended against the use of generic T_4. A study of the bioavailability of generic preparations compared with brand name T_4, however, found no significant difference between generic and nongeneric T_4 and concluded that generic drugs may be used safely; however, experts consider it beneficial for the patient to receive the same brand or generic preparation to limit variability in bioavailability, especially in children and pregnant women. Furthermore, in 2007, the U.S. Food and Drug Administration (FDA) required that all manufacturers of levothyroxine products provide evidence of potency between 95% and 105%, a narrower window than the previous 90% to 110%, to limit the variability among the various products (U.S. Food and Drug Administration, 2015).

Levothyroxine is readily absorbed from the GI tract. Serum T_4 levels peak at 2 to 4 hours, although the rise in serum T_3 levels is slower because of the time needed for conversion from T_4. Synthetic T_4 has a half-life of 1 week and requires approximately 6 to 8 weeks of therapy to reach steady state; therefore, patients may not notice improvement in symptoms for 1 week or more.

Dosage

When initiating therapy, clinicians must consider the patient's age, the duration of hypothyroidism, and any concomitant conditions. For adolescents and young adults, treatment can begin with the full replacement dose (100 to 125 mcg/d, or 1.6 mcg/kg/d, or approximately 0.75 mcg/lb/d). Children require approximately 4 to 10 mcg/kg/d depending on age. In older adults or patients at risk for cardiac disease, thyroid hormone replacement should begin at 25 or even 12.5 mcg/d. Prescribers should increase the dosage incrementally (by 25 mcg/d every 4 to 6 weeks) until reaching the full replacement dose. Clinicians must monitor serum TSH levels and adjust the dose of T_4 accordingly. Many different dosage strengths (25 to 300 mcg) are available to allow titration to appropriate levels.

Interactions

Some drugs interfere with the absorption of thyroid hormone from the GI tract. (See Box 47.3.) These include cholestyramine (Questran), sucralfate (Carafate), aluminum-containing antacids, and calcium carbonate. Patients should not take T_4 several hours before or after ingesting these agents.

The concentration of total T_4 and T_3 depends on the concentration of serum TBGs. Any drug or condition that interferes with TBG levels can affect the interpretation of thyroid function tests. Furthermore, in patients who are taking T_4, the changing concentration of TBGs may necessitate adjustment of the dose. The most common causes of an increased serum TBG concentration are increased estrogen production (e.g., as in pregnancy) and the administration of estrogen, in the form of either an oral contraceptive or as estrogen replacement therapy. Patients receiving these therapies will likely need higher doses of T_4 to maintain the euthyroid state because the estrogen increases the level of TBGs, and more thyroid hormone is in the bound, inactive state rather than in the free, active state. Androgens and niacin can decrease TBG concentrations and have opposite effects on thyroid function tests; patients taking these drugs will likely need lower doses of T_4.

Several drugs decrease the affinity of T_4 and T_3 to TBGs, causing displacement of hormones and resulting in a transient increase in free T_4 and free T_3 levels. Salicylates and high doses of furosemide (Lasix) can exert this effect.

Another concern is for the patient taking oral anticoagulants. When hypothyroid

patients become euthyroid, metabolism of vitamin K–dependent clotting factors increases. Therefore, the patient's prothrombin time may increase, as does the risk of bleeding. The opposite occurs in patients treated for hyperthyroidism. Thus, clinicians need to monitor carefully coagulation studies in patients taking warfarin (Coumadin) who are being treated for thyroid disease.

Drugs like phenytoin (Dilantin) and carbamazepine (Tegretol) alter the metabolism of thyroid hormones. Patients who use these agents require more frequent monitoring of thyroid function.

Patients on some chemotherapeutic agents (e.g., sunitinib and imatinib) may develop or experience worsening of hypothyroidism. Clinicians should monitor these patients carefully and may need to start or adjust the dose of T4.

Special Population Considerations

Pediatric

In children, developmental defects like thyroid aplasia or hypoplasia or inborn errors in thyroid hormonogenesis may result in thyroid deficiency. Routine screening of newborns allows early identification and treatment of this potentially devastating condition. Children with congenital hypothyroidism require referral to a pediatric endocrinologist for treatment. Older children also may become hypothyroid as a result of lymphocytic (Hashimoto) thyroiditis or secondary to irradiation or surgery on the thyroid. Treatment is similar to that for adults, but children may require doses of up to 4.0 to 10.0 mcg/kg/d of T_4 due to rapid metabolism (Buck, 2008).

Geriatric

Clinicians need to maintain a high level of suspicion for thyroid disease in older adults because the presentation of illness may differ from that in younger patients. This difference is partly because of alterations in the rate of hormone secretion and clearance as well as increased nodularity and fibrosis of the thyroid gland. Furthermore, concomitant illnesses and medications can modify thyroid function in older adults. Symptoms of hypothyroidism may be subtle or nonexistent. Ataxia, paresthesias, and carpal tunnel syndrome may be the presenting symptoms of hypothyroidism in older adults. Psychiatric manifestations of thyroid disease (e.g., depression or change in sensorium) also are more common in this age group. Older adults also are more susceptible to complications of therapy. Treatment should be initiated at a lower dose for elderly patients.

Pregnancy

Hypothyroidism in pregnancy deserves special mention. Because of the increased amount of thyroglobulin during pregnancy, more T_4 is bound in the circulation. Total T_4 and T_3 increase early in the first trimester, even in women without hypothyroidism. The free T_4 consequently declines to such a degree that symptoms of hypothyroidism may develop in many pregnant women with previously controlled hypothyroidism treated with T_4, necessitating a dose increase by approximately 50 mcg until after delivery. Clinicians should evaluate thyroid function in pregnant women during every trimester by means of a TSH level. The serum total T_3 level returns to normal approximately 1 week after delivery, whereas the total T_4 level declines by 3 to 4 weeks if the patient is not using an oral contraceptive.

Monitoring Patient Response

Patients require clinical and laboratory evaluation with a serum TSH 6 to 8 weeks after initiating therapy or adjusting the dose of T_4. Because it takes this long for the TSH level to decline in response to T_4 replacement, a TSH test should not be ordered before this time. Clinicians should perform an interval history and physical examination, focusing on symptoms and signs of hyperthyroidism, which suggest overdosage, and residual symptoms of hypothyroidism to assess for underdosage.

Practitioners should check TSH levels 6 months after normalization to ensure stable metabolism of T_4, then annually unless new symptoms or medical conditions develop or new drugs are prescribed that may interact with T4 in the interim. Therapy is usually lifelong (although spontaneous recovery may occur in up to 20% of patients with hypothyroidism related to Hashimoto thyroiditis), so clinicians must encourage patients to comply with their medication regimens. The finding of a very high TSH but a normal free T_4 level suggests intermittent compliance with T_4 therapy.

Patient Education

Patients with primary hypothyroidism most likely will require lifelong replacement with thyroid hormone. Patients should not expect to see a difference in their symptoms until 2 to 4 weeks after beginning therapy. Follow-up laboratory testing is necessary relatively frequently until a therapeutic dosage that results in a stable TSH is reached; at that point, testing should be done annually.

Drug Information

Patients are advised against taking excessive thyroid hormone replacement because of the increased risk of drug-induced hyperthyroidism, which would put patients at risk for osteoporosis and arrhythmias. Thyroid replacement should be taken on an empty stomach 30 minutes to 1 hour before ingestion of the first food of the day.

Patients on thyroid hormone replacement therapy should limit the use of adrenergic agents (e.g., nonprescription decongestants). Patients should not take thyroid hormone at the same time as iron or calcium supplements, antacids, bile acid sequestrants, or simethicone; these preparations require administration at least 2 hours before or after administration of thyroid hormone. Finally, clinicians should reassure patients that although hypothyroidism is a chronic condition, treatment is usually safe and effective.

Hyperthyroidism

Hyperthyroidism results from the presence of an excess amount of thyroid hormone(s), which may result in thyrotoxicosis, a term that refers to the effect of inappropriately high thyroid hormone levels on tissues. Overt hyperthyroidism occurs in up to 2.2% of the population (Bahn et al., 2011; Hollowell et al., 2002), with a female-to-male ratio of 5:1 (Kahaly et al., 2011).

Causes

Graves disease, an autoimmune disease that occurs most commonly in patients ages 20 to 50 with a female-to-male ratio of 4 to 8:1, is the most common cause of overt hyperthyroidism (Box 47.4). It develops as a result of stimulation of the thyroid gland by TSH receptor autoantibodies on the follicular cell surface. The autoantibodies act like TSH in stimulating thyroid gland function. The gland is not susceptible to the usual negative feedback mechanism of the thyroid hormones; thus, levels of thyroid hormone escalate.

BOX 47.4 Drugs and Conditions that May Alter the Levothyroxine Dose Required by a Patient by Affecting Levothyroxine Absorption

Drugs, Supplements, and Inert Ingredients	Food and Beverages	Medical and Physiologic Conditions
Calcium carbonate	Meals	Gastritis
Phosphate binders	Timing with regard to meals	Celiac disease
Inert ingredients (contained in different LT_4 products)	Fiber	Lactose intolerance
Antacids	Soy products	Aging
Ferrous sulfate	Espresso coffee	Severe obesity
Cholestyramine		
Colesevelam		
Sucralfate		
Raloxifene		
Proton pump inhibitors		
Orlistat

Toxic nodular goiter (Plummer disease) is another frequent cause of hyperthyroidism, especially in older adults. In this condition, one or more thyroid nodules begin to "hyperfunction" and are not dependent on the feedback mechanisms of the pituitary–thyroid axis. As a result of the increased systemic T_4 produced by the nodule, TSH is suppressed, and the remainder of the gland begins to atrophy. Eye findings (i.e., exophthalmos and lid lag sometimes found with Graves disease) are absent in this condition.

A less common cause of hyperthyroidism is thyrotoxicosis factitia, in which patients intentionally take T_4 in doses high enough to suppress their TSH. This finding is more common among those in the medical profession with access to prescription medications. These patients may want to use T_4 to help with weight loss or to treat fatigue or depression.

Several forms of thyroiditis may result in hyperthyroidism with a characteristically low radioactive iodine uptake. These are discussed in a later section.

Amiodarone and other drugs that contain iodine, including radiographic contrast agents, may induce hyperthyroidism in patients with autonomously functioning nodules. Clinicians must monitor such patients closely to evaluate ongoing need for these agents.

Diagnostic Criteria

The patient with hyperthyroidism classically exhibits symptoms of enhanced metabolic activity (i.e., palpitations, sweating, heat intolerance, weight loss). Examination may reveal elevated blood pressure, tachycardia, a bruit over the thyroid gland, or exophthalmos in patients with Graves disease (Box 47.5). The diagnosis is confirmed by finding a low, or suppressed, TSH level with an elevated free T_4 level. A nuclear ^{123}I thyroid scan can confirm Graves disease, which causes a diffuse increase in uptake of radioactive iodine. Hyperthyroidism caused by a hyperfunctioning nodule appears as a localized area of increased radioiodine uptake (a "hot" nodule), with the remainder of the gland exhibiting generalized decreased uptake of the isotope.

BOX 47.5 Causes of Hyperthyroidism/Thyrotoxicosis

Thyrotoxicosis Associated with a Normal or Elevated Radioiodine Uptake Over the Neck

Graves disease
Toxic adenoma or toxic multinodular goiter
Trophoblastic disease
TSH-producing pituitary adenomas
Resistance to thyroid hormone (T3 [triiodothyronine] receptor mutation)[b]

Thyrotoxicosis Associated with a Near-Absent Radioiodine Uptake Over the Neck

Painless (silent) thyroiditis
Amiodarone-induced thyroiditis
Subacute (granulomatous, de Quervain) thyroiditis
Iatrogenic thyrotoxicosis
Factitious ingestion of thyroid hormone
Struma ovarii
Acute thyroiditis
Extensive metastases from follicular thyroid cancer

Initiating Drug Therapy

There are three main options to treat hyperthyroidism: (1) antithyroid drugs, (2) radioactive iodine ablation with ^{131}I, and (3) surgery (Table 47.3 and Figure 47.4). In general, radioactive iodine is the treatment of choice for patients older than age 40; it often is used in younger patients as well. Because of the high rate of permanent hypothyroidism after treatment and the eventual need for lifelong thyroid replacement, as well as concerns about subsequent cancers after exposure to radioiodine at a young age, many clinicians initially attempt to treat younger patients with antithyroid medications. Data on this issue have been conflicting, but many providers are now using radioactive iodine as first-line therapy in young patients (Bahn et al., 2011). Radioactive iodine is contraindicated in pregnancy; however, it may be used in women of childbearing age and in children. Women should postpone pregnancy until 6 months after radioiodine therapy. Lactating women should not receive radioiodine because it passes into breast milk.

TABLE 47.3 Recommended Order of Treatment for Hyperthyroidism

Order	Agents	Comments
First line	Radioactive iodine	Usually recommended in patients older than age 40 but may be used for younger patients High incidence of hypothyroidism when used to treat Graves disease; less when used for toxic nodules
Second line	Antithyroid drugs	Often used in younger patients to induce remission of Graves disease; also used to prepare some patients for treatment with radioiodine or surgery
Third line	Surgery	Usually reserved for patients with large goiters or suspected malignancy

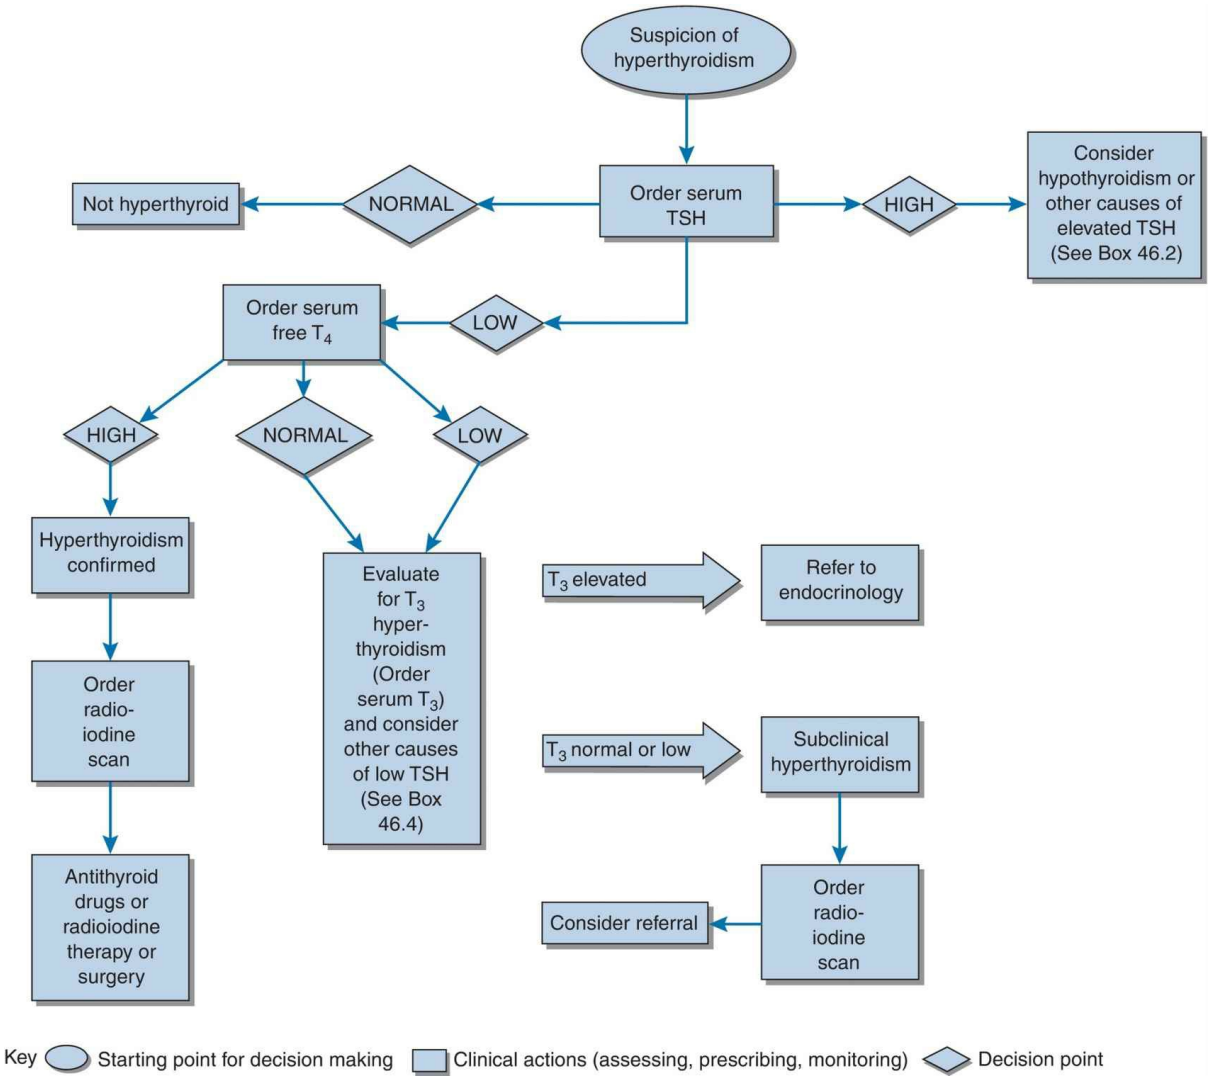

FIGURE 47.4 Treatment algorithm for hyperthyroidism.

Practitioners should follow patients treated with ^{131}I every 4 to 6 weeks for 3 months after radioiodine treatment, then less frequently. Because most patients with Graves disease become hypothyroid after treatment, clinicians must screen for symptoms and measure TSH and free T_4 levels intermittently. Conversely, when radioactive iodine is used to treat toxic nodules, the rate of posttherapeutic hypothyroidism is lower, likely related to the degree of suppression of the remainder of the gland by the nodule. If the free T_4 becomes low and the TSH elevated, patients should start T_4 supplementation with the goal of reaching the replacement dosage and maintaining euthyroidism. TSH levels should be done yearly or more frequently if the patient's clinical condition changes.

Surgery is reserved for patients with large goiters that compress vital structures or for those in whom there is a concern about a malignancy in the gland. It also may be used in pregnant women who are unable or unwilling to take antithyroid drugs. Before surgery, patients are often treated with antithyroid drugs until they are euthyroid, with inorganic

iodide (discussed later) added 10 days after surgery.

Potential complications of surgery include hypoparathyroidism and injury to the recurrent laryngeal nerve, although in experienced hands, these complications are rare. Hypothyroidism develops after thyroidectomy in up to 70% of cases depending on the extent of surgery, so postsurgical patients need regular follow-up and supplementation with T_4 as necessary.

Goals of Drug Therapy

The goals of therapy are to restore patients to the euthyroid state and eliminate the risks associated with chronic hyperthyroidism. Pharmacologic therapy for hyperthyroidism is usually not lifelong. Patients usually stop taking antithyroid drugs after 1 to 2 years. If permanent hypothyroidism develops as a result of radioactive iodine treatment or surgery, however, then treatment of hypothyroidism (discussed previously) is lifelong.

Antithyroid Drugs

Antithyroid drugs commonly used in the United States are methimazole (Tapazole) and propylthiouracil (PTU [Propyl-Thyracil]; Table 47.4).

TABLE 47.4 Overview of Drugs Used to Treat Hyperthyroidism

Generic (Trade) Name and Dosage	Adverse Effects	Contraindications	Special Considerations
Antithyroid Drugs			
propylthiouracil (PTU [Propyl-Thyracil]) Start: 100–600 mg/d Maintenance: 50–100 mg q8h	See Table 47.5.	Hypersensitivity to drug	Monitor for fever, sore throat; check CBC
methimazole (Tapazole) Start: 15–30 mg/d Maintenance: 5–15 mg/d	See Table 47.5.	Same as above	Same as above
Beta-blockers			
propranolol (Inderal) long acting: 80–160 mg/d	Fatigue, sexual dysfunction	Sinus bradycardia, heart block greater than first degree	For symptom control only Use with caution in asthma, diabetes, congestive heart failure, and depression
atenolol (Tenormin) 50–200 mg/d	Same as above	Same as above	Same as above
Iodine-Containing Compounds			
SSKI (Lugol solution) 0.1–0.3 mL tid sodium iodide (Iodopen) 0.5–1 g q12h	Rash, sialadenitis, vasculitis	Allergy to iodine	Administer after starting antithyroid drug
Iodinated contrast agents: ipodate (Oragrafin) iopanoate acid (Telepaque) 0.5–2 g/d	Itching, skin rash, hives, diarrhea, nausea, vomiting; bruising/bleeding with iopanoate	Same as above	Reserved for severe thyrotoxicosis or thyroid storm Administer after starting antithyroid drug
Other Agents			
lithium (Eskalith, others) Starting and maintenance: 900–1,200 mg/d in divided doses	May have multisystem effects		Monitor lithium levels
Glucocorticoids dosage depends on agent selected	May have multisystem effects		Adjunctive therapy for thyroid storm

Mechanism of Action

These drugs act by inhibiting iodine organification. They also block the conversion of T_4 to T_3 in the periphery, although this mechanism has minimal clinical relevance. The drugs are rapidly absorbed and concentrated in the thyroid follicular cells. PTU has a short duration of action and thus requires multiple doses per day. Methimazole has a longer duration and may be dosed once a day, making it the drug of choice in most instances.

Dosage

The starting dose for PTU is 200 to 400 mg/d, whereas the initial dose of methimazole is 10 to 30 mg/d. Treatment usually continues for 12 to 24 months. Success rates for antithyroid drugs range from 10% to 75%, with remission rates inversely related to the duration of hyperthyroidism and the size of the goiter.

Antithyroid drugs also are used to prepare patients with severe hyperthyroidism for ablative therapy with either radioactive iodine or surgery, especially in those at risk for cardiac complications. The drugs usually are given for several weeks then stopped several days before definitive therapy, although some patients may need to continue the drugs for several months after ^{131}I therapy to control persistent hyperthyroidism.

Adverse Events

Side effects are fairly minimal (Table 47.5), with the most common being rash, arthralgias,

itching, and hepatic abnormalities. Patients who have difficulty with one medication may be given a trial of another, although cross-sensitivity among the antithyroid drugs may occur. Rarely (0.3% of patients), a potentially fatal agranulocytosis may result, which occurs somewhat more often with PTU than with methimazole. Clinicians should consider routine monitoring of the complete blood count (CBC) during the first 3 months of therapy. They should warn patients who are taking these drugs to report symptoms of sore throat and fever immediately; they should obtain a CBC and stop the drug if the patient's white blood cell count is low.

TABLE 47.5 Side Effects of Antithyroid Drugs

Minor

Common (1%–5%)

Urticaria or other rash
Arthralgia
Fever
Transient granulocytopenia

Uncommon (<1%)

Gastrointestinal upset
Abnormalities of taste and smell
Arthritis

Major

Rare (0.2%–0.5%)

Agranulocytosis

Very rare (<0.1%)

Aplastic anemia
Thrombocytopenia
Toxic hepatitis (PTU)
Cholestatic hepatitis (methimazole)
Vasculitis, systemic lupus-like syndrome
Hypoprothrombinemia (PTU)
Hypoglycemia (due to anti-insulin antibodies) (methimazole)

Reprinted with permission from Cooper, D. S. (2013). *Treatment of thyrotoxicosis. Werner & Ingbar's the thyroid; A fundamental and clinical text* (10th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

In 2010, the FDA added a black box warning to PTU because of reports of severe liver injury, including some deaths, in pediatric and adult patients taking this medication. The FDA also recommends that PTU be reserved for patients who cannot tolerate other therapies for hyperthyroidism (http://www.fda.gov/Drugs/DrugSafety/PostmarketDrugSafetyInformationforPatientsandP

Interactions

Because antithyroid drugs decrease iodine uptake and organification, they can interfere with subsequent radioactive iodine therapy. Higher doses of ^{131}I may be needed to increase success rates in these patients.

Adjunctive Agents Used to Manage Hyperthyroidism

Beta-Blockers

Beta-blockers are used to treat the symptoms of hyperthyroidism. They do not affect thyroid hormone synthesis; rather, they act by decreasing the symptoms of adrenergic stimulation caused by the increased concentration of thyroid hormones. Practitioners should prescribe a nonselective beta-blocker like long-acting propranolol starting at a dose of 80 mg/d. Alternatively, atenolol may be used. These drugs can help prevent hyperthyroid-induced atrial fibrillation or control the ventricular rate in patients with established atrial fibrillation. Clinicians should consider anticoagulation to reduce the risk of stroke in patients with atrial fibrillation; treatment of these patients should be in consultation with a cardiologist. Prescribers should taper beta-blockers gradually and discontinue them as soon as the patient is euthyroid and asymptomatic. Patients in whom beta-blockers are not tolerated or are contraindicated (e.g., those with asthma) may be treated with calcium channel blockers like diltiazem.

Iodine-Containing Compounds

Other agents used adjunctively in the treatment of hyperthyroidism are iodine-containing compounds like potassium iodide (in the form of saturated solution of potassium iodide [SSKI] 35 mg/drop or Lugol solution 7 mg/drop) and the iodinated contrast agents ipodate (Oragrafin) and iopanoate acid (Telepaque). These drugs are reserved for the treatment of severe thyrotoxicosis or thyroid storm. Such patients are usually treated in an intensive care unit under the care of an endocrinologist, intensivist, or both. Pharmacologic doses of iodine inhibit the release of thyroid hormones from the gland in the short term; however, because new hormone synthesis proceeds during treatment with iodine, iodine must be used in combination with antithyroid drugs, which are given 1 hour before the iodine compound.

Lithium

Lithium, which is chemically similar to iodine, is used rarely to block the release of thyroid hormone from the gland in those patients who are intolerant of antithyroid drugs. The dose is 900 to 1,200 mg/d, divided, and clinicians should monitor lithium levels.

Glucocorticoids

Glucocorticoids are occasionally used in thyroid storm. They reduce peripheral conversion of T_4 to T_3.

Treatment of Ophthalmopathy of Graves Disease

None of the aforementioned therapies for hyperthyroidism affects the ophthalmopathy of Graves disease. Anti-inflammatory drugs, immunosuppressive drugs (e.g., prednisone and dexamethasone), and surgery are offered to patients as treatment for the ophthalmopathy. Sunglasses and artificial tears are used adjunctively for comfort.

Special Population Considerations

Geriatric

The term *apathetic hyperthyroidism* has been used to describe the atypical presentation of hyperthyroidism in some older patients. Rather than the usual symptoms of increased metabolic rate, these patients may present with weakness, dyspnea, anorexia, depression, or constipation. Physical examination may be unrevealing. Occasionally, new-onset atrial fibrillation or congestive heart failure is the initial presentation of hyperthyroidism in the older person.

Pregnancy

Radioactive iodine is contraindicated during pregnancy because it crosses the placenta and adversely affects fetal thyroid development. Because of an increased risk of birth defects related to methimazole use during the first trimester of pregnancy, PTU is the drug of choice for hyperthyroidism during and just before this time. Since it enters the breast milk less than methimazole, PTU may be a safer alternative for a lactating woman. During pregnancy, practitioners should prescribe the lowest dosages possible of antithyroid drugs that still maintain euthyroidism. The dosage usually decreases as pregnancy progresses and the severity of Graves disease lessens, then increases again after delivery. Clinicians should treat pregnant patients who have hyperthyroidism in consultation with an endocrinologist.

Monitoring Patient Response

Patients usually become euthyroid within 6 to 12 weeks of beginning antithyroid drugs; however, permanent hypothyroidism may develop many years after a course of therapy, so long-term follow-up is necessary. Patients taking antithyroid drugs should be evaluated every 1 to 3 months after starting treatment depending on the degree of hyperthyroidism and comorbid conditions. Once euthyroidism is achieved, practitioners can decrease the dose of antithyroid drugs and reevaluate the patient in 3 to 4 months. Clinicians should order free T_4 levels to monitor the patient because the TSH level remains suppressed for several months after the patient becomes euthyroid. They should continue to reduce and eventually discontinue the antithyroid drugs, after which they should see patients every 4 to 6 weeks for 3 to 4 months and less frequently thereafter.

Patient Education

Patients with hyperthyroidism may have very troublesome symptoms that resemble those of anxiety disorders, such as panic attacks. Clinicians should advise them that these symptoms (which can be severe) will resolve with treatment of their thyroid disease.

Practitioners should review all treatment options with patients. They should tell patients that antithyroid drugs will put their disease into remission, but that the relapse rate is high. They should discuss the high likelihood of permanent hypothyroidism after radioactive iodine therapy. Patients will likely gain weight after therapy for hyperthyroidism, even if they do not become hypothyroid. Clinicians should emphasize the chronic nature of the condition and the importance of long-term follow-up regardless of the chosen treatment.

Drug Information

There can be increased effects of digoxin, metoprolol, and propranolol when the patient becomes euthyroid. The effects of anticoagulants can be altered. Drugs should be taken at equal intervals.

Complementary and Alternative Medicine

Bugleweed has been shown to treat a mildly overactive thyroid. It decreases thyroid hormone activity and increases the absorption and storage of thyroid hormone, causing a decreased metabolism. This is not used in patients with hypothyroidism.

Lemon balm is used in hyperthyroidism for its sedative effects.

Special Populations

Women of childbearing age with Graves disease may want to consider definitive treatment (radioiodine or surgery) before conception. It is recommended to prescribe PTU during the first trimester of pregnancy. Clinicians must monitor thyroid function closely because of variations in the course of the disease in pregnancy.

Thyroid Nodules

Thyroid nodules are encountered relatively often in clinical practice. The gland may have one or multiple nodules. Most are the result of adenomas, cysts, large collections of colloid, or focal areas of thyroiditis. Five percent of solitary nodules result from thyroid cancer, with higher rates in the very young and older age groups. Fine-needle aspiration biopsy (FNAB) is the initial diagnostic procedure to rule out carcinoma in a solitary nodule.

Initiating Drug Therapy

Treatment of thyroid cancer is beyond the scope of this work; however, clinicians should be aware that high doses of T_4 are used in patients who have been treated for thyroid cancer in an effort to suppress the growth of any remaining cancer cells. Once a thyroid nodule is proved benign histologically, some clinicians previously attempted to reduce the size of the nodule medically (Figure 47.5). T_4 was given in higher than replacement doses (2.2 mcg/kg/d) in an attempt to turn off the secretion of TSH by the pituitary, with the presumption that growth of the nodule depends on TSH. With less circulating TSH, the nodule in theory will not increase in size and may decrease. The literature yields conflicting results in this regard, with some studies showing a significant effect on nodule size but most showing no effect. Therefore, this therapy is no longer utilized.

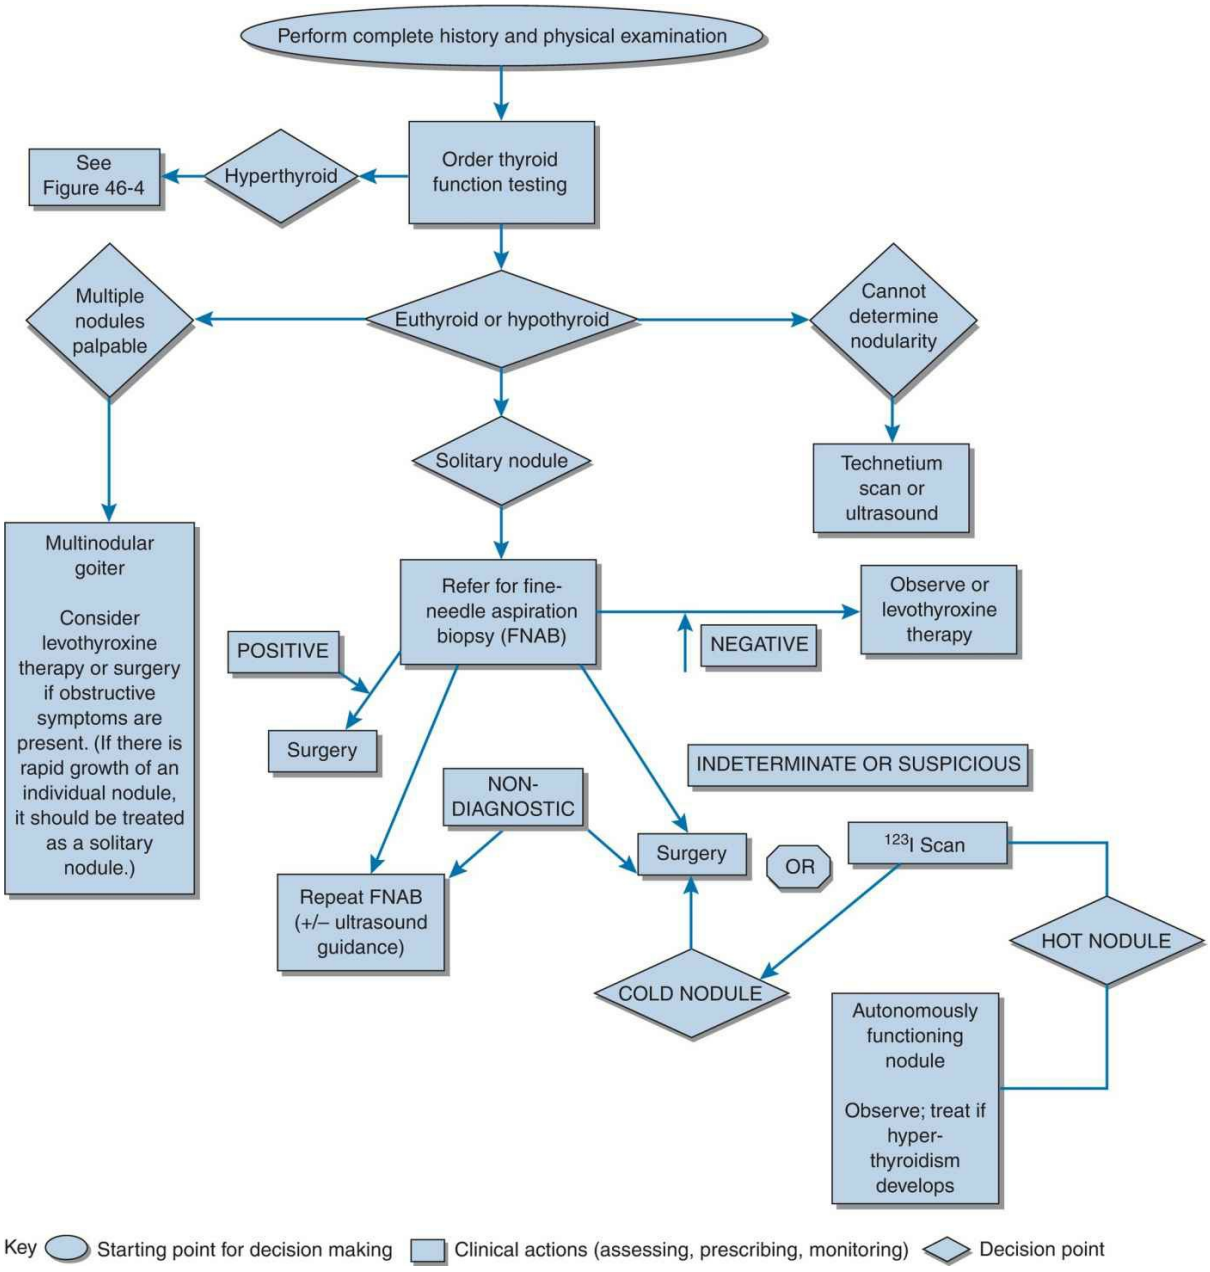

FIGURE 47.5 Evaluation and management of thyroid nodules.

Radioactive iodine and surgery are appropriate for patients with large single nodules or multiple nodules.

Monitoring Patient Response

Patients with thyroid nodules should be monitored at least annually. If there are ongoing concerns about malignancy, practitioners should perform a repeat FNAB. Patients with hyperthyroidism as a result of toxic nodules respond to antithyroid drugs either in conjunction with or in lieu of ablative therapy.

Patient Education

Patients with thyroid nodules often are unaware of a problem. Therefore, practitioners need to emphasize the potential (although small) for malignancy and the need for further evaluation with FNAB.

If the nodule is found to be benign, clinicians must discuss treatment options. Patients need to follow up at least annually with a physical examination and an ultrasound to evaluate whether the existing nodule has enlarged or if new nodules have developed.

Subclinical Thyroid Disease

The entity of subclinical hypothyroidism presents a therapeutic challenge. This condition is defined as an elevated TSH level with a normal free T_4 concentration, usually in a patient with no symptoms. Many authorities believe that subclinical hypothyroidism requires the same treatment as overt hypothyroidism because both entities have been associated with adverse cardiovascular outcomes (Franklyn, 2013).

Proponents of therapy for mild thyroid failure cite studies showing higher levels of LDL cholesterol and lower levels of high-density lipoprotein cholesterol in these patients, as well as increased systolic time intervals and decreased cognitive function. After treatment with T_4, some of these problems show improvement. Patients who have coexisting cardiovascular disease or dysrhythmias probably should not be treated for subclinical hypothyroidism because the risks of therapy outweigh the potential benefits. If treatment is attempted, it should be with T_4 at doses to lower the TSH level to the normal range. The incidence of subclinical hypothyroidism is higher in older adults, occurring in up to 20% of people older than age 60; however, since TSH levels have been found to rise naturally in geriatric populations, this may be an overestimate of the prevalence.

A subclinical hyperthyroid entity has been defined by normal free T_4 and T_3 concentrations with a low TSH level in asymptomatic patients. This condition results from overreplacement of T_4, Graves disease, autonomously functioning nodules, surreptitious intake of T_4, nonthyroid illness, or certain medications that decrease TSH. (See Box 47.6.) Risks of subclinical hyperthyroidism include increased bone turnover, which may predispose to osteoporosis and an increased risk of atrial fibrillation and other adverse cardiovascular outcomes. The risk of progression to overt hyperthyroidism is higher in patients with undetectable TSH levels, compared with low but detectable levels. Antithyroid therapy similar to that of overt hyperthyroidism should be considered in consultation with an endocrinologist. Treatment recommendations are based on age of the patient, coexistent conditions, and level of TSH suppression (Palmeiro et al., 2013).

BOX 47.6 Symptoms and Signs of Hyperthyroidism

- Dyspnea
- Heat intolerance
- Palpitations
- Infertility
- Insomnia
- Irritability
- Nervousness
- Sweatiness
- Frequent bowel movements
- Pretibial myxedema (with Graves disease)
- Goiter
- Brisk reflexes
- Tachycardia
- Tremor
- Lid lag
- Exophthalmos (with Graves disease)
- Weight loss
- Amenorrhea or oligomenorrhea

Thyroiditis

After delivering a child, up to 10% of women without previous thyroid disease have postpartum (also known as *painless* or *silent*) thyroiditis, a variant of Hashimoto thyroiditis. Patients present within 1 year after delivery with nonspecific symptoms of fatigue, palpitations, and depression. Tachycardia and goiter may be present on examination.

Patients often go through a hyperthyroid phase that resolves in a few months. Some then have transient hypothyroidism that can last from 2 to 6 months. This condition is usually self-limited, so treatment is indicated only to relieve the symptoms of hyperthyroidism. Beta-blockers are the treatment of choice. Antithyroid drugs are not helpful because the hyperthyroidism that develops is a result of the gland's spilling of preformed thyroid hormone. Some patients require replacement doses of T_4 during the hypothyroid phase of their condition. Women with high titers of antithyroid peroxidase antibodies during or after the pregnancy are at increased risk for development of permanent hypothyroidism; these women should be followed closely.

Women with postpartum thyroiditis may experience symptoms similar to postpartum depression; therefore, practitioners should reassure these women that their symptoms will resolve once the condition subsides. Clinicians should encourage those women at higher risk for permanent hypothyroidism (those with a high titer of antithyroid peroxidase antibodies) to return for periodic follow-up.

Patients sometimes develop subacute (de Quervain) thyroiditis several weeks after an upper respiratory tract infection. They present with a painful, enlarged gland and symptoms and signs of hyperthyroidism, which is the result of leakage of thyroid hormones from the inflamed gland. If a radioiodine scan is performed, it shows diffusely *decreased* uptake of tracer (as opposed to the increased uptake seen in Graves disease).

This condition is self-limited and requires symptomatic treatment only. As in postpartum thyroiditis, beta-blockers are used to reduce tachycardia, tremor, and nervousness. Aspirin or other nonsteroidal anti-inflammatory drugs can reduce the pain in the gland. Rarely, steroids are needed to reduce swelling and pain. These patients may experience a brief period of hypothyroidism but do not usually become permanently hypothyroid, so that vigilant follow-up is not required.

Clinicians should reassure patients with subacute thyroiditis that their condition will resolve spontaneously, but may take weeks.

Case Study*

M.E. is a 29-year-old woman with a 7-month history of heavy, irregular menses, a 5-lb weight gain, constipation, and decreased energy. Her past history is unremarkable. She

takes no prescription medications but uses iron and calcium supplements. She has a family history of thyroid disease. On examination, her weight is 152 lbs, her heart rate is 64 bpm, and her blood pressure is 138/86. Her thyroid gland is mildly enlarged, without nodularity. She has trace edema in her lower extremities, and her reflexes are slow. Laboratory studies are as follows: TSH is 15.3 mIU/mL (elevated), free T_4 is 0.3 mIU/mL (decreased), total cholesterol is 276 mg/mL.

Diagnosis: Primary Hypothyroidism

1. List specific goals of treatment for M.E.
2. What drug therapy would you prescribe? Why?
3. What are the parameters for monitoring the success of the therapy?
4. Discuss specific patient education based on the prescribed therapy.
5. List one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What would be the choice for second-line therapy?
7. What over-the-counter and/or alternative medications would be appropriate for M.E.?
8. What lifestyle changes would you recommend to M.E.?
9. Describe one or two drug–drug or drug–food interactions for the selected agent.* Answers can be found online.

UNIT 11
Pharmacotherapy for Immune Disorders

48 Allergies and Allergic Reactions

Lauren M. Czosnowski ■ Andrew M. Peterson

The term *allergy* is derived from the Greek words *allos* (differing from the normal or usual) and *ergon* (work or energy). To describe it in simple, nonclinical terms, allergy is an abnormal release of energy in the body. In clinical or physiologic terms, allergy is an exaggerated immune response resulting from an antibody–antigen reaction.

Antibodies are soluble protein molecules made by B lymphocytes in response to foreign substances. Antibodies, also referred to as *immunoglobulins*, are tailored specifically and uniquely to bind to each foreign substance and remove it from the circulation. Invasion or contact with a foreign substance results in the production and secretion of antibodies. Therefore, the foreign substance is an *anti*body *gen*erator—hence the term *antigen*. Antigens also are referred to as *allergens*; the terms are interchangeable.

All people come in contact with the same antigens, yet not all people display allergic symptoms. Allergy symptoms appear when the immune response is exaggerated or inappropriate, causing inflammation and tissue damage. This exaggerated response to an antigen is referred to as *hypersensitivity*. Hypersensitivity is a characteristic of an individual. It is manifested on the second or a subsequent contact with a particular antigen.

Allergens can be food based, chemical, or environmental. Typical food allergens include milk or egg protein, peanut, shellfish, and wheat or soy. Parabens and lanolin, commonly found in makeup and sunscreens; thimerosal, a preservative found in contact lens solutions; and fragrance enhancers found in perfumes are common chemical allergens. Drugs, such as the local anesthetics lidocaine and benzocaine, are also chemical allergens. Environmental allergens include mold, pollen, and dust.

In contrast to allergy, *anergy* is the term used to describe the unexpected failure of the immune system to respond to the challenge of a foreign substance (antigen or allergen). Several skin test antigens may be applied to the skin (an anergy panel) to determine the status of the immune system. The antigens selected are those to which a majority of the population would exhibit a reaction. Examples of these include *Candida* species and histoplasmin. If the characteristic wheals do not appear in the prescribed period, it can be interpreted that the patient has not had prior exposure to the antigen or potentially has a compromised immune system.

Classification of Allergic Reactions

The medical literature describes four types of hypersensitivity reactions (Coombs and Gell classification) that are listed and described in Box 48.1 (Nairn & Helbert, 2007). There are four types of reactions under this classification system. Type I reactions involve the interaction between an antigen and a specific immunoglobulin (Ig) E antibody. These antibodies are bound to member receptors on mast cells and basophils. When an antigen binds to these antibodies, the cell releases histamine, leukotrienes, and prostaglandins. These vasoactive substances produce vasodilation and increase capillary permeability, both of which allow for eosinophils and other inflammatory cells to infiltrate tissues, furthering the allergic response. The first contact results in the formation of the antibody. Subsequent contact with the same antigen results in the antibody–antigen reaction, resulting in this type I hypersensitivity reaction. The antibody–antigen reaction triggers the immune response that results in allergic symptoms (Figure 48.1). Allergies can affect the airways, eyes, skin, or the entire body. Type I reactions are typically anaphylactic in nature and can be life-threatening.

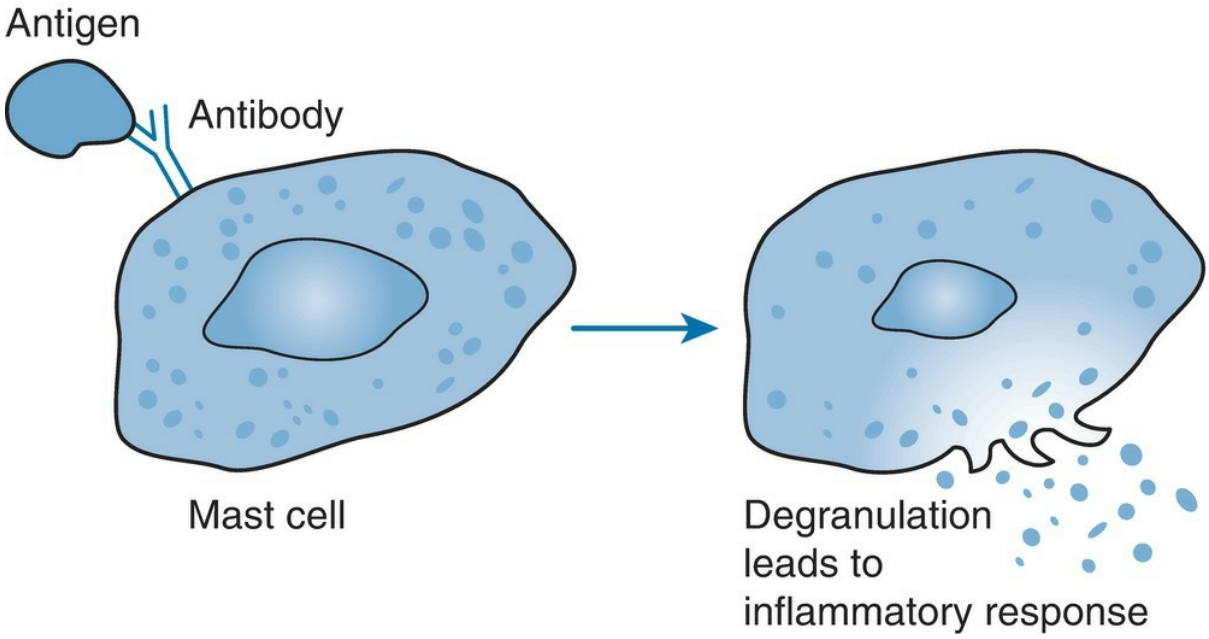

FIGURE 48.1 Antibody–antigen reaction.

BOX 48.1 Coombs and Gell Classification of Hypersensitivity

- Type I (immediate hypersensitivity)—Immunoglobulin (Ig) E attached to mast cells binds with an antigen, inducing degranulation and release of histamine and other

mediators of inflammation. (Asthma and allergic rhinitis are examples of type I hypersensitivity.)

- Type II—IgG attached to a T lymphocyte killer cell is directed against antigens on target cell. This leads to direct cytotoxic action or complement-mediated lysis.
- Type III—Immune complexes of antibody and antigen are deposited in the tissue. Complement is activated, and polymorphonuclear leukocytes are attracted to the site of the complex. Local tissue damage occurs. (Autoimmune disease is an example of type III hypersensitivity.)
- Type IV (delayed hypersensitivity)—Antigen-sensitized T cells release inflammatory substances after a second contact with the same antigen. (Contact dermatitis, such as poison ivy, and the tuberculin skin test [PPD] are examples of delayed hypersensitivity.)

Type II reactions, also known as *cytotoxic reactions*, occur when an antibody reacts with an antigenic component of a cell. This antibody–antigen reaction in turn activates killer T cells or macrophages to aid in the destruction of the antigenic cell. Complement activation is also involved in this process, furthering the cytotoxic process leading to tissue destruction. Transfusion reactions are typically type II allergic reactions.

Type III reactions result from immune complexes that activate the complement system. Activating this system promotes the migration and release of cells such as polymorphonuclear cells that can release proteolytic enzymes and factors that promote tissue permeability. Systemic lupus erythematosus is a form of a type III allergic reaction.

Type IV reactions are also called delayed hypersensitivity reactions. These cell-mediated reactions are the result of sensitized T lymphocytes coming into contact with a specific antigen. The delay typically takes 2 to 3 days or up to a week. Allergic dermatitis is an example of a type IV reaction.

Immunologic Versus Nonimmunologic Reactions

Some cutaneous reactions, such as contact dermatitis, may appear to be allergic reactions, but they do not involve the immune system. Irritant contact dermatitis is the most common cutaneous reaction and is often caused by skin irritants such as powders or chemicals found in gloves.

Contact dermatitis differs from allergic dermatitis in that there is direct tissue insult from the skin irritant that causes the release of inflammatory mediators from skin cells. A common example of irritant contact dermatitis is a reaction to repeated hand-washing with soap or other cleaners. In some instances, the cracked, dry skin occurring with contact dermatitis no longer can prevent allergens from entering the systemic circulation. With latex allergies, for example, the powder already present in the glove can give rise to a contact dermatitis, thus allowing for the latex antigens to enter the circulation. This in turn increases the likelihood of an allergic reaction, resulting in allergic contact dermatitis. Because of this phenomenon, it is often difficult to distinguish allergic from nonallergic contact dermatitis. See Chapter 11 for more details on dermatitis.

General Treatment Overview of Allergic Reactions

The first step in treating an allergic reaction is to remove the allergen, if possible. This may involve removing the person from the environment causing the allergy, stopping the offending drug, or washing off the offending chemical. Most allergic reactions clear up within a few days of removing the cause. Symptomatic cutaneous reactions, such as pruritic rash, urticaria, or morbilliform eruptions as well as reactions involving multiple organs, should be treated.

Cutaneous Reactions

Cutaneous reactions such as urticaria, pruritus, and hives are often secondary to the release of histamine, making antihistamine therapy the mainstay of treatment. There are two types of antihistamines used in the general treatment of allergic reactions: first generation and second generation. The first-generation antihistamines include diphenhydramine, hydroxyzine, and chlorpheniramine, among others. These agents are typically very effective, but they may also be very sedating. The second-generation agents, such as loratadine and fexofenadine, are nonsedating antihistamines (NSAs) that work fairly well at controlling mild to moderate symptoms of cutaneous reactions. However, if the symptoms persist for more than a few days, or are not well controlled, a first-generation antihistamine may be substituted, or added, to the NSA. Close communication with the patient regarding resolution of the symptoms is necessary, along with balancing quality-of-life issues related to side effects, such as sedation, dry mouth, and urinary retention. If the reaction is moderate to severe or if there is no relief from antihistamine therapy, systemic glucocorticoids may be used. Short courses of treatment with oral prednisone or methylprednisolone are usually used. See Chapter 11 for more information on the use of oral steroids for treating cutaneous reactions.

Anaphylaxis and Anaphylactoid Reactions

Anaphylaxis is a type I hypersensitivity reaction involving IgE-mediated release of histamine, leukotrienes, and other mediators from already sensitized mast cells and basophils. The release of these mediators initiates a systemic chain of events that includes symptoms such as angioedema, flushing, pruritus, urticaria, nausea, vomiting, and wheezing. The onset of the reaction is quick, generally within 1 to 30 minutes. The histamine release causes a smooth muscle contraction and vasodilation. The wheezing resulting from smooth muscle contraction in the lungs decreases oxygenation, whereas vasodilation results in a release of fluids into the tissues, thus causing a lower effective plasma volume, leading to shock. Prolonged vasodilation, coupled with decreased oxygenation, can lead to arrhythmias, convulsions, and death.

Anaphylactoid reactions are similar in appearance to anaphylaxis but may occur after the *first* injection of certain drugs and contrast media. They are non-IgE mediated, and the agent causes a direct release of histamine and other inflammatory toxins. They have a dose-related, idiosyncratic mechanism rather than an immunologically mediated one. A classic example of an anaphylactoid reaction is the "red man syndrome" associated with vancomycin. Patients may experience itching, redness, and hives with rapid infusion of vancomycin due to histamine release; slowing the infusion rate usually improves the reaction.

Treatment

Immediate treatment with epinephrine is imperative. Epinephrine effectively increases the blood pressure and is an antagonist to the effects of histamine on smooth muscle and other tissues.

At the onset of anaphylactic symptoms, such as generalized pruritus, urticaria, angioedema, or wheezing, 0.01 mL/kg aqueous epinephrine 1:1,000 (1 mg/mL) subcutaneously or intramuscularly (usual dose, 0.2 to 0.5 mL in adults; 0.3 mL maximum for children) should be given. This dose may be repeated every 5 to 15 minutes as necessary to control symptoms. Intramuscular injection into the lateral thigh muscle results in a shorter time to peak concentrations of epinephrine in the blood, compared to subcutaneous injection or intramuscular injection into the deltoid muscle. An injectable antihistamine such as diphenhydramine (usual dose for adults, 25 to 50 mg; children, 1 mg/kg) may also be given in addition to epinephrine to treat symptoms related to anaphylaxis such as itching and hives. These agents alone do not treat airway obstruction, hypotension, or shock.

If the reaction does involve the cardiovascular system, then intravenous fluids should be rapidly infused to maintain volume. Hypovolemia is usually the major cause of the hypotension due to fluid moving out of the intravascular space. Colloid plasma expanders such as dextran are rarely necessary. Normal saline is an appropriate choice for most patients, and 1 to 2 L should be given as an initial bolus. Fluids may be continued as

necessary to maintain hemodynamic stability. If fluid replacement is ineffective at restoring blood pressure, then dopamine or norepinephrine may be *cautiously* introduced. Alternatively, if the patient is experiencing bradycardia, atropine may be used to increase heart rate. Patients with severe reactions should be observed in the hospital for 24 hours after recovery in case of relapse.

Systemic corticosteroids may help prevent late-phase reactions in some cases of anaphylaxis, although they will not have an effect for 4 to 6 hours. Typically, methylprednisolone 1 to 2 mg/kg/d divided every 6 to 8 hours for adults and 1 to 2 mg/kg/d divided every 8 to 12 hours for children is needed to prevent the onset of late-phase reactions. For milder attacks, oral prednisone dosed at 0.5 mg/kg/d may be administered, although there are not strong data to support in administering glucocorticoids.

Prophylaxis

The primary means of preventing an allergic reaction is avoidance. However, when this is not feasible or practical, immunotherapy is an effective means of preventing reactions, particularly anaphylactic reactions from insect bites. This form of "desensitization" is only effective when a specific allergen can be identified. Some ragweed and pollen allergies respond well to immunotherapy, though it may take several months before immunity is conferred.

Desensitization may be rapidly achieved in patients requiring drug therapy to which they have an established allergy. For example, patients with anaphylactic reactions to penicillin may be desensitized by administering increasing concentrations of penicillin every 15 minutes. To ensure patient safety, desensitization is best done under constant supervision and in consultation with an experienced allergist. There are numerous protocols for penicillin desensitization and an increasing number for patients who are allergic to sulfa drugs.

Allergic Rhinitis (Hay Fever or Pollen Allergy)

Allergic rhinitis is an *airway allergy*. (Asthma, also an airway allergy, is discussed in Chapter 25.) Many people have hay fever. The National Institute of Allergy and Infectious Diseases states that pollen allergy may affect approximately 7% of adults and 9% of children in the United States. (NIAID July 2015).

Causes

Common inhaled allergens that cause allergic rhinitis in sensitized people include pollen (grass, trees, weeds), dust mites, mold spores, enzymes (in detergents), and insect body parts. The two most common types of allergic rhinitis are seasonal and perennial (Table 48.1). The incidence of seasonal rhinitis is approximately 10 times greater than that of perennial rhinitis.

TABLE 48.1 Seasonal Versus Perennial Allergies

Causes of Seasonal Allergies	Causes of Perennial Allergies
Tree pollen (spring)	Mold (indoor)
Grass pollen (spring through fall)	Dust (dust mites)
Weeds (late summer)	Animal dander (skin flakes)
Leaf mold (early spring and late summer)	Animal fur
	Foods (nuts, shellfish, milk, eggs)

In seasonal allergic rhinitis, symptoms correspond with seasonal peaks in tree, grass, and weed pollens. During the spring, tree pollens such as alder, birch, and oak cause problems for many people. In the summer, grass pollens, such as timothy grass, can cause allergies. Weeds, such as mugwort and ragweed, pollinate in late summer and autumn. Pollens usually are windborne, and patients with seasonal allergic rhinitis often are said to have "hay fever." The most common cause of seasonal allergic rhinitis is ragweed pollen.

Patients with perennial allergic rhinitis have symptoms throughout the year, instead of only during certain months. They usually require chronic treatment. The most common causes of perennial rhinitis are animal dander and dust mites. In many cases, causative agents are difficult for patients to avoid because many such agents are indoor allergens. Perennial rhinitis may worsen when patients are exposed to nonnatural irritants such as paint, cleaners, or tobacco smoke.

Genetic predisposition plays a major role in the development of allergic rhinitis. The genetically determined tendency to produce increased quantities of IgE expresses itself after prolonged exposure to an allergen. Consequently, allergic rhinitis is uncommon before age 3. Those in later childhood or young adulthood are at greatest risk for development of new symptoms. In general, neither sex exhibits more of a predilection for allergic rhinitis;

however, some sources indicate that the perennial form is more common in women.

Patients with a family history of asthma or eczema are more likely to have an allergic basis for rhinitis. The incidence of allergic rhinitis increases by approximately 20% to 30% when one parent has a history and is even higher when both parents have allergic disorders. Studies of pediatric populations have uncovered certain factors that may increase the expression of allergy: maternal smoking, especially during pregnancy, female gender, and exposure to air pollution (Corren et al., 2014).

Pathophysiology

Initial exposure to the antigen/allergen stimulates the B lymphocytes (plasma cells) to produce an antigen-specific antibody (IgE) that binds to mast cell membranes (tissue-fixed antibody). The person is now sensitized to that specific antigen and susceptible to allergic reactions when re-exposed to it. On subsequent exposure, the antigen binds to the tissue-fixed IgE antibody and triggers breakdown of the mast cells (degranulation) and release of mediators (histamine, prostaglandins, leukotrienes, kinins, thromboxanes, and serotonin). Histamine, which is stored primarily in mast cells and basophils, is believed to be the mediator most responsible for the clinical signs and symptoms of allergic rhinitis.

Common symptoms in patients with allergic rhinitis are ocular pruritus (itching of the eyes) and conjunctival inflammation (inflammation of the membrane lining the eyelids). Other symptoms of allergic rhinitis are irritability, lethargy, fatigue, and loss of appetite. Once released into the nasal mucosa, the mediators cause vasodilation, increased capillary permeability, increased mucus production, and stimulation of nerve endings. The resulting symptoms are rhinorrhea (profuse, watery nasal discharge), nasal congestion (obstruction by mucus), and nasal pruritus. The most severe symptoms include violent episodes of sneezing (often a dozen or more times in a row) and total obstruction of nasal airflow resulting from copious amounts of mucus (Figure 48.2).

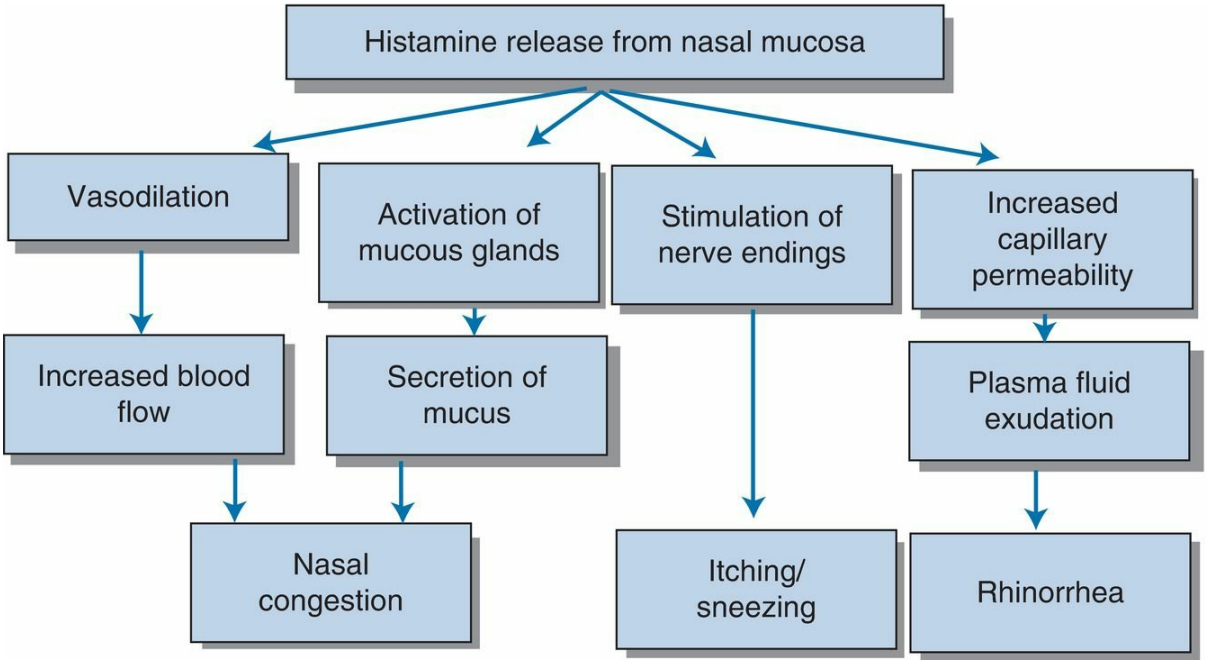

FIGURE 48.2 Results of histamine release in the nasal mucosa.

The specific IgE antibody made in response to the allergen also may attach to eosinophils. Antigen-provoked degranulation of eosinophils also causes allergic symptoms. The

symptoms associated with eosinophils are related to a late-phase allergic response, occurring hours to days after the initial reaction.

Diagnostic Criteria

The diagnosis of allergic rhinitis begins with a thorough history determining the presence of classic signs and symptoms and the time, place, and circumstances under which they occur. A family history is also important because it may establish the familial predisposition to allergy.

Physical examination of the patient with suspected allergic rhinitis begins with assessment of facial appearance, which often includes teary eyes and a red, swollen nose with scaling and crusting from frequent blowing and rubbing with facial tissues. There also may be dark circles under the eyes (allergic shiners), pinched nostrils, and a gaping mouth (from mouth breathing). The nasal mucous membranes are typically pale, swollen, and coated with a clear, watery secretion. Some erythema and bleeding may be noted. Swelling, streaks of erythema, and mucus may be present in the posterior pharynx. Other positive physical findings include swelling around and watery discharge from the eyes.

Nasal Smears

Practitioners may use the Wright stain for nasal secretions to detect eosinophils. Although eosinophilia suggests an allergic etiology for rhinitis symptoms (in infectious rhinitis, neutrophils predominate), it is not diagnostic. Conversely, an absence of eosinophilia does not rule out allergy. Eosinophilia may be absent in patients who have superimposed infections or have not had a recent exposure to allergens.

Skin Testing

Skin testing with extracts of suspected allergens usually provides the most effective means of identifying specific sensitivities in patients with allergic rhinitis. In this test, a superficial scratch or prick is made in the skin and a diluted extract of antigen is applied. If the patient has allergen-specific IgE antibodies bound to tissue mast cells, a classic wheal-and-flare reaction appears over the next 15 to 30 minutes. To avoid false-negative results, patients should discontinue the use of antihistamines before they undergo skin testing. Clinicians should individualize this time frame based on the pharmacokinetics of the specific antihistamine that the patient is taking. In most cases, it is adequate to stop taking antihistamines 48 to 72 hours before testing. If patients do not stop taking antihistamines before skin testing, practitioners may mistakenly exclude a diagnosis of allergic rhinitis and subject patients to unnecessary further evaluations.

If the results of the scratch test are negative or unclear, practitioners may administer a more dilute extract of antigen intradermally. Clinicians should not use the intradermal test in patients with a positive response to scratch testing because of the risk of significant allergic reaction, including anaphylaxis.

Radioallergosorbent Testing

Radioallergosorbent testing (RAST) permits in vitro detection of serum IgE antibodies to allergens. Because only 1% of IgE molecules circulate in the blood (the remainder are bound to tissue), RAST results may not reflect the biologic situation. Although RAST is more specific, skin testing is less costly, more sensitive, and simpler to perform. Despite these shortcomings, RAST is helpful when the results of skin testing are unclear. The test is likewise useful when patients are unable to undergo skin testing because of dermatologic conditions or a history of anaphylactic reaction to the suspected allergen. RAST is also indicated for evaluating children younger than age 2 as well as for patients unable to discontinue using antihistamines, as required before skin testing.

Differential Diagnosis

Symptoms similar to those of allergic rhinitis may result from *mechanical nasal obstruction* (foreign body or anatomic factors); as a *side effect of medications* (oral contraceptives, hormone replacement therapy, tricyclic antidepressants, propranolol [Inderal], reserpine [Serpasil], methyldopa [Aldomet], and aspirin-containing compounds); or from *medical conditions associated with increased vasodilation* (e.g., hypothyroidism, cystic fibrosis, tumors, alcoholism, or pregnancy). Table 48.2 compares the symptoms of seasonal rhinitis with common cold symptoms to illustrate the similarities and differences between these conditions.

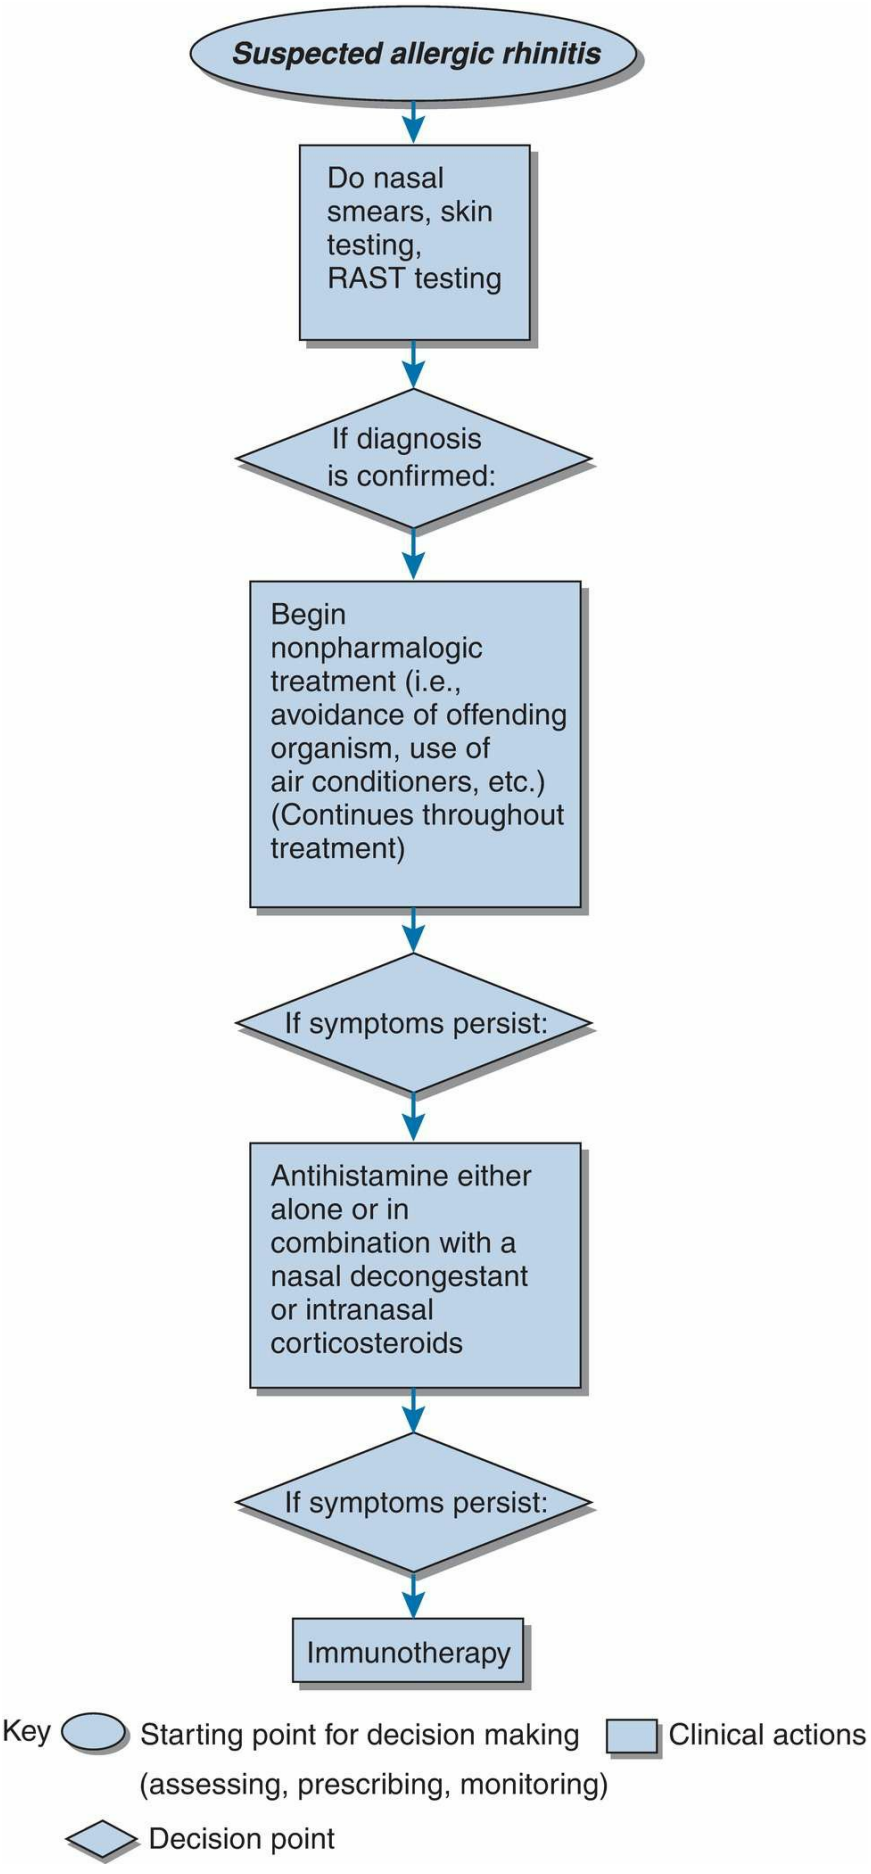
TABLE 48.2 Symptoms of Seasonal Allergies Versus Respiratory Infections

Symptoms	Seasonal Allergy (Hay Fever)	Upper Respiratory Infection
Head congestion/ runny nose	Yes	Yes
Sneezing	Yes	Sometimes
Itchy, watery eyes	Yes	No
Cough	Usually dry	Dry or productive
Predictable seasonal patterns	Yes	Uncommon
Fever	No	Yes
Short duration (3–7 d)	No	Yes
Long duration (weeks)	Yes	No
Productive cough	Uncommon (except in asthma)	Yes

Although seasonal rhinitis usually is relatively easy to diagnose, identification of perennial rhinitis may be more elusive. Other nonallergic conditions could cause similar symptoms. *Vasomotor rhinitis* (congestion of the nasal mucosa without infection or allergy) could be difficult to differentiate from perennial rhinitis. In vasomotor rhinitis, however, irritants (e.g., fumes, cold air, high humidity, alcoholic beverages, or emotional stress) rather than allergens usually trigger symptoms. Moreover, vasomotor rhinitis is associated with an absence of nasal, palatal, or conjunctival pruritus. In *nonallergic rhinitis with eosinophilia*, testing likewise fails to indicate a specific allergen.

Initiating Drug Therapy

Allergic rhinitis may be treated through avoidance of the allergen, pharmacologic agents, and immunotherapy. The basic approach to pharmacologic management of allergic rhinitis is the use of antihistamines, nasal decongestants, and intranasal corticosteroids (Figure 48.3).



Suspected allergic rhinitis
Do nasal smears, skin testing, RAST testing
If diagnosis is confirmed:
Begin nonpharmalogic treatment (i.e., avoidance of offending organism, use of air conditioners, etc.) (Continues throughout treatment)
If symptoms persist:
Antihistamine either alone or in combination with a nasal decongestant or intranasal corticosteroids
If symptoms persist:
Immunotherapy
Key
Starting point for decision making (assessing, prescribing, monitoring)
Clinical actions
Decision point

FIGURE 48.3 Treatment algorithm for allergic rhinitis.

The ideal treatment for allergic rhinitis is avoidance of the offending allergen. Complete avoidance often is not feasible, but most patients usually can reduce exposure. Basic strategies include the use of air conditioners in homes and automobiles to lessen exposure to pollen by keeping windows closed and use of dehumidifiers to discourage the growth of molds and mites. If possible, humidity should be maintained at 30% to 40% throughout the year. Patients can lessen exposure to mites by encasing mattresses in plastic, washing all bedding in very hot water each week, and removing carpeting and upholstered furniture. They can use high-efficiency particulate air (HEPA) cleaners to help filter out dust molds and pollen. Ideally, pets should be removed from the home; however, many patients and their families find doing so unacceptable. At a minimum, families should keep pets out of the allergic person's bedroom, as well as away from heating and cooling systems.

Immunotherapy, also known as *desensitization*, *hyposensitization*, or *allergy shots*, has been used for decades for the treatment of allergic rhinitis and asthma. It consists of repeated subcutaneous injections of gradually increasing concentrations of the allergens considered to be specifically responsible for the patient's allergy symptoms. However, patients must have documented IgE antibodies to these allergens. The injections are purified extracts of the "trigger" substances, such as ragweed, grass, dust mite, and animal dander. Clinical benefits are related to the administration of high doses of allergens weekly or every other week. The duration of treatment is typically 3 to 5 years, but if there is no improvement after 1 year, consider discontinuing immunotherapy. Treatment is discontinued based on minimal symptoms over two consecutive seasons of exposure. The benefit is derived from a reduction in the percentage of histamine released after immunotherapy compared with before treatment. The result is milder or no symptoms of allergy. Immunotherapy is not the first-line treatment. It is usually initiated when avoidance of the triggers and drug therapy fail to control the symptoms of hay fever and other allergies.

Goals of Drug Therapy

The goal of drug therapy for patients with allergies is to alleviate the symptoms with a little to no adverse effects from medications. This is accomplished primarily through decreasing the release or inhibiting the effect of histamine release and other mediators of inflammation from mast cells. Mast cells are distributed throughout the body; however, the greatest concentration of histamine occurs in the skin, respiratory system, and gastrointestinal (GI) mucosa. Relief of symptoms with minimal drug side effects should lead to an improved quality of life.

Histamine released in the GI tract does not cause allergic symptoms. It may result in hyperacidity by stimulating histamine type 2 (H_2) receptors and lead to peptic ulcer disease or gastroesophageal reflux disease. Treatment of these conditions is with H_2 blockers. It is the histamine released in the skin and respiratory tract (H_1 receptors) that causes classic allergic symptoms. The medications used to treat these symptoms are antihistamines (H_1 blockers), nasal decongestants, intranasal corticosteroids, and intranasal cromolyn. Suggestions for their selection are outlined in the following sections. The decision to treat with medications will depend on the severity of symptoms and patient tolerance of symptoms, as well as the balance of symptoms versus medication side effects. If drug treatment is chosen by the patient, it will be required as long as exposure to the triggers continues or until the patient becomes desensitized to the trigger, either naturally ("outgrowing the allergy") or through immunotherapy (described earlier).

Antihistamines

Antihistamines are classified according to their sedative effects or as first generation (older) and second generation (newer) depending on when they were marketed. The older antihistamines cross the blood–brain barrier, causing the greatest degree of sedation as well as other central nervous system (CNS) effects. These agents can be subclassified on the basis of chemical structure. The main groupings include the ethanolamines, alkylamines, phenothiazines, piperazines, and piperidines.

Mechanism of Action

Antihistamines are drugs that exert their effect in the body primarily by blocking the actions of histamine at receptor sites. They are classified as pharmacologic antagonists of histamine. They do not prevent histamine release, but act by competitive inhibition. Most antihistamines can be classified as either H_1-receptor blockers, which block the smooth muscle response, or H_2-receptor blockers, which block the histaminic stimulation of gastric acid. In general, H_2-receptor blockers are not used for patients with allergies. If the concentration of antihistamine drug at the receptor site exceeds the concentration of histamine, then the effects of histamine are blocked. Antihistamines usually ameliorate itching, sneezing, ocular symptoms, and nasal discharge but do not always reduce nasal congestion.

First-Generation Antihistamines

The first-generation antihistamines, such as diphenhydramine, chlorpheniramine, and brompheniramine, are the older antihistamines. As noted earlier, these tend to be more sedating than newer, second-generation agents such as loratadine or cetirizine.

Dosage

The dosage varies depending on the age and weight of the patient. The frequency of dosing is typically every 4 to 6 hours as needed, but can be upward of every 12 hours depending on the half-life of the drug and the formulation. For example, diphenhydramine (Benadryl) is given every 4 to 6 hours, but brompheniramine is dosed every 12 to 24 hours. These are often over-the-counter (OTC) agents and are supplied as tablets, capsules, elixirs, or suspensions. Further, these formulations come in a variety of flavors, and some are even free of dye.

Time Frame for Response

The onset of action of these agents typically ranges from 15 to 30 minutes and lasts nearly as long as the dosing interval. Those agents with a longer half-life will take longer to get to steady state, but the initial effect is often seen fairly rapidly.

Some regular users of antihistamines find that tolerance, or drug failure, develops after several weeks or months. One reason for this decreased effectiveness is that some antihistamines are capable of hepatic enzyme induction, resulting in increased metabolism in the liver. Essentially, the antihistamine drug hastens its own destruction and removal from circulation. The various antihistamine classes differ in their capacity to induce hepatic enzymes. Some practitioners have found that if tolerance develops, patients may benefit by switching to another antihistamine in a different chemical category. The effectiveness of this technique has not been evaluated by controlled studies.

Contraindications

First-generation antihistamine therapy is contraindicated in lactating mothers. Additionally, the anticholinergic side effects of the first-generation antihistamines put patients with narrow-angle glaucoma at risk for an increase in intraocular pressure. Similarly, men with benign prostatic hyperplasia (BPH) should avoid these agents due to the drug's ability to decrease urine flow. The sedating effects of these agents should also be considered when patients are required to perform hazardous tasks or drive. Because of the sedating and anticholinergic properties, first-generation antihistamines are on the Beers list, a list of drugs that should be avoided or used with extreme caution in elderly patients (AGS, 2012). Antihistamines are recommended for the treatment of itching and rhinitis in pregnant women; diphenhydramine is pregnancy category B.

Adverse Events

Knowledge of the chemical category to which an antihistamine belongs can help determine the relative degree of sedation and anticholinergic effects associated with the particular agent. In general, the ethanolamine derivatives, such as diphenhydramine, and the phenothiazine derivatives, such as promethazine (Phenergan), cause the greatest degree of sedation and anticholinergic effects. The most problematic anticholinergic effects are dry mouth, blurred vision, urinary hesitancy, constipation, confusion, and mental cloudiness.

The sedative effects of the older antihistamines vary among patients and may not cause problems for some. Tolerance to the sedative effect develops, and many patients find that sedation either disappears or becomes less bothersome after several days of continued use. Nonetheless, sedation may affect the patient's acceptance of the older antihistamine drugs.

Less Sedating Antihistamines

More recently, antihistamines have been developed that do not cross the blood–brain barrier to the extent exhibited by the older agents. These newer antihistamines, commonly referred to as *NSAs*, are considered to act peripherally and do not produce sedation or cause clinically important changes in mental status. In general, the anticholinergic effects of these agents are also minimal. Cetirizine, a metabolite of the antipruritic hydroxyzine (Atarax), is not always accepted as an NSA because it is reported to have a higher incidence of sedation than the other newer antihistamines. It is generally classified as a peripherally acting antihistamine and is often still listed in the same category. Nonetheless, it is an effective antihistamine approved by the U.S. Food and Drug Administration (FDA) for seasonal and perennial rhinitis. The NSAs are listed and compared in Table 48.3.

TABLE 48.3 Overview of Selected Antihistamines and Decongestants

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Nonsedating Antihistamines			
cetirizine (Zyrtec) 5–10 mg PO daily Children 2–6 y: 2.5 mg daily 6–11 y: 5–10 mg daily	Somnolence, dry mouth, pharyngitis, dizziness	Known hypersensitivity to cetirizine or hydroxyzine	Renal or hepatic impairment: Adults—5 mg qd; Children—not recommended Pregnancy category B
levocetirizine (Xyzal) 2.5–5 mg PO daily Children 2–5 y: 1.25 mg daily 6–11 y: 2.5 mg PO daily	Same as cetirizine	Known hypersensitivity to levocetirizine or cetirizine, end-stage renal disease, renal impairment in children	Use with caution in patients with renal impairment. Pregnancy category B
fexofenadine (Allegra) 60 mg PO bid 180 mg tablet PO daily Children 2–11 y: 30 mg bid	Viral infection (cold, influenza), nausea, dysmenorrhea, drowsiness, dyspepsia, fatigue	Known hypersensitivity to any of its ingredients	Erythromycin and ketoconazole may increase plasma levels of fexofenadine. Pregnancy category C
loratadine (Claritin) 10 mg PO qd Children 2–5 y: 5 mg daily	Headache, somnolence, fatigue, dry mouth	Known hypersensitivity to any of its ingredients	Give same dose every other day in renal or hepatic impairment. Pregnancy category B
desloratadine (Clarinex) 5 mg PO daily Children 2–5 y: 1.25 mg daily 6–11 y: 2.5 mg daily	Same as loratadine	Known hypersensitivity to any ingredients or loratadine	Give same dose every other day in renal or hepatic impairment. Pregnancy category C
Intranasal Antihistamines			
olopatadine (Patanase) two sprays per nostril twice daily Children 6–11 y: One spray per nostril twice daily	Headache, somnolence, cough, epistaxis, throat irritation, bitter taste, dry mouth	None	Amount of drug per actuation (spray): 127 mcg
azelastine (Astelin or Astepro nasal spray) 1–2 sprays in each nostril bid; 100 doses per bottle	Bitter taste, headache, somnolence, nasal burning, pharyngitis, dry mouth, paroxysmal sneezing, nausea, rhinitis, fatigue, dizziness	Known hypersensitivity	Amount of drug per spray: 137 mcg (Astelin), 205.5 mcg (Astepro) Astepro may be dosed two sprays once daily rather than BID. Not recommended in children 6–12 y

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Oral Nasal Decongestants			
pseudoephedrine 60 mg q6h (240 mg); extended release, 120 mg q12h; controlled release 240 mg q24h Children 6–12 y: 30 mg q6h (120 mg) Children 2–6 y: 15 mg q6h (60 mg)	Headache, insomnia, dry mouth, somnolence, nervousness, dizziness, fatigue, dyspepsia, nausea, pharyngitis, anorexia, thirst	Hypersensitivity to drug or its components, use within 14 days of an MAO inhibitor	Extended release should not be recommended for children <12 y. Pregnancy category C
phenylephrine 10–20 mg q4h Children 6–12 y: 10 mg q4h	Same as pseudoephedrine	Same as pseudoephedrine	Pregnancy category C
Intranasal Cromolyn			
cromolyn (Nasalcrom nasal solution) Patients ≥2 y: one spray in each nostril three to six times a day until symptom relief, then every 8–12 h	Common: burning, stinging, or irritation inside nose, increase in sneezing Rare: cough, headache, unpleasant taste, bloody nose	Hypersensitivity to cromolyn or the formula; acute asthma attacks	Comes in 13-mL bottle and 26-mL bottle—13-mL bottle = 100 sprays, 26-mL bottle = 200 sprays Not recommended in children <2 y

Dosage

Loratadine (Claritin) is dosed as 10 mg once daily for adults and children ages 6 and older. For children ages 2 to 5, the dose is 5 mg once daily. Cetirizine (Zyrtec) is given 5 to 10 mg

once daily for children older than age 6 and adults. The lower dosage can be used for younger children or for patients with less severe symptoms. Children ages 2 to 5 should be started on 2.5 mg once daily. Levocetirizine and desloratadine are generally half the dose of cetirizine and loratadine. Fexofenadine (Allegra) doses are for adults and children age 12 and older. The starting dose is 60 mg twice daily or 180 mg once daily for the extended-release formulation. Children ages 6 to 11 should start at 30 mg twice a day.

Time Frame for Response

This class of agents has a rapid onset of action, with a time to maximum effect ranging from 1 to 2.5 hours. The half-life of these drugs is 8 to 28 hours, leading to a 1- to 3-day delay in reaching a steady state. Food can delay the time to peak of cetirizine and loratadine, but not fexofenadine.

Contraindications

The lower propensity for anticholinergic effects allows for wider use of NSAs in the elderly, patients with glaucoma, and men with BPH because they do not share the same contraindications. NSAs are contraindicated in patients with previous hypersensitivity to these drugs and are not recommended in lactating mothers. Using antihistamines is generally considered safe during pregnancy, although the NSAs are generally considered second line.

Adverse Events

Overall, this class of drugs is well tolerated in patients. Common adverse events include headache, dry mouth, dyspepsia, nausea, and fatigue. See Table 48.3 for specific agents. It is important to note that cetirizine and levocetirizine are known to be more sedating than the other drugs in this class. More serious but rare side effects include dizziness, myalgia, somnolence, and dysmenorrhea.

Interactions

While loratadine and desloratadine do not have any significant drug interactions, fexofenadine does have some interactions that should be clinically considered. Fexofenadine concentrations may be increased by azole antifungals and erythromycin. Antacids and grapefruit juice administered with fexofenadine may decrease the absorption of fexofenadine. There is also a remote possibility that fexofenadine may prolong the QT interval on an electrocardiogram when administered with other drugs that concurrently prolong the QT interval. Cetirizine or levocetirizine administered with sedating drugs may increase sedation.

Intranasal Antihistamines

Azelastine (Astelin) and olopatadine (Patanase) intranasal antihistamines are also available to treat allergic rhinitis. In placebo-controlled trials, they significantly improved the symptoms of rhinorrhea, sneezing, and nasal pruritus. The adverse events that occurred more frequently than in the patients treated with placebos were bitter taste (19.7% vs. 0.6% for placebo) and somnolence (11.5% vs. 5.4%) (Astelin Package Insert, 2014). These agents still have some systemic absorption, so it is important to remember that they may cause side effects and interact with allergy skin tests. Intranasal prescribing information is noted in Table 48.3.

Nasal Decongestants

Mechanism of Action

Nasal decongestants are sympathomimetic amines chemically related to norepinephrine, a major neurotransmitter of the sympathetic nervous system. These drugs are vasoconstrictors. They offer relief from nasal congestion by constricting the blood vessels of the nasal mucosa that have been dilated by histamine and are available in either oral or topical nasal formulations. The results are a shrinking of swollen nasal passages and more air movement to make breathing easier. However, just as norepinephrine is a CNS stimulant, so are the synthetic oral and topical (nasal) decongestants, which is an important clinical consideration.

Dosage

Dosing for common nasal decongestant products is noted in Table 48.3. Many decongestants are available in combination with antihistamines. Fixed combination products containing antihistamines and sympathomimetic amines are convenient, but the effective dose of oral decongestants varies among patients. If use of a fixed combination causes side effects or does not relieve symptoms, then clinicians should titrate with single agents to achieve the required dosage.

Because these agents are available OTC, counsel patients to read all labels carefully in order to select a product with only the components that they need to treat symptoms. Many of these combination products may also contain pain relievers or caffeine in addition to antihistamines and decongestants. If patients are also taking separate doses of pain relievers, they could be in danger of overdose.

Starting in September 2006, the sale of OTC pseudoephedrine has been restricted to "behind-the-counter" status, which means that customers may not directly access any products containing this drug. This could be behind the pharmacy counter or in a locked cabinet. This change was the result of the "Combat Methamphetamine Epidemic Act of 2005," which sought to deter citizens from synthesizing illicit methamphetamine from pseudoephedrine-containing products. Purchasers are not required to have a prescription, but must present photo identification. The seller must keep a record of the purchaser's name and information, along with the quantity purchased. The quantity limits may vary per state, but most states have a maximum of 3.6 g that may be purchased in a 24-hour period; many states set a limit of 9 g in a 30-day period (FDA, 2014). Some states have also imposed a minimum age for purchasing pseudoephedrine (e.g., 18 years and older).

Time Frame for Response

The onset of action for these agents, in immediate-release form, is typically 15 to 30 minutes with a peak response within 30 to 60 minutes. The half-life of pseudoephedrine is

9 to 16 hours, but the effect of the decongestant activity wears off within 4 to 6 hours after administration.

Contraindications

Caution should be used when recommending OTC oral decongestants. Patients with high blood pressure, heart disease, hyperthyroidism, narrow-angle glaucoma, seizure disorders, and BPH may see exacerbation of their disease. In addition, use of oral decongestants is contraindicated in patients taking monoamine oxidase (MAO) inhibitors within 14 days of the administration of pseudoephedrine. Pseudoephedrine and phenylephrine cause the release of norepinephrine into the synapse, and MAO inhibitors inhibit the enzymatic degradation of norepinephrine. As such, the concomitant use of these agents increases the sympathetic activity of the nervous system and can lead to hypertensive crisis. Nasal decongestants are not recommended during pregnancy, and pseudoephedrine should be avoided during the first trimester of pregnancy.

Adverse Events

Oral decongestants constrict blood vessels throughout the body and also act as CNS stimulants, thus increasing blood pressure and heart rate and causing palpitations. Stimulation of the CNS can lead to insomnia, irritability, restlessness, and headache. Many patients find that they can use oral decongestants only during the daytime because the stimulatory effects of these drugs can cause nervousness, agitation, and insomnia.

Topical (Intranasal) Decongestants

Intranasal application (sprays or drops) of sympathomimetic amines provides a prompt and dramatic decrease of nasal congestion. A rebound phenomenon (rhinitis medicamentosa), however, often follows topical application of these drugs. In this scenario, the nasal mucous membrane becomes even more congested and edematous as the drug's vasoconstrictor effect wears off. This secondary congestion is believed to result from ischemia caused by the drug's intensive local vasoconstriction and local irritation of the agent itself. If the use of a topical decongestant is limited to 3 or 4 days, rebound congestion is minimal. With chronic use or overuse of these drugs, rebound nasal stuffiness may become quite pronounced. This phenomenon may begin a vicious cycle, leading to more frequent use of the drug that causes the problem. Should this occur, patients should discontinue topical decongestant therapy. They may use an oral decongestant, isotonic saline drops or spray, or both instead (Table 48.4). Side effects from topically administered agents include local irritation and rebound congestion.

TABLE 48.4 Topical Nasal Decongestants

			Patient Age			
Generic	**Trade**	**Concentration (%)**	**>6 mo**	**2–6 y**	**6–12 y**	**>12 y**
phenylephrine	Neo-Synephrine	0.125	Yes	Yes	Yes	Yes
	Neo-Synephrine	0.25	No	No	Yes	Yes
	Neo-Synephrine	0.5	No	No	No	Yes
naphazoline	Privine	0.05	No	No	No	Yes
oxymetazoline	Afrin	0.05	No	Yes	Yes	Yes
tetrahydrozoline	Tyzine Pediatric	0.05	No	Yes	Yes	Yes
	Tyzine	0.1	No	No	Yes	Yes
xylometazoline	Triaminic Nasal and Sinus Congestion	0.05	No	Yes	Yes	Yes

Intranasal Corticosteroids

Nasal-inhaled corticosteroids are the most effective forms of therapy for allergic rhinitis. They help to relieve congestion and rhinorrhea by limiting the late-phase response and reducing inflammation. Corticosteroids have a wide range of inhibitory activities against multiple cell types (e.g., mast cells, eosinophils, neutrophils, macrophages, and lymphocytes) and mediators of inflammation (e.g., histamine, eicosanoids, leukotrienes, and cytokines).

Mechanism of Action

Corticosteroids exert their anti-inflammatory effect by disabling the cells that present antigen to antibody. Interfering with the antigen–antibody reaction reduces the stimulus for mast cell degranulation. With reduced mast cell degranulation, secretion of cytokines is diminished. The result is a weaker inflammatory reaction with milder or no symptoms of runny nose, nasal congestion, itching, and sneezing.

Dosage

The dosage of the individual intranasal steroids is listed in Table 48.5. In general, mometasone furoate, fluticasone propionate, and budesonide have been rated as most potent in vitro. However, these differences have not been shown to translate into meaningful clinical differences in patients. Intranasal corticosteroids must be primed before initial use. Clinicians should counsel patients to squeeze the pump a few times until a fine spray appears. If patients do not use the pump for more than 1 week, they should reprime it.

TABLE 48.5 Intranasal Corticosteroid Prescribing Information

Drug	Brand Name (Manufacturer)	Amount of Drug per Spray/Doses per Bottle	How Supplied	Suggested Dose	
				Adult	Pediatric (6–12 y)
beclomethasone	Beconase AQ (GlaxoSmithKline)	42 mcg/200	25-g amber glass bottle with spray pump	One or two sprays in each nostril bid spray pump	Same as adult
budesonide	Rhinocort Aqua (Astra)	32 mcg/120	8.6-g bottle with spray pump	One to four sprays in each nostril daily	Same as adult
ciclesonide	Omnaris (Sepracor)	50 mcg/120	12.5-g bottle with spray pump	Two sprays in each nostril daily	Same as adult
flunisolide	N/A	25 µg/200	25-mL bottle with spray pump	Two sprays in each nostril bid	Same as adult
fluticasone	Flonase (GlaxoSmithKline)	50 mcg/120	16-g bottle with spray pump, available OTC	Two sprays in each nostril daily	One spray in each nostril daily
	Veramyst (GlaxoSmithKline)	27.5 mcg/120	10-g bottle with spray pump	Two sprays in each nostril daily	One spray in each nostril daily
mometasone	Nasonex (Schering)	50 mcg/120	17-g bottle with spray pump	Two sprays in each nostril daily	One spray in each nostril daily
triamcinolone	Nasacort AQ (Aventis)	55 mcg/100	10-g aerosol canister	One spray up to four sprays in each nostril daily	One spray up to two sprays in each nostril qd

Time Frame for Response

The therapeutic effects of intranasal corticosteroids are not immediate, but will begin working within 3 to 12 hours. Clinicians must counsel patients that they may not experience maximal effects for 1 to 2 weeks if they are using intranasal steroids continuously. Although continuous use is more efficacious, as-needed dosing has also been shown to be useful in patients with seasonal allergic rhinitis. Intranasal corticosteroids should be initiated 2 to 4 weeks before the start of allergy season in patients with recurrent seasonal allergic rhinitis for maximal benefit.

If nasal blockage is severe, patients should use a topical nasal decongestant for the first 2 to 3 days to reduce the swelling and increase the delivery of corticosteroid to the nasal mucosa. Use of nasal corticosteroids should not continue beyond 3 weeks in the absence of significant symptomatic improvement, according to the manufacturers' professional product information.

Contraindications

All intranasal corticosteroids are designated as pregnancy category C. This means that either animal reproduction studies have shown adverse effects on the fetus and there are no controlled studies in women or there are no studies in women or animals. The drug should be given only if potential benefit justifies potential risk.

Adverse Events

These agents are supplied as aqueous solutions in manually activated metered-dose nasal spray pumps, with separate patient instructions for use with every package. Some of these formulations have a flowery odor that some patients may find annoying. Local side effects

such as irritation, bleeding, and septal perforation may occur but are rare; ensure that patients are using these products correctly in order to minimize these side effects.

Overall, intranasal steroids do not achieve significant systemic concentrations, although the effects of long-term systemic absorption could be concerning. Probably, the most concerning adverse effects of intranasal steroids are the possibility of decreasing the rate of growth and suppressing the hypothalamic–pituitary–adrenal axis. Transient effects on growth in children have been noted, but the studies looking at this end point have varied widely. At normal recommended doses, fluticasone, mometasone, and budesonide have not shown growth suppression. The only study to show growth suppression used higher than recommended doses for long periods, so this should not be a serious concern in clinical practice.

All aqueous preparations contain preservatives. Benzalkonium chloride, which may cause ciliary dysfunction, is the preservative in the beclomethasone, flunisolide, fluticasone, mometasone, and triamcinolone products, whereas budesonide contains potassium sorbate as the preservative.

Interactions

Interactions with other drugs are generally not a concern due to low systemic absorption of intranasal corticosteroids.

Intranasal Cromolyn

Cromolyn is classified as a mast cell stabilizer. It prevents antigen-induced degranulation, thereby inhibiting the release of histamine and other cytokines that mediate inflammatory cell function. Cromolyn is of no value in treating acute allergic rhinitis. It is helpful only in preventing the nasal symptoms of allergic rhinitis. Treatment is more effective if it begins 2 to 4 weeks before exposure and continues throughout the exposure period. Intranasal cromolyn is available to patients as Nasalcrom 4% Nasal Solution. It does not require a prescription. Patient use information is noted in Table 48.3.

Selecting the Most Appropriate Agent

Nasal symptoms of allergic rhinitis include watery rhinorrhea (runny nose), paroxysmal sneezing (sudden fits of sneezing), nasal congestion (stuffy nose, sinus headache, or both), and postnasal drip that may cause coughing. Allergic rhinitis also may involve the conjunctiva (allergic conjunctivitis). The resulting symptoms are ocular pruritus (itching eyes), lacrimation (watery eyes), conjunctival hyperemia (bloodshot eyes), and chemosis (swollen eyelids). Drug treatment must be tailored to address the most bothersome symptoms. See Box 48.2 and Figure 48.3 for a stepwise approach to treating allergic rhinitis. Table 48.6 lists the recommended treatment order for allergies.

TABLE 48.6 Recommended Order of Treatment for Allergies

Order	Agents	Comments
First line	Intranasal corticosteroids	Intranasal corticosteroids are the most potent agents available for relief of established seasonal or perennial rhinitis
Second line	Antihistamines/ nasal decongestants	Either first- or second-generation agent can be used Product selection is based on dosing frequency, potential for adverse effects, and cost Second-generation antihistamines may be given only once or twice a day, and they are relatively nonsedating. First-generation antihistamines are given three to four times a day. Pseudoephedrine and phenylephrine are the most popular oral nasal decongestants
Third line	Intranasal cromolyn	Must be used prophylactically

BOX 48.2 A Stepwise Approach Is Used to Manage the Symptoms of Allergic Rhinitis

1. Identify the offending allergens by history with confirmation of the allergy by skin test.
2. Teach the patient to avoid the offending allergens.
3. For mild symptoms, prophylactic treatment with cromolyn nasal spray (Nasalcrom) or treatment with an antihistamine/decongestant combination may be necessary.
4. For prominent symptoms, begin with topical corticosteroid nasal spray.
5. For treatment failures despite avoidance and pharmacotherapy, progress to immunotherapy.

First-Line Therapy

Intranasal corticosteroids are the most potent agents available for the relief of *established* seasonal or perennial rhinitis. They provide efficacy with substantially reduced side effects compared with oral corticosteroids. Selection of the best agent mostly depends on the patient's insurance formulary.

However, due to the long time frame for response and that they may not be as effective for systemic symptoms, these agents are often given in combination with antihistamines. First-generation antihistamines were considered first-line agents for the prevention and treatment of allergic symptoms. However, the sedative side effects of the traditional antihistamines limit their usefulness in patients who must remain awake and alert. Fortunately, NSAs, also known as *newer* or *second-generation antihistamines*, cause minimal sedation because they do not cross the blood–brain barrier into the CNS.

The various first- and second-generation antihistamines are equally effective in treating symptoms of allergic rhinitis. Product selection is based on dosing frequency (i.e., duration of action), potential for adverse effects, and cost. Second-generation antihistamines may be given only once or twice a day, and they are relatively nonsedating. First-generation antihistamines are given three to four times a day. Some products are available in long-acting dosage forms that may be given only twice a day. While more sedating, first-generation antihistamines are also significantly less expensive than the second-generation drugs. These agents have the best results when patients take them before exposure to a known allergen. During seasonal attack, patients may need to take antihistamines around-the-clock for maximal effectiveness.

Second-Line Therapy

Because antihistamines do not reduce nasal congestion, they are often used in combination with nasal decongestants. Pseudoephedrine and phenylephrine are the most popular oral nasal decongestants. Nasal decongestants are α-adrenergic receptor agonists. As such, they stimulate α-adrenergic receptors, causing vasoconstriction in the nasal mucosa, decreasing congestion, and opening nasal passages. Side effects include CNS and cardiovascular stimulation. Elevation in blood pressure may also occur. Many prescription and nonprescription drugs contain a combined antihistamine and nasal decongestant. Some examples are given in Table 48.3.

Topical (intranasal) decongestants avoid systemic adverse effects. Prolonged use leads to rebound nasal congestion, however, so they are impractical for seasonal or perennial allergies. Their use should be limited to short periods (a few days).

Third-Line Therapy

Cromolyn, in the form of a metered-dose nasal spray, could be considered a first-line treatment for allergic rhinitis, but it is a prophylactic measure only. It is classified as a mast

cell stabilizer in that it prevents or attenuates the allergen activation of nasal mast cells. To be efficacious, cromolyn must be administered continuously (usually four times a day) during seasonal allergen exposure or immediately before an anticipated exposure such as animal dander.

Intranasal cromolyn is an alternative to antihistamines and nasal decongestants for allergic rhinitis. It generally is considered less effective than intranasal corticosteroids, but it is virtually free of side effects.

Special Population Considerations

Pediatric

If one parent has allergies, the child has a 50% chance of having allergies. Allergies may also be more common in children who were formula fed, of low birth weight, or exposed to tobacco smoke early in life. In childhood, more boys have allergic rhinitis than do girls, but this difference begins to disappear after adolescence. No sex differences are found in adults.

To determine the dose of allergy medication for a child, practitioners should use weight if possible. Otherwise, they may base according to age. The official product literature usually provides child dosage recommendations by age and weight. Parents should also be counseled to look at package labeling carefully and use dose recommendations for their child's weight if the directions specify. Also, parents should use appropriate teaspoon or tablespoon measurements rather than kitchen utensils. Counsel patients to ask the pharmacist at their local pharmacy if they are not sure if they have an accurate measuring tool.

In determining the dose of medication for a child, practitioners must recognize that infants and small children are not merely "scaled-down" adults. Organs such as the GI tract, liver, and kidneys are not developed enough in children for them to handle medications. Estimating a child's dose based on the adult dose is not always safe. Most pharmaceutical manufacturers do not provide such comprehensive pediatric dosing guidelines. Usually, an age range for children's doses is stated in the official package insert or on the commercial package. If not, prescribers should contact the manufacturer or consult with a specialist who is experienced with the treatment.

As noted earlier, a major consideration in prescribing intranasal steroids in children is the impact on growth. The FDA has approved the use of mometasone and fluticasone furoate for children older than age 2, fluticasone propionate for children older than age 4, and ciclesonide, budesonide, and flunisolide for children age 6 and older. The other agents are approved for use in children older than age 6.

Geriatric

Although few factors provoke rhinitis in older adults, treatments need to be more tailored because of slower metabolism and the potential for side effects, especially in the CNS. Also, this population is more likely to be taking multiple medications and therefore runs a greater risk of drug interactions than most other patients.

Women

In women, allergic rhinitis symptoms may worsen during pregnancy. The antihistamines diphenhydramine, loratadine, and cetirizine are pregnancy category B agents, whereas

desloratadine and fexofenadine are category C agents. All intranasal steroids are category C agents.

Monitoring Patient Response

Assessing the efficacy of treatment requires monitoring the patient's adherence to the drug therapy plan, quality of life, and degree of satisfaction with the care provided. Box 48.3 could be a useful office tool for this purpose.

BOX 48.3 Questions to Ask the Allergic Patient at Every Office Visit

Monitoring Signs, Symptoms, and Functional Status

- Has your allergy been better or worse since your last visit?
- In the past 2 weeks, how many days have you had: (*Ask the patient to tell you how symptoms developed, what they were like, and how long they lasted.*)
  A runny, stuffy, or itchy nose?Any wheezing or coughing?Any hives or swelling? Eczema or other skin rashes?Reactions to foods?Reactions to insects?
- Since your last visit, how many days has your allergy caused you to:
  Miss work or school?Reduce your activities?(For caregivers) change your activity because of your child's allergies?
- Since your last visit, have you had any unscheduled or emergency department visits or hospital stays?
- Since your last visit, have you had any times when your allergy symptoms were a lot worse than usual?
  If yes, what do you think caused the symptoms to get worse?If yes, what did you do to control the symptoms?
- Have there been any changes in your home, school, or work environment (e.g., new smokers or pets)? Any new hobbies or recreational activities?
- Has there been difficulty sleeping at night due to symptoms of allergy?

Monitoring Pharmacotherapy

- What medications are you taking?
- How often do you take each medication? How much do you take each time?
- Have you had any unusual reactions to your medications?
- Have you missed or stopped taking any regular doses of your medications for any reason?
- Have you had trouble filling your prescriptions (e.g., for financial reasons, not on

formulary)?
- Have you tried any other medications?
- Has your allergy medicine caused you any problems (e.g., sleepiness, bad taste, sore throat)?
- Have you had any nighttime awakenings?

Monitoring Patient–Provider Communication and Patient Satisfaction

- What questions do you have about your allergy management?
- What problems have you had in following your allergy management plan, such as taking your medications or reducing your exposure to allergens?
- Has anything prevented you from getting the treatment you need for your allergies?
- Have the costs of your allergy treatment interfered with your ability to get appropriate care?
- How can we improve your allergy care?

This information is provided by the Asthma and Allergy Foundation of America (AAFA) as part of its educational outreach to patients and their caregivers. The information was adapted from the 2007 National Asthma Education and Prevention Program's Guidelines for the Diagnosis and Treatment of Asthma published by the National Heart, Lung, and Blood Institute.

Patient Education

Patient education is extremely important in the prevention and management of allergy symptoms. Teaching each patient about the causes of allergic reactions, how triggers evoke symptoms, the various medications available and their use, when to self-treat and when to seek medical help, and how to assess whether treatment is working is highly desirable and appropriate during an office visit. But comprehensive teaching may not be practical because of time constraints. It may be more efficient to determine what the patient *does not* understand and fill in the gaps at that time. For example, at the end of the visit, practitioners could ask the patient three very basic questions about treatment:

- What is the name of the medication you are taking for allergy symptoms?
- What beneficial effects do you expect, and what side effects may occur?
- How do you take the medication (i.e., dose, time of day, with meals, and what to avoid taking with it)?

If the patient can articulate the correct answers to these questions, little more needs to be discussed about treatment. Practitioners could provide verbally or in writing those things that the patient does not know or understand. Also, they should encourage patients to accept written materials that pharmacists provide when they fill prescriptions and to question any ambiguous or contradictory information.

Drug Information

A variety of sources provide information regarding the treatment of allergic rhinitis. The American Association of Allergies, Asthma, and Immunology provides practice parameters for the treatment of allergic rhinitis (www.aaaai.org). Further, the FDA provides drug information specific to the product, particularly in relation to children or pregnant women.

Patient-Oriented Information Sources

The American Association of Allergies, Asthma, and Immunology provides patient-directed information (http://www.aaaai.org/patients/resources/fastfacts/rhinitis.stm). Similarly, the FDA has information regarding medications in an easy-to-use format for patients.

Complementary and Alternative Medications

There is some suggestion that acupuncture and biofeedback may be effective means of treating allergic rhinitis. However, controlled studies evaluating the effectiveness of these treatment modalities are lacking. Further, although few studies have examined the effectiveness of specific homeopathic therapies, *nux vomica* has been used to help in the treatment of nasal congestion and discharge.

Allergic Conjunctivitis

The signs and symptoms of allergic conjunctivitis result from the same allergens that cause allergic rhinitis. Mast cells are abundant in the eyelid and conjunctiva, but are infrequently found in the eye. This limits allergic ocular inflammation to the lining of the eyelid and the ocular surface (the conjunctiva).

Histamine and arachidonic acid derivatives are the mediators that probably cause most ocular signs and symptoms. Mast cell activation, however, also leads to recruitment of eosinophils, which can be found in the conjunctiva 3 to 5 hours after mast cell degranulation.

Many patients experience ocular symptoms only when allergens directly contact the eyes. For example, patients with sensitivity to cat dander may not have reactions in a room with cats but experience symptoms if they bring their hands to their face. Patients who have symptoms even without direct contact need to be particularly rigorous in their efforts to eliminate or avoid allergens in their homes, workplaces, or schools. Eye rubbing not only introduces allergens into the eye but also may degranulate mast cells mechanically.

Practitioners should encourage patients to apply cool compresses to their eyelids rather than rubbing their eyes to alleviate symptoms. Artificial tears also may reduce symptoms and wash away allergens and inflammatory mediators from the conjunctiva. Often, however, these approaches are inadequate. In such cases, patients require pharmacologic intervention. The types of eye drop medications used to treat allergic conjunctivitis are corticosteroids, antihistamines, vasoconstrictor/antihistamine combinations, mast cell stabilizers, and nonsteroidal anti-inflammatory drugs (NSAIDs).

First-generation oral antihistamines, which can help reduce ocular itching, may cause more problems by decreasing tear production due to anticholinergic effects. NSAIDs provide temporary relief of ocular itching due to seasonal allergic conjunctivitis. They work by inhibiting biosynthesis of prostaglandin, a mediator of pain and inflammation. See Chapter 17 for more information on treating Allergic Conjunctivitis.

Case Study*

G.B. an 18-year-old African American female college student, lives on campus with three other students. Her home is approximately 100 miles away. She has been at college since the beginning of the fall semester, approximately 2 weeks. She presents today with a chief complaint of fits of sneezing (sometimes 10 in a row); a runny, itchy, stuffy nose; and red, tearing eyes. Her temperature is 99°F; blood pressure is 118/78. She denies cough and headache. Her chest is clear. Her past medical history is unremarkable, except for “hay fever” when she was younger, which she “outgrew” during high school. These symptoms

are the same. She is having difficulty studying because of the sneezing and itching nose, and she is embarrassed to be in class with these symptoms. She was nervous about meeting the challenges of college and making new friends. Her local physician prescribed lorazepam (Ativan) 1.0 mg as needed for stress, anxiety, or both. So far, she has taken two doses of a prescription for 30 tablets.

Diagnosis: Allergic Rhinitis/Conjunctivitis

1. List specific goals for treatment for G.B.
2. What drug therapy would you prescribe? Why?
3. What are the parameters for monitoring success of the therapy?
4. Discuss specific patient education based on the prescribed therapy.
5. List one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What would be the choice for second-line therapy?
7. What over-the-counter and/or alternative medications would be appropriate for G.B.?
8. What lifestyle changes would you recommend to G.B?
9. Describe one or two drug–drug or drug–food interaction for the selected agent.

* Answers can be found online.

49 Human Immunodeficiency Virus

Linda M. Spooner

The first known case of human immunodeficiency virus (HIV) infection was documented in 1959 in a man from Kinshasa, Congo. How he became infected with the virus is unknown. Furthermore, how the disease grew to epidemic proportions also is unclear. In the United States, HIV infection was first recognized in 1981 after it was discovered that young homosexual men were contracting unusual cases of pneumonia and rare cancers that typically were not seen in immunocompetent patients.

HIV is the virus that causes acquired immunodeficiency syndrome (AIDS). A diagnosis of AIDS is based on the presence of an AIDS-defining condition (Box 49.1) or a $CD4^+$ T-cell count of less than 200/mm^3 (Centers for Disease Control and Prevention [CDC], 1992). Although rates of progression from HIV infection to AIDS vary greatly among individuals, the median is approximately 10 years in patients not receiving antiretroviral medications.

BOX 49.1 AIDS-Defining Conditions

Candidiasis, pulmonary or esophageal
Cervical cancer
Coccidioidomycosis
Cryptococcosis
Cryptosporidiosis
Cytomegalovirus
Herpes simplex virus
Histoplasmosis (microscopy [histology or cytology], culture, or detection of antigen in a specimen obtained directly from the tissues affected or a fluid from those tissues)
HIV-associated dementia
HIV-associated wasting
Isosporiasis
Kaposi sarcoma
Lymphoma
Mycobacterium avium infection
Pneumocystis jiroveci pneumonia
Other pneumonias, recurrent (more than one episode in a 1-year period)
Progressive multifocal leukoencephalopathy

Salmonella septicemia
Toxoplasmosis
Tuberculosis

Adapted from Centers for Disease Control and Prevention. (1992). 1993 revised classification system for HIV infection and expanded surveillance case definition for AIDS among adolescents and adults. *Morbidity and Mortality Weekly Report*, 41(RR-17), 1–19.

The two types of HIV that have been identified are HIV-1 and HIV-2. HIV-1 accounts for the majority of cases worldwide, including in the United States, whereas HIV-2 is primarily found in West Africa. HIV-2 is less efficiently transmitted and results in a slower disease progression than HIV-1. Unfortunately, since there are no randomized clinical trials that have assessed the efficacy of antiretroviral medications for treatment of HIV-2 infection, the ideal initial treatment regimen is unknown. It appears reasonable to base a regimen on a protease inhibitor (PI) boosted with ritonavir or an integrase inhibitor for patients with HIV-2 infection (Panel on Antiretroviral Guidelines, 2016).

Over the past three decades, HIV infection has reached epidemic proportions. The World Health Organization (WHO) estimates that approximately 35 million people worldwide are infected with HIV, with more than two thirds of cases occurring in sub-Saharan Africa (WHO, 2015). Of these, 3.2 million children younger than age 15 are infected. In 2013, 2.1 million people were newly infected with HIV, and there were 1.5 million deaths attributed to HIV throughout the world. Explanations for these overwhelming numbers include limited access to health care and antiretroviral medications as well as lack of education about prevention and transmission of HIV.

According to the most recent estimates, 1.1 million individuals were living with HIV in the United States at the end of 2010 (CDC, 2012). The number of new infections occurring annually has remained stable at approximately 50,000 per year.

The management of patients infected with HIV is challenging for several reasons. First, selection of antiretroviral therapy (ART) regimens can be complex, requiring the practitioner to individualize treatment selection based upon genotypic resistance testing results, comorbidities, concomitant medications, and patient preferences. Second, adverse effects of the medications may affect a patient's ability to tolerate and comply with therapy. Third, nonadherence to ART results in treatment failure as well as the development of resistance due to suboptimal serum concentrations of antiretroviral drugs. The health care practitioner should collaborate with the individual patient to select a regimen that the patient can take successfully and still manage potential adverse effects and drug interactions.

Causes

HIV is transmitted through four types of contact: sexual intercourse, blood-borne contact, perinatal transmission, and breast-feeding. *Prevention is the key to avoiding transmission* (Box 49.2). The most common route of transmission worldwide is through sexual contact with an infected person's genital fluids. The virus is also transmitted via intravenous (IV) transfer of infected blood through transfusions, IV drug use and needle sharing, or occupational exposure. An infected mother may transmit the virus to her baby prior to or during birth as well as during breast-feeding. It is important to note that HIV is *not* transmitted through casual contact (e.g., contact with tears, saliva, toilet facilities).

BOX 49.2 Preventing HIV Transmission

Preventing Sexual Transmission

Abstinence, safer sexual practices, use of latex condoms, risk factor modification, notification of sexual partners, education (especially to adolescents), treating sexually transmitted infections, and consistent and effective use of ART may be used to prevent sexual transmission of HIV.

Preventing Blood Exposure Transmission

Since 1985, all donated blood is tested for the presence of HIV. Implementation of universal precaution training programs has decreased transmission among health care workers. Needle exchange and drug treatment programs are available throughout the United States.

Preventing Perinatal Transmission

Lowering antepartum viral load in the mother with combination ART, combined with pre- and postexposure prophylaxis of the infant with ART, aggressive family planning services (e.g., HIV testing, counseling), and recommending against breast-feeding for infected women.

Effective treatment with ART reduces the risk of transmission to sexual partners, as lower concentrations of HIV ribonucleic acid (RNA) in plasma are associated with decreased levels of HIV in genital secretions. Therefore, consistent use of ART leading to sustained reductions in HIV viral loads should be combined with safer sexual and drug use practices to prevent HIV transmission.

Pathophysiology

HIV is a retrovirus; each viral particle contains two single-stranded molecules of RNA rather than deoxyribonucleic acid (DNA). Following infection of host cells, the viral enzyme reverse transcriptase allows synthesis of a DNA molecule that is then inserted into the DNA of the host cell, allowing the virus to replicate. In the case of HIV, the host cells are $CD4^+$ T lymphocytes, a white blood cell involved in cell-mediated immunity. As the virus replicates, it destroys the $CD4^+$ T lymphocytes, thereby leading to immune deficiency.

HIV incorporates itself into the host cell through a number of steps. A viral envelope surrounding the HIV RNA contains proteins on its outer surface that react specifically with the $CD4^+$ receptor on the T lymphocyte ($CD4^+$ T cell). Additionally, the viral membrane uses coreceptors (CCR5 or CXCR4) to attach to the $CD4^+$ T cell. Once this is completed, the viral envelope fuses to the host cell and allows the HIV RNA to enter the host cell. Next, reverse transcriptase catalyzes the formation of a single-stranded DNA intermediate from the viral RNA. This step is followed by duplication of the single-stranded DNA to form a double-stranded DNA. Catalyzed by the enzyme integrase, viral DNA is integrated into the host cell's nucleus. After the DNA is transcribed and translated back to RNA, the virus then makes long chains of polyproteins that are split by the enzyme protease to form new copies of HIV RNA. To protect the viral RNA, a protective core protein called a *capsid* surrounds the genetic material. This process is rapidly repeated, producing an estimated 10 billion new particles each day. The average half-life of a viral particle is 6 hours. The largest concentration of viral particles can be found in lymph node tissue and genital secretions.

Diagnostic Criteria

The signs and symptoms of HIV disease vary among patients. The acute retroviral syndrome occurs 2 to 3 weeks following exposure to the virus. During this time, the number of $CD4^+$ T lymphocytes ($CD4^+$ count) declines dramatically, and the number of HIV RNA particles in the plasma (viral load) increases greatly. Clinically, the patient may experience fever, swollen lymph nodes, sore throat, skin rash, muscle soreness, headache, nausea, vomiting, and diarrhea. The specific symptoms and their duration vary among patients, and their presence alone does not constitute a diagnosis. Diagnosis of HIV is based on the presence of HIV RNA or p24 antigen in the plasma or serum, often with a negative or indeterminate HIV antibody test (Panel on Antiretroviral Guidelines, 2016).

The currently used method for diagnosing HIV-1 infection is a combination immunoassay, which detects circulating antibodies to the virus and p24 antigen. This assay is highly sensitive and specific for established infection (99% to 100% sensitivity and specificity), but false-positive results may occur in patients who recently received hepatitis B or rabies vaccines, have acute infections, or have autoantibody formation. False-negative results may occur in newly infected patients whose antibody titer has not risen to detectable levels. Antibodies develop within 6 months after infection in 95% of patients, and the median time for antibody development is 2 months. If the initial test is reactive, further testing is performed to determine HIV RNA concentrations.

Laboratory Parameters

Once the diagnosis of HIV has been confirmed using the above tests, initiation of therapy should be guided by the patient's clinical status as well as two main laboratory parameters, including the $CD4^+$ T-cell count, the plasma HIV RNA (viral load), and viral resistance testing. Determination of these results allows the clinician to understand the patient's risk of opportunistic infections and risk for disease progression and to monitor response to the selected drug therapy.

CD4+ T-Cell Count

The $CD4^+$ T-cell count indicates the extent to which HIV has damaged the immune system. Normally, the $CD4^+$ T-cell count ranges between 500 and 1,600/mm^3. As the viral infection progresses, the $CD4^+$ count declines, correlating with increasing immunosuppression. Its value is especially important *before* initiating ART. $CD4^+$ T-cell counts of less than 200/mm^3 are associated with an increased risk of AIDS malignancies, such as Kaposi sarcoma, and opportunistic infections, such as *Pneumocystis jiroveci* pneumonia, toxoplasmosis, and cytomegalovirus infection.

Plasma HIV RNA (Viral Load)

Quantification of HIV replication is determined by measuring the viral load in number of copies per milliliter of plasma. The primary assay used is the HIV-1 reverse transcriptase polymerase chain reaction assay, which has a lower limit of detection of 20 to 75 copies/mL. Clinical trials demonstrate that viral loads that are undetectable (e.g., <20 to 75 copies/mL) are associated with longer duration of suppression of viral replication as compared with detectable levels. The viral load is a useful tool to monitor a patient's virologic status, disease progression, and ART regimen.

HIV Drug Resistance Testing

Because of the significant association between the presence of drug-resistant HIV and failure of antiretroviral treatment regimens, HIV resistance assays have become useful mechanisms for guiding the selection of appropriate therapy. When used in combination with medication histories and patient counseling, these assays have assisted in the attainment of more efficient and sustained viral suppression. Drug resistance testing is recommended for all patients in the initial laboratory testing they receive as they enter into care.

The two methods used to assess resistance include genotypic and phenotypic assays. Genotypic assays detect genetic mutations that may confer viral resistance. Interpretation of these genotypes requires an understanding of the mutations and their correlation with resistance to specific classes of antiretroviral medications. Results are typically available within 1 to 2 weeks. Phenotypic assays calculate the concentrations of antiretroviral drugs required to inhibit HIV replication by 50%. This value is known as the *median inhibitory concentration* and is abbreviated as the IC_{50}. The ratio of the IC_{50} of the patient's and reference virus is noted as the fold increase in IC_{50} for a variety of antiretroviral medications. Results of phenotypic assays are available within 2 to 3 weeks due to automation techniques, but they are more expensive to perform than genotypic assays and more complicated to interpret. Both assays may be unsuccessful in patients with low viral loads (<500 to 1,000) due to inadequate presence of the virus.

Several limitations exist with HIV drug resistance testing. First, there is no standardized method for quality assurance for the available genotypic and phenotypic assays. Second, they are expensive to perform. Lastly, if drug-resistant virus comprises less than 10% to 20% of a patient's total virus population, the assays will not detect the resistant virus. Overall, these assays provide a method for making decisions on initiating ART, changing ART in patients experiencing virologic failure or suboptimal response, and selecting ART in pregnant women.

Initiating Drug Therapy

When considering treatment of patients with HIV infection, it is important to note that all patients, regardless of $CD4^+$ count, should be offered treatment with ART (Panel on Antiretroviral Guidelines, 2016). Additionally, regardless of $CD4^+$ count, effective ART reduces the risk of sexual transmission of HIV infection. Initiation of ART should be provided for any individual with AIDS-defining illnesses, pregnancy, HIV-associated nephropathy, early HIV infection, hepatitis B or C coinfection, and rapidly declining $CD4^+$ counts.

Before therapy is started for any patient, a thorough history and physical examination should be performed, in addition to a complete blood count, basic chemistry profile, liver function tests, fasting lipid profile and glucose, urinalysis, $CD4^+$ T-cell count, viral load, genotypic resistance testing, and additional evaluation of various serologies (e.g., hepatitis B and C).

Goals of Therapy

Because currently available antiretroviral regimens cannot achieve eradication of HIV, goals of therapy primarily focus on sustained suppression of viral replication to undetectable levels. There are five main goals of ART (Panel on Antiretroviral Guidelines, 2016). These include maximal and sustained suppression of viral load, restoration and preservation of immune system function, enhancement of quality and duration of life, reduction in morbidity and mortality from HIV-related complications, and prevention of HIV transmission. Patients' responses to ART are variable, although successful regimens initiated in treatment-naive patients can decrease viral loads to undetectable levels within 12 to 24 weeks. Virologic success is improved with high-potency ART, excellent treatment adherence, low baseline viral load, higher baseline $CD4^+$ count, and rapid reduction of viral load in response to treatment.

To maximize the benefits of ART, it is important to select drug regimens carefully based on drug resistance testing, pretreatment viral load (e.g., greater than or less than 100,000 copies/mL), adverse effects, convenience, patient preference, drug interaction profile, pregnancy or pregnancy potential, comorbidities, and cost. There are several recommended regimens that may be used as initial therapy for HIV infection, as they have potent efficacy in suppressing viral replication. These include nonnucleoside reverse transcriptase inhibitor–based regimens, protease inhibitor–based regimens, and integrase inhibitor–based regimens. Table 49.1 lists the characteristics of all of the currently available antiretroviral medications.

TABLE 49.1 Overview of Drugs Used to Treat HIV Infection

Generic (Trade) Name and Adult Dosage in Treatment-Naive Patients	Selected Adverse Effects	Contraindications	Special Considerations
Nucleoside Reverse Transcriptase Inhibitors			
abacavir (Ziagen) 300 mg PO bid or 600 mg PO daily	Hypersensitivity reaction (fever, rash, malaise, fatigue, nausea, vomiting, respiratory symptoms), possible increased risk of myocardial infarction	Hypersensitivity to any component Moderate-to-severe hepatic impairment Rechallenge following the hypersensitivity reaction	Take without regard to meals Hypersensitivity reaction can be fatal (black box warning) Discontinue immediately. Do not rechallenge Requires HLA-B*5701 screening prior to use Available in combination with lamivudine (Epivir), zidovudine + lamivudine (Trizivir), and lamivudine + dolutegravir (Triumeq)
didanosine (Videx) ≥60 kg: 400 mg PO daily; with tenofovir, 250 mg PO daily <60 kg: 250 mg PO daily; with tenofovir, 200 mg PO daily	Pancreatitis, peripheral neuropathy, optic neuritis, lactic acidosis with hepatic steatosis, noncirrhotic portal hypertension	Concomitant use of allopurinol or ribavirin	Take 30 min before or 2 h after a meal Dose adjustment is required for renal insufficiency
emtricitabine (Emtriva) 200 mg PO daily	Skin hyperpigmentation, severe acute exacerbation of hepatitis B in coinfected patients who discontinue treatment	Hypersensitivity to any component	Take without regard to meals. Dose adjustment is required for renal insufficiency Available in combination with tenofovir (Truvada), tenofovir + efavirenz (Atripla), tenofovir + rilpivirine (Complera), and tenofovir + elvitegravir/cobicistat (Stribild) and tenofovir alafenamide + elvitegravir/cobicistat (Genvoya)

Generic (Trade) Name and Adult Dosage in Treatment-Naive Patients	Selected Adverse Effects	Contraindications	Special Considerations
lamivudine (Epivir) 150 mg PO bid or 300 mg PO daily	Severe acute exacerbation of hepatitis B in coinfected patients who discontinue treatment	Hypersensitivity to any component	Take without regard to meals Dose adjustment is required for renal insufficiency Available in combination with zidovudine (Combivir), abacavir (Epzicom), zidovudine + abacavir (Trizivir), and abacavir + dolutegravir (Triumeq)
stavudine (Zerit) ≥60 kg: 40 mg PO bid <60 kg: 30 mg PO bid	Peripheral neuropathy, pancreatitis, lactic acidosis with hepatic steatosis, lipoatrophy, hyperlipidemia	Hypersensitivity to any component	Take without regard to meals Do not use with zidovudine Dose adjustment is required for renal insufficiency
tenofovir disoproxil fumarate (Viread) 300 mg PO daily	Nausea, vomiting, diarrhea, headache, asthenia, renal insufficiency, decreased BMD, severe acute exacerbation of hepatitis B in coinfected patients who discontinue treatment	Hypersensitivity to any component	Take without regard to meals Dose adjustment is required for renal insufficiency Available in combination with emtricitabine (Truvada), emtricitabine + efavirenz (Atripla), emtricitabine + rilpivirine (Complera), and emtricitabine + elvitegravir/cobicistat (Stribild)
zidovudine (Retrovir) 200 mg PO tid or 300 mg PO bid	Nausea, headache, malaise, bone marrow suppression, lactic acidosis with hepatic steatosis, nail pigmentation	Hypersensitivity to any component	Take without regard to meals Dose adjustment is required for renal insufficiency Available in combination with lamivudine (Combivir) and lamivudine + abacavir (Trizivir)
Nonnucleoside Reverse Transcriptase Inhibitors			
efavirenz (Sustiva) 600 mg PO hs	Neuropsychiatric symptoms (hallucinations, abnormal dreams, suicidality, dizziness, impaired concentration, euphoria, confusion), rash, elevated liver function tests, hyperlipidemia, false-positive cannabinoid and benzodiazepine screening tests, teratogenic	Hypersensitivity to any component Avoid pregnancy Numerous drug interactions; see **Table 49.2** for contraindicated combinations	Take on empty stomach at bedtime Available in combination with emtricitabine + tenofovir (Atripla)
etravirine (Intelence) 200 mg PO bid	Rash (including Stevens–Johnson syndrome), hypersensitivity reactions, nausea	None	Take following a meal
nevirapine (Viramune, Viramune XR) 200 mg PO daily for 14 d, followed by 200 mg PO bid or XR tablet 400 mg PO daily	Rash (including Stevens–Johnson syndrome), fatal hepatic necrosis (significantly higher risk in treatment-naive women with CD4⁺ count > 250 and men CD4⁺ count > 400)	Moderate–severe hepatic impairment	Take without regard to meals. Lead-in period can be extended in patients who develop a rash without constitutional symptoms but should not exceed 28 d
rilpivirine (Edurant) 25 mg PO daily	Rash, depression, headache, insomnia, hepatotoxicity	Coadministration of anticonvulsants (phenytoin, phenobarbital, carbamazepine, oxcarbazepine), rifampin Numerous drug interactions; see **Table 49.2** for contraindicated combinations	Take with a meal Available in combination with tenofovir + emtricitabine (Complera) and tenofovir alafenamide + emtricitabine (Odefsey)

Generic (Trade) Name and Adult Dosage in Treatment-Naive Patients	Selected Adverse Effects	Contraindications	Special Considerations
Protease Inhibitors			
	Class adverse effects: lipodystrophy, GI intolerance, hepatotoxicity, hyperlipidemia, hyperglycemia	Numerous drug interactions; see **Table 49.2** for contraindicated combinations	
atazanavir (Reyataz) 300 mg PO daily plus ritonavir 100 mg PO daily OR 300 mg PO daily plus cobicistat 150 mg PO daily	Prolonged PR interval with 1st-degree AV block, indirect hyperbilirubinemia, nephrolithiasis, cholelithiasis, rash	Hypersensitivity to any component	Take with food Use caution when dosing with acid-reducing agents Available coformulated with cobicistat (Evotaz) Dose adjustment is required in hepatic insufficiency
darunavir (Prezista) 800 mg PO daily plus ritonavir 100 mg PO daily OR 600 mg PO bid plus ritonavir 100 mg PO bid OR 900 mg PO daily plus cobicistat 150 mg PO daily	Rash (Stevens–Johnson syndrome and erythema multiforme reported), headache		Take with food. Available coformulated with cobicistat (Prezcobix)
fosamprenavir (Lexiva) 1,400 mg PO bid **or** 1,400 mg PO daily plus ritonavir 100–200 mg PO daily **or** 700 mg PO bid plus ritonavir 100 mg PO bid	Rash, headache, naphrolithiasis	Same as above	Take with a meal if boosted with ritonavir. Dose adjustment is required for hepatic insufficiency
indinavir (Crixivan) 800 mg PO q8h or 800 mg PO bid plus ritonavir 100–200 mg PO bid	Nephrolithiasis, hyperbilirubinemia, headache, dizziness, metallic taste, rash	Same as above	Should be taken 1 h before or 2 h after meals when unboosted. Take without regard to meals when boosted with ritonavir Drink 1.5 L fluid daily to avoid renal stones Dose adjustment is required for hepatic insufficiency
lopinavir/ritonavir (Kaletra) 400/100 mg PO bid or 800/200 mg PO daily	Prolonged PR interval or QT interval, asthenia	Same as above	Take with food Alternative dosing is required in patients taking concomitant efavirenz or nevirapine
nelfinavir (Viracept) 1,250 mg PO bid or 750 mg PO tid	Diarrhea	Same as above	Take with food
ritonavir (Norvir) Use only as a booster with other PIs; 100–400 mg PO daily in 1–2 divided doses	Circumoral and peripheral paresthesias, taste perversion, asthenia	Same as above	Take with food
saquinavir (Invirase) 1,000 mg PO bid plus ritonavir 100 mg PO bid	Prolonged PR interval, prolonged QT interval, headache	Same as above, plus severe hepatic impairment	Take with large meal Avoid use in patients with pretreatment QT interval > 450 msec
tipranavir (Aptivus) 500 mg PO bid plus ritonavir 100 mg PO bid	Hepatotoxicity (including hepatic decompensation and fatal hepatitis) rash, fatal and nonfatal intracranial hemorrhage	Same as above, plus moderate-to-severe hepatic impairment	Take without regard to meals Must be boosted with ritonavir

Generic (Trade) Name and Adult Dosage in Treatment-Naive Patients	Selected Adverse Effects	Contraindications	Special Considerations
Fusion Inhibitors			
enfuvirtide (Fuzeon) 90 mg subcutaneously bid	Local injection site reactions (almost 100% of patients), increased rate of bacterial pneumonian, hypersensitivity reaction (<1%)	Hypersensitivity to any component	Store reconstituted solution in refrigerator and use within 24 h
Integrase Inhibitors			
dolutegravir (Tivicay) 50 mg PO once daily or 50 mg PO bid	Hypersensitivity reactions, insomnia, headache	Hypersensitivity to any component Concomitant use with dofetilide	Take without regard to meals Twice-daily dosing used when coadministered with efavirenz, fosamprenavir/ritonavir, tipranavir/ritonavir, rifampin. Also used for treatment-experienced patients with resistance mutations Available coformulated with abacavir + lamivudine (Triumeq)
elvitegravir (Vitekta) 150 mg PO daily plus cobicistat 150 mg PO daily	Nausea, diarrhea, renal impairment	None listed	Take with a meal Not recommended for patients with baseline creatinine clearance <70 mL/min Available coformulated with tenofovir + emtricitabine + cobicistat (Stribild) and tenofovir alafenamide + emtricitabine + cobicistat (Genvoya). Numerous drug interactions
raltegravir (Isentress) 400 mg PO bid	Nausea, diarrhea, headache, creatine kinase elevation, muscle weakness, fever	Hypersensitivity to any component	Take without regard to meals When dosed with rifampin, administer raltegravir 800 mg PO bid Use caution with concomitant agents that cause myopathy
CCR5 Antagonists			
maraviroc (Selzentry) 150 mg PO bid with strong CYP450 3A inhibitors (including PIs other than tipranavir/ritonavir); 300 mg PO bid with nonstrong CYP450 3A inhibitors or inducers; 600 mg PO bid with CYP450 3A inducers (efavirenz, etravirine)	Hepatotoxicity, cough, dizziness, rash, orthostatic hypotension	Severe renal impairment or end-stage renal disease with concomitant use of potent CYP450 3A inhibitors or inducers Numerous drug interactions; see **Table 49.2** for contraindicated combinations	Take without regard to meals

Reverse Transcriptase Inhibitors

There are two subclasses of reverse transcriptase inhibitors (RTIs): the nucleoside reverse transcriptase inhibitors (NRTIs) and the nonnucleoside reverse transcriptase inhibitors (NNRTIs).

Nucleoside Reverse Transcriptase Inhibitors

There are six NRTIs marketed in the United States. These include abacavir (Ziagen), didanosine (Videx), emtricitabine (Emtriva), lamivudine (Epivir), stavudine (Zerit), and zidovudine (Retrovir). There is one nucleotide RTI, tenofovir, available as tenofovir disoproxil fumarate and tenofovir alafenamide, which is similar in mechanism of action but is slightly different in structure than the nucleoside analogs. In addition, several combination products are available for dosing convenience; these are listed in Table 49.1.

Mechanism of Action

The NRTIs must be phosphorylated in the target cells before becoming active. This intracellular phosphorylation results in an active triphosphorylated form that interferes with the transcription of viral RNA to DNA. This interference can occur through two mechanisms: chain termination and competitive inhibition.

The *chain termination* process results in the reverse transcriptase enzyme adding the NRTI to the growing chain of HIV viral DNA instead of the needed DNA nucleoside. The NRTI acts as a nucleoside analog in the DNA production, and its addition is relatively simple. Once this is accomplished, no more DNA nucleosides can be added to the chain, thus terminating its growth and halting the production of viral DNA.

Competitive inhibition occurs when the active (phosphorylated) NRTI competes with the cell's own nucleoside building block. By competing for the cell's building block, these agents also halt the production of viral DNA.

Dosing

With the exception of abacavir, all NRTIs require elimination by the kidneys and therefore must be dose adjusted for patients with renal insufficiency. This is an important concept because it helps to minimize the incidence of adverse effects.

The first NRTI that received U.S. Food and Drug Administration (FDA) approval in the United States was zidovudine. It has been studied extensively as a component of ART and has proven to be effective in delaying progression of the disease, reducing the incidence of opportunistic infections, and prolonging survival. Significant adverse effects of zidovudine include bone marrow suppression, which can lead to clinically significant anemia and neutropenia, gastrointestinal (GI) toxicity, fatigue, and lactic acidosis with hepatic steatosis. Thus, it is not recommended as a component of initial treatment of

nonpregnant adults.

Lamivudine is one of the better-tolerated NRTIs and was the second NRTI to receive FDA approval. Other NRTIs have been available for many years, including didanosine and stavudine. The bioavailability of didanosine is decreased in the presence of gastric acidity. Therefore, it is formulated as an enteric-coated capsule or as a solution that is reconstituted with liquid antacid to allow for improved absorption. Dosing of didanosine and stavudine should be based on weight (see Table 49.1). Both of these NRTIs have similar toxicities, including pancreatitis, peripheral neuropathy, and GI disturbances. Didanosine also has been associated with noncirrhotic portal hypertension. Neither of these agents is recommended as part of initial treatment for treatment-naive patients.

Contraindications

Abacavir is an effective component of ART. Patients who initiate treatment with this agent must be cautioned about the hypersensitivity reaction that occurs in 2.5% to 8% of patients. Symptoms of the hypersensitivity reaction include fever, rash, GI disturbances, lethargy, and malaise. These can occur at any time after initiating therapy (median, 9 days), although the majority of reactions occur within the first 6 weeks of therapy. Symptoms resolve after discontinuation of the drug but may recur and result in death if abacavir is restarted. The risk of this reaction is correlated with the presence of the HLA-B*5701 allele. As a result, pretreatment screening for this allele should be performed before initiating therapy. Abacavir should not be used in those individuals who test positive for the HLA-B*5701 allele on the screening test, and they should be considered allergic to abacavir. Patients who test negative for the allele should still be counseled about the signs and symptoms of the hypersensitivity reaction. Additionally, there is controversy over an association between abacavir and cardiovascular disease, as some analyses have demonstrated increased risk of myocardial infarction, while others have not. At this time, it is recommended to use caution when considering initiation of abacavir in patients with risk factors for cardiovascular disease.

Tenofovir and emtricitabine are the two newest NRTIs available for use as a part of an ART regimen. Both are well tolerated, are dosed once daily, and can be taken without regard to meals. Tenofovir may cause renal insufficiency, with a higher risk in patients with advanced HIV infection, long treatment duration, low body weight, and preexisting renal impairment. Baseline and periodic assessment of serum creatinine and phosphorous, along with urinary glucose and protein, should be performed. Tenofovir and emtricitabine, which are also available in a coformulated tablet (Truvada), are recommended as one of the dual NRTI combinations for treatment-naive patients, as they are very potent in suppressing viral replication and are superior to zidovudine plus lamivudine in virologic efficacy and adverse effect profile. Also, since both tenofovir and emtricitabine exhibit activity against hepatitis B virus, they are the agents of choice for the management of patients who are coinfected with HIV and hepatitis B.

Dual NRTIs are used as part of ART in combination with a boosted PI, an NNRTI, or an integrase inhibitor. Recommended dual NRTIs include tenofovir/emtricitabine (coformulated as Truvada) and abacavir/lamivudine (coformulated as Epzicom). Triple NRTI regimens are less effective than PI- or NNRTI-based regimens; therefore, they should not be used in routine clinical practice.

Adverse Effects

A class adverse effect observed with all NRTIs includes lactic acidosis with hepatic steatosis. Although this adverse effect is rare, especially with newer NRTIs, it results in a high risk of death. This may be due to mitochondrial dysfunction that occurs on administration of NRTIs. The clinical presentation of lactic acidosis varies greatly among patients but often includes nonspecific GI symptoms (nausea, vomiting, abdominal pain) as well as generalized weakness, myalgias, and paresthesias that can progress to tachycardia, tachypnea, mental status changes, and multiorgan failure. Hepatic steatosis may manifest as an enlarged fatty liver on computed tomography scan as well as increased liver transaminases.

Risk factors for development of this syndrome include female gender, pregnancy, obesity, regimen components (stavudine, didanosine, zidovudine), and prolonged use of NRTIs. If this syndrome develops, the NRTIs should be discontinued immediately, and supportive care should be initiated. Because other clinical interventions such as administration of thiamine, riboflavin, and levocarnitine have not been adequately assessed in clinical trials, their efficacy cannot be determined at this time. Patients taking NRTIs should be cautioned about the signs and symptoms of lactic acidosis, and if these are observed, the patient should notify the practitioner immediately. It is optimal to use NRTIs with less risk of mitochondrial toxicity, such as tenofovir, emtricitabine, lamivudine, or abacavir, instead.

Additionally, all NRTIs can decrease bone mineral density (BMD). The risk is greater with regimens containing tenofovir. BMD assessment can be considered for individuals with a history of fractures or other risk factors for osteoporosis or BMD loss. Calcium and vitamin D supplementation can also be considered.

Nonnucleoside Reverse Transcriptase Inhibitors

Mechanism of Action and Clinical Use

By binding to reverse transcriptase, NNRTIs also interfere with the conversion of RNA to DNA. The five available NNRTIs are delavirdine (Rescriptor), efavirenz (Sustiva), etravirine (Intelence), nevirapine (Viramune), and rilpivirine (Edurant). This class of agents demonstrates a low genetic barrier for resistance development. Delavirdine is the least potent NNRTI and therefore is not recommended as part of initial ART. Nevirapine has a higher incidence of rash and hepatotoxicity than efavirenz; thus, it is no longer

recommended for initial treatment. It can be continued in patients who are stabilized on the drug already. Etravirine has primarily been studied in treatment-experienced patients with prior virologic failure, and its use is reserved for this purpose. Trials have shown that efavirenz-based regimens have similar virologic efficacy as compared with PI- and integrase inhibitor–based regimens, although some studies show that other regimens are superior to efavirenz because of fewer discontinuations due to central nervous system side effects and possible association with suicidality. Thus, the DHHS Panel considers efavirenz as an alternative agent in NNRTI-based regimens. Rilpivirine is also an alternative NNRTI, since it was shown to be noninferior to efavirenz overall. However, its use should be restricted to individuals with a pretreatment viral load of less than 100,000 copies/mL and $CD4^+$ count above 200 cells/mm^3. This is because comparative clinical trials with rilpivirine and efavirenz showed a higher rate of virologic failure with rilpivirine in patients with very high viral loads or low $CD4^+$ counts, due to the development of resistance mutations. Both efavirenz and rilpivirine are available in coformulations with tenofovir and emtricitabine in order to reduce pill burden.

Adverse Effects

The most frequently reported adverse effects of NNRTIs include GI disturbances, rash, and elevations in hepatic transaminases. Efavirenz commonly causes central nervous system adverse effects, including dizziness, impaired concentration, abnormal dreams, and hallucinations. These events occur within the first few days of initiating therapy but resolve over 2 to 4 weeks with continued treatment. Dosing at bedtime is helpful in minimizing these adverse effects. Congenital defects have been observed in offspring of both animals and humans exposed to efavirenz during pregnancy; therefore, this agent must be avoided in pregnant women in their first trimester of pregnancy or those of childbearing potential who are not using consistent and effective contraception.

Nevirapine has been associated with severe, life-threatening hepatotoxicity, including hepatic necrosis and hepatic failure, primarily occurring within the first few weeks of initiation. This may also occur along with a hypersensitivity reaction that includes rash and fever. A black box warning in the nevirapine labeling notes that women with $CD4^+$ counts greater than 250 cells/mm^3 and men with $CD4^+$ counts greater than 400 cells/mm^3 have a considerably higher risk of hepatotoxicity. Therefore, all patients who initiate therapy with nevirapine should initiate dosing once daily for 14 days followed by twice daily, and they should receive close monitoring of liver function tests and clinical symptoms throughout the treatment course. If hepatotoxicity occurs, nevirapine should be discontinued permanently.

Etravirine demonstrates activity against some HIV viruses that express mutations conferring resistance to the other four NNRTIs and is reserved for treatment-experienced patients. Its adverse effects include nausea, rash, and hypersensitivity reactions associated with organ dysfunction.

Rilpivirine is the newest NNRTI on the market; it causes fewer central nervous system adverse effects than efavirenz. Its side effects include depression, headache, insomnia, and rash.

Drug Interactions

All of the NNRTIs are metabolized by the cytochrome P-450 (CYP450) 3A4 isoenzyme system in the liver. Each NNRTI also has variable effects on inhibiting or inducing this enzyme system. Therefore, caution should be used when administering NNRTIs with drugs dependent on CYP450 3A4 for metabolism, including PIs, phenytoin, phenobarbital, and clarithromycin. Concomitant use of rifampin with etravirine or rilpivirine is contraindicated because of increased metabolism of etravirine that results in reduced serum concentrations and reduced efficacy. Rifampin may be used with caution with nevirapine. Rifampin must be used with an increased dose of efavirenz (800 mg daily). Concomitant use of St. John's wort is contraindicated with all NNRTIs due to risk of virologic failure secondary to the resulting suboptimal NNRTI concentrations. Use of rilpivirine with proton pump inhibitors is contraindicated due to reduced absorption and subsequent decreased concentrations of rilpivirine. Additional contraindicated concomitant medications can be found in Table 49.2.

TABLE 49.2 Nonantiretroviral Medications That Are Contraindicated for Concomitant Use with NNRTIs, PIs, or INSTIs

Class/Drug	Contraindicated Medications and/or Classes	Comments
All NNRTIs	St. John's wort	Results in virologic failure
	rifapentine	Results in tuberculosis treatment failure
	simeprevir, dasabuvir, ombitasvir, paritaprevir	Results in concomitant medication toxicity
efavirenz	cisapride, pimozide, midazolam, triazolam	Results in concomitant medication toxicity
etravirine	rifampin, carbamazepine, phenytoin, phenobarbital	Results in decreased etravirine concentrations
rilpivirine	proton pump inhibitors, rifampin	Results in virologic failure
	rifampin, carbamazepine, oxcarbazepine, phenytoin, phenobarbital	Results in decreased rilpivirine concentrations
All PIs	simvastatin, lovastatin	Results in increased risk of rhabdomyolysis
	amiodarone, dronedarone, ranolazine, cisapride, pimozide, midazolam, triazolam, lurasidone, ergot alkaloids, alfuzosin, salmeterol, fluticasone, salmeterol, simeprevir, dasabuvir, ombitasvir, paritaprevir, sildenafil (when used for pulmonary arterial hypertension)	Results in concomitant medication toxicity
	rifampin	Results in virologic failure
	rifapentine	Results in tuberculosis treatment failure
	St. John's wort	Results in virologic failure
atazanavir	Proton pump inhibitors	When used with unboosted atazanavir, results in decreased atazanavir concentrations
darunavir	carbamazepine, oxcarbazepine, phenytoin, phenobarbital	Results in concomitant medication toxicity Results in decreased concentrations of phenytoin and phenobarbital
dolutegravir	dofetilide	Results in concomitant medication toxicity
	carbamazepine, oxcarbazepine, phenytoin, phenobarbital	Results in virologic failure
elvitegravir/cobicistat	cisapride, pimozide, ranolazine, midazolam, triazolam, lurasidone, ergot alkaloids, alfuzosin, salmeterol, fluticasone, salmeterol, simeprevir, ledipasvir, dasabuvir, ombitasvir, paritaprevir sildenafil (when used for pulmonary arterial hypertension)	Results in concomitant medication toxicity

Protease Inhibitors

Mechanism of Action

Introduced in the mid-1990s, PIs have demonstrated potent virologic efficacy, durable effects, and high barriers to resistance. They act near the final stage of HIV viral replication through inhibiting the protease-mediated cleavage of the polyproteins. These polyproteins are responsible for creating new HIV RNA copies. Inhibiting this final stage by the use of PIs decreases the production of HIV RNA copies.

Nine PIs are available: atazanavir (Reyataz), darunavir (Prezista), fosamprenavir (Lexiva), indinavir (Crixivan), lopinavir/ritonavir (Kaletra), nelfinavir (Viracept), ritonavir (Norvir), saquinavir (Invirase), and tipranavir (Aptivus). These agents vary greatly in terms of their potency, adverse effects, and pharmacokinetic characteristics.

Dosing

PI-based regimens provide excellent efficacy in virologic suppression. Either ritonavir or cobicistat, potent CYP450 3A4 isoenzyme inhibitors, can be used to increase the concentrations of other PIs, allowing greater exposure of the virus to the PI. These "boosted" regimens demonstrate more potent virologic activity while reducing pill burden and adverse effects. However, it is important to note that there are numerous drug–drug interactions that result from the presence of these pharmacokinetic enhancing agents in a regimen. Despite this, boosting regimens with low-dose ritonavir or cobicistat is now the standard of care in PI-based ART regimens.

The pharmacokinetic characteristics of the PIs vary greatly across the class. Food affects the bioavailability of many of the PIs (see Table 49.1). For example, administration of atazanavir with food increases its bioavailability substantially and therefore should be administered with a meal. In contrast, concentrations of indinavir decrease by 77% with food, resulting in the requirement that this drug be taken on an empty stomach or with a small, low-fat snack (e.g., pretzels) when used without ritonavir booster doses.

Adverse Effects

The adverse effects of all PIs include GI disturbances, such as nausea, vomiting, and diarrhea, occurring upon treatment initiation. All PIs can cause increases in levels of hepatic transaminases. Clinical hepatitis and hepatic decompensation are more common in patients receiving regimens containing tipranavir/ritonavir. Risk factors for hepatotoxicity with PIs include hepatitis B or C coinfection, alcohol abuse, underlying liver disease, and concomitant use of hepatotoxic agents. This should be monitored carefully.

A class effect of the PIs includes fat maldistribution, also known as *lipodystrophy*. This results in accumulation of fat in the abdomen, breasts, and dorsocervical fat pad ("buffalo

hump"). This occurs in a large percentage of patients receiving ART, depending upon the regimen used and the duration of treatment. Fat maldistribution may be accompanied by metabolic abnormalities such as hyperlipidemia and hyperglycemia. Management of lipodystrophy includes use of diet and exercise as well as administration of tesamorelin, a growth hormone–releasing factor. Improvements have been demonstrated in clinical trials of patients changed from lopinavir/ritonavir to atazanavir.

All of the PIs, with the exception of unboosted atazanavir, have been associated with hyperlipidemia, including increased levels of triglycerides, total serum cholesterol, and low-density lipoproteins. Lopinavir/ritonavir and fosamprenavir/ritonavir cause a substantial increase in triglycerides when compared to atazanavir/ritonavir or darunavir/ritonavir. These lipid abnormalities may be associated with accelerated coronary artery disease in HIV patients. Management includes dietary modifications, exercise, smoking cessation, and changing to agents with a lower likelihood of lipid abnormalities, as well as the addition of lipid-lowering treatments, such as 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins). However, it is important to note that most statins cause drug interactions with the PIs, and some are contraindicated (Table 49.2). Therefore, pravastatin is the preferred agent because it does not have as many interaction concerns.

Another class effect of PIs includes hyperglycemia, which may lead to new-onset diabetes mellitus as a result of insulin resistance in approximately 3% to 5% of patients. Patients should be cautioned about warning signs of hyperglycemia, including polydipsia, polyphagia, and polyuria. Management of hyperglycemia includes lifestyle modifications (diet and exercise), consideration of NNRTI or integrase inhibitor use as an alternative, and pharmacologic management according to the American Diabetes Association.

Clinical Use

Based upon virologic efficacy and durability data, dosing convenience and low pill burden, and good tolerability, the guidelines published by the Panel on Antiretroviral Guidelines (2016) list darunavir/ritonavir as the recommended component of an initial PI-based regimen (Table 49.3). Clinical trials comparing darunavir/ritonavir to lopinavir/ritonavir demonstrated superior virologic efficacy with darunavir/ritonavir after 96 weeks of treatment. Darunavir contains a sulfa moiety and therefore can cause a rash. The rash is typically mild to moderate in severity and self-limited. However, the agent should be discontinued if the rash is severe or in the presence of fever or elevated liver function tests. Atazanavir/ritonavir has fewer adverse effects on lipids when compared to other PI-based regimens, but it has a higher rate of discontinuation due to adverse effects when compared to darunavir/ritonavir or raltegravir; thus, it is considered to be an alternative agent for initial therapy. The primary adverse effect of atazanavir is hyperbilirubinemia with or without jaundice or icteric sclerae. It may also cause nephrolithiasis, nephrotoxicity, and cholelithiasis. Since it requires an acidic GI environment for dissolution, acid-reducing agents such as antacids, histamine$_2$ receptor antagonists, and proton pump inhibitors may inhibit the absorption of atazanavir, requiring staggered dosing and limitations on the use

of these agents.

TABLE 49.3 Recommended Regimens for Initial Treatment of HIV Infection in Treatment-Naive Patients

PI Based	darunavir/ritonavir + tenofovir/emtricitabine*
INSTI Based	raltegravir + tenofovir/emtricitabine*
	OR
	elvitegravir†/cobicistat/tenofovir disoproxil fumarate/emtricitabine
	OR
	elvitegravir#/cobicistat/tenofovir alafenamide/ emtricitabine
	OR
	dolutegravir + abacavir‡/lamivudine*
	OR
	dolutegravir + tenofovir/emtricitabine*

*May substitute lamivudine for emtricitabine or vice versa.

†Do not initiate if creatinine clearance <70 mL/min.

‡Do not use abacavir in patients who are HLA-B*5701 positive.

#Do not initiate if creatinine clearance <30 mL/min. Panel on Antiretroviral Guidelines for Adults and Adolescents. (2015). Guidelines for use of antiretroviral agents in HIV-1–infected adults and adolescents. Department of Health and Human Services [Online]. Retrieved from http://www.aidsinfo.nih.gov/ContentFiles/AdultandAdolescentGL.pdf

Drug Interactions

All PIs are metabolized by the CYP450 3A4 isoenzyme system in the liver. Each of the PIs has a different effect on inducing or inhibiting the efficiency of this isoenzyme system. Therefore, caution must be used when combining PIs with any medications that are metabolized by CYP450 3A4 or that induce or inhibit this system. Concurrent use of PIs with ergot alkaloids, simvastatin, lovastatin, rifampin, and St. John's wort is contraindicated. A summary of these contraindicated medications is provided in Table 49.2.

Fusion Inhibitors

Enfuvirtide (Fuzeon) is the only available agent in this class of antiretroviral drugs. It inhibits fusion of the virus to the cell membrane of the $CD4^+$ T cell, thereby preventing HIV from entering the cell. Because its mechanism of action is distinct from the intracellular agents previously discussed, it may be useful for highly treatment-experienced patients with the virus that is resistant to other currently available antiretroviral agents.

Enfuvirtide must be injected subcutaneously twice daily. Adverse effects include local injection site reactions, such as erythema, induration, and pain, which occur in almost all patients. Less than 1% of patients experience hypersensitivity reactions, including rash and fever. Enfuvirtide significantly increases tipranavir/ritonavir concentrations, resulting in an increased risk of adverse effects.

Integrase Inhibitors

Three integrase strand transfer inhibitors (INSTIs) are available for treatment of HIV infection. These include dolutegravir (Tivicay), elvitegravir (Vitekta), and raltegravir (Isentress). They prevent the integration of viral DNA into the host cell's genome. Each of these agents is recommended for use with a dual NRTI backbone as initial therapy in treatment-naive individuals, per the Panel's guidelines (2016), as they have similar virologic efficacy as other recommended regimens and are well tolerated.

Raltegravir was the first INSTI approved, and it is dosed twice daily. It is metabolized via UGT1A1-mediated glucuronidation and therefore exhibits minimal drug–drug interaction risk. This agent can cause elevations in creatine kinase with possible rhabdomyolysis and should be used with caution in patients receiving concomitant medications that have similar adverse effects. Rare cases of hypersensitivity reactions have been documented in postmarketing surveillance.

Elvitegravir is marketed as a single agent or coformulated with the booster agent cobicistat and tenofovir, emtricitabine (Stribild or Genvoya), which permits the product to be dosed once daily but results in numerous drug interactions. The most common adverse effects of elvitegravir include nausea, headache, and diarrhea. Additionally, because cobicistat inhibits the active renal tubular secretion of creatinine, increases in serum creatinine and decreases in creatinine clearance occur without reducing renal function. This combination product is not recommended for use in individuals with baseline creatinine clearance of less than 70 mL/min, and it should be discontinued if creatinine clearance decreases to less than 50 during treatment.

Dolutegravir is the newest INSTI available for use and is considered a second-generation INSTI, in that it may have a higher genetic barrier to resistance. The dosing is once daily for treatment-naive patients and twice daily in treatment-experienced patients. It is available as a single agent or coformulated with abacavir and lamivudine (Triumeq). It is well tolerated, causing insomnia or headache in rare cases. Because its absorption is affected by agents containing polyvalent cations (e.g., calcium supplements, antacids, iron supplements), its dosing should be 2 hours before or 6 hours after administration of these products.

CCR5 Antagonists

Maraviroc (Selzentry) is the only available agent in this class of antiretrovirals. It blocks the CCR5 receptor on the membrane of $CD4^+$ T cells, preventing entry of the HIV virus. Prior to use, a coreceptor tropism assay (e.g., Trofile) must be performed to determine if the patient's virus utilizes the CCR5 receptor, since not all HIV strains do. Maraviroc has a black box warning in its package insert describing hepatotoxicity that may be preceded by a systemic allergic reaction. This agent may also cause cough, orthostatic hypotension, rash, and fever. It also has a multitude of drug–drug interactions associated with its use, requiring dose adjustment. At this time, the Panel (2016) does not recommend maraviroc-based regimens as initial therapy for treatment-naive patients.

Selecting the Most Appropriate Regimen

Although guidelines exist for the combinations of agents to be used in ART, each patient must have a highly individualized regimen. Although current regimens are effective at keeping the viral load at undetectable levels, eradication of the virus is not yet attainable. This is due to the early development of latently infected $CD4^+$ T cells with a long half-life that, even with prolonged therapy, persist.

Previously Untreated Patients

One of the most important therapeutic interventions in the care of the patient with HIV infection is the initial treatment regimen (Tables 49.1 and 49.3). It is essential to select the most potent and appropriate therapy possible, keeping in mind adverse effects and adherence issues. Discontinuing recommended therapy due to nonadherence increases the risk of drug resistance and failure with alternate regimens.

"Recommended regimens" have been selected by the DHHS Panel based on optimal efficacy and durability demonstrated in clinical trials as well as tolerability and convenience of use. "Alternative regimens" demonstrate efficacy and tolerability but have disadvantages or less evidence supporting their use. The list of alternative regimens is brief because the list of recommended regimens has been expanded, permitting most treatment-naive patients to receive a recommended agent.

Recommended initial therapy is comprised of two NRTIs (also known as the dual nucleoside "backbone") plus a third drug, either a boosted PI or INSTI (Table 49.3). Recommended dual NRTI backbones include either tenofovir/emtricitabine or abacavir/lamivudine. Since they are each available as coformulated tablets with once-daily dosing, selection depends upon consideration of clinical data, adverse effects, and comorbidities. Since tenofovir can cause nephrotoxicity and decreased BMD, use of abacavir/lamivudine can be considered in patients at increased risk of these adverse effects. Prior to initiation of abacavir, testing for the HLAB*5701 allele to determine risk of hypersensitivity should be performed. If a patient is coinfected with HIV and hepatitis B, tenofovir/emtricitabine is the preferred backbone due to its activity against hepatitis B virus.

Selection of the third drug in the regimen, either a boosted PI or INSTI, depends upon clinical data, adverse effects, dosing convenience, genetic barrier to resistance, comorbid conditions, and drug interaction potential. PI-based regimens contain a PI with a booster dose of ritonavir or cobicistat in combination with two NRTIs. These combinations have proven to be effective in numerous clinical trials. The recommended PI-based regimen is darunavir/ritonavir plus tenofovir/emtricitabine (Table 49.2). Darunavir contains a sulfa group and may cause rash. It also has a higher pill burden than some of the coformulated INSTI products discussed below.

The INSTI-based regimens of raltegravir, elvitegravir, or dolutegravir plus a dual NRTI backbone are also recommended as initial regimens in treatment-naive patients. Their advantages include comparable virologic efficacy to other regimens with fewer adverse effects and lipid abnormalities. They also have fewer drug interactions than PI-based regimens. Raltegravir requires twice-daily dosing and may be less convenient than all of the other recommended options. Elvitegravir is coformulated in a once-daily tablet, but can cause elevations in serum creatinine and more drug interactions than raltegravir. Dolutegravir was shown to be superior to darunavir/ritonavir and efavirenz in virologic

efficacy, primarily due to fewer discontinuations for side effects. It appears to have a higher genetic barrier to resistance than other INSTIs, but has more drug interactions than raltegravir.

Treatment-Experienced Patients

When antiretroviral treatment failure occurs, it is necessary to assess why this occurred to determine the appropriate therapy change. Antiretroviral treatment failure is a term that encompasses all potential reasons for suboptimal response to therapy that must be assessed, including patient factors (e.g., incomplete medication adherence, psychiatric illness, presence of resistant virus, interruption of access to ART) and drug-related factors (e.g., drug toxicities, suboptimal pharmacokinetic issues, drug interactions, medication errors) (Panel on Antiretroviral Guidelines, 2016). Treatment regimen failure often results in virologic failure, incomplete virologic response, or virologic rebound. *Virologic failure* is defined as the failure to achieve or maintain HIV RNA plasma levels less than 200 copies/mL. An *incomplete virologic response* results when two consecutive viral loads are above 200 copies/mL after 24 weeks on ART. *Virologic rebound* occurs when the viral load increases to 200 copies/mL or higher after virologic suppression has been achieved. It is also important to note that virologic blips can occur, where an isolated occurrence of detectable virus happens, but is followed by return to undetectable concentrations.

After the practitioner considers the causes and types of treatment failure, the drug regimen should be changed accordingly. The patient's previous treatment experience and current drug resistance pattern must be considered because there may be cross-resistance between agents within the same therapeutic class. In addition, if an adverse effect or unacceptable toxicity caused a cessation of therapy, the practitioner should avoid alternative agents likely to cause that adverse effect. Furthermore, agents with complicated dosing schedules and strict food and timing requirements should be avoided if that is what caused the first treatment failure. Selecting agents that are free of side effects and strict food or timing requirements may not be easy, but each patient must be given the regimen to which he or she will most likely adhere.

When changing therapy, one or more of the agents in the regimen may need to be replaced. This will vary depending on the individual patient's situation. Expert advice from an HIV clinician is crucial to selecting the most appropriate option.

Special Population Considerations

Pediatric

Guidelines exist for treating HIV infection in the pediatric patient (Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children, 2016). Although the principles remain the same in all HIV-infected individuals, unique considerations in subsets of the pediatric population need brief discussion. These include diagnosis of disease, differences in $CD4^+$ T-cell counts and viral loads, changes in pharmacokinetic parameters, and adherence issues.

Diagnostic testing for suspected HIV-infected infants can be performed as early as at birth and by age 4 months in almost all infants. Testing in high-risk infants should occur by 48 hours of life because in nearly 30% to 40% of infected infants, the diagnosis can be made within this time frame. If the initial test is negative, repeat testing should be performed at age 1 to 2 months and age 4 to 6 months. HIV DNA polymerase chain reaction or RNA assays are the preferred virologic methods for diagnosing HIV in infants. Antibody testing is not accurate due to the transfer of maternal HIV antibodies to the infant.

The $CD4^+$ T-cell counts in children younger than age 5 are typically higher than adult counts. Therefore, monitoring absolute $CD4^+$ counts may not be as reliable as measuring the percentage change in $CD4^+$ counts as disease progresses. Pediatric patients with a positive virologic test should have $CD4^+$ T-cell counts and viral loads monitored every 3 to 4 months if not on ART, or more frequently in those initiating or changing ART. $CD4^+$ counts can be monitored every 6 to 12 months in children who have demonstrated treatment adherence, sustained virologic suppression, stable clinical status, and high $CD4^+$ counts for at least 2 to 3 years. Similarly, because of immunologic differences, particularly in those patients acquiring the disease perinatally, viral loads may be difficult to interpret during the first year of life. Using $CD4^+$ T-cell count and viral load together can more accurately predict prognosis and survival.

Pharmacokinetic variables, particularly volume of distribution and clearance, change as a person ages. These changes should be considered when designing drug therapy regimens for children. Similarly, the issue of medication adherence in this population is crucial. Some of the solution formulations for these agents may be unpalatable, depending on the child's preferences. Also, absorption of drugs can be affected by food, and timing of drug administration around food schedules can be extremely difficult. Mixing medications in bottles with formula may increase palatability but may create compatibility issues. Additionally, children depend upon their caregivers to administer ART; therefore, the complexity and convenience of the regimen must be considered. It is preferable for an HIV expert to manage these patients in order to select optimal treatment and monitor short- and long-term adverse effects and quality of life.

Women/Pregnancy

Thresholds for the initiation of ART in HIV-infected women are the same as those for HIV-infected men. Selection of antiretrovirals in women of childbearing potential should reflect regimen efficacy as well as its potential for teratogenicity if the woman becomes pregnant. For example, efavirenz should be avoided in women considering pregnancy or who are not using reliable contraception. It is also important to note that the efficacy of many oral contraceptives is reduced by ART.

When considering the use of ART in pregnant women with HIV infection, practitioners must consider two main issues: ART of HIV in the mother and prophylaxis to reduce the risk of perinatal HIV infection (Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission, 2015). The benefits and risks of using ART must be assessed prior to initiating therapy in a pregnant patient as well as special considerations for dosing, adverse effects, and other medication counseling points.

The acquisition of disease through exposure in utero is a major source of HIV infection in infants. Therefore, early identification of HIV-infected women is crucial before or during pregnancy. Preconception HIV prevention counseling and testing for all pregnant women have been advocated by national organizations, including the American College of Obstetricians and Gynecologists and the CDC.

One of the more remarkable aspects of zidovudine therapy was the discovery that this agent reduced the maternal–fetal transmission of HIV. The pivotal study by Connor and colleagues showed a maternal–fetal transmission rate of 8.3% with zidovudine versus 25.5% with placebo in expectant mothers between 14 and 34 weeks of gestation (Connor et al., 1994). Therefore, antiretroviral chemoprophylaxis with IV zidovudine during labor is recommended for all pregnant women with viral loads greater than 1,000 copies/mL or unknown viral loads at the time of delivery. This is not required for women adherent to ART whose viral loads have remained consistently below 1,000 copies/mL during late pregnancy and delivery. Postnatally, the infant should receive oral chemoprophylaxis in an effort to reduce perinatal transmission. Additionally, breast-feeding is not recommended for any HIV-positive woman in the United States, regardless of ART regimen.

Health Care Workers/Occupational Exposure

The primary means of transmission of HIV in the health care worker population is through an accidental needlestick. However, transmission can occur through exposure of HIV-infected blood or other infected body fluids to a health care worker's nonintact skin or mucous membranes. The risk of HIV transmission after a percutaneous exposure to infected blood is approximately 0.3%; the risk decreases to approximately 0.09% for a mucous membrane exposure.

In theory, initiation of antiretroviral postexposure prophylaxis (PEP) within hours after exposure may prevent or inhibit systemic infection by limiting the replication of virus in

the lymphocytes and lymph nodes. As such, the U.S. Public Health Service has published recommendations regarding the initiation and continuation of PEP in health care personnel (Kuhar et al., 2013). The primary role of PEP is to prevent HIV infection after an accidental occupational exposure.

Current guidelines recommend a preferred PEP regimen of tenofovir/emtricitabine plus raltegravir, due to its potency, tolerability, dosing convenience, and minimal drug interactions. Alternative regimens are listed in Table 49.4; these can be considered if there are contraindications, cost concerns, or intolerability with the preferred regimen. PEP should be initiated as soon as possible after exposure, while awaiting results of source identification, resistance profile, or both. Therapy should be continued for 28 days and should only be discontinued early if the source patient is proven to be HIV negative, if the exposed health care worker is shown to be HIV positive, if the adverse effects of PEP are intolerable and there is no other alternative available, or if the exposed health care worker decides to discontinue treatment based on risks and benefits. HIV antibody testing should be performed at baseline, 6 weeks, 12 weeks, and 6 months after exposure. If a fourth-generation combination HIV antigen/antibody test is used, the final test can be completed at 4 weeks. Extended follow-up (e.g., at 12 months) is recommended for health care workers who become infected with hepatitis C virus following exposure to a coinfected patient.

TABLE 49.4 Recommended HIV PEP for Occupational Exposure

Column A	Column B
atazanavir 300 mg PO daily + ritonavir 100 mg PO daily	tenofovir/emtricitabine tablet PO daily
darunavir 800 mg PO daily + ritonavir 100 mg PO daily	tenofovir 300 mg PO daily + lamivudine 300 mg PO daily
etravirine 200 mg PO bid	zidovudine/lamivudine tablet PO bid
lopinavir/ritonavir 2 tablets PO bid	zidovudine 300 mg PO bid + emtricitabine 200 mg PO daily
raltegravir 400 mg PO bid	
rilpivirine 25 mg PO daily	

Preferred regimen: tenofovir/emtricitabine tablet PO daily PLUS raltegravir 400 mg PO bid

Alternative regimen: Choose one drug or drug pair from Column A and one drug or drug pair from Column B. May also use elvitegravir/cobicistat/tenofovir/emtricitabine (Stribild) po daily

Nonoccupational Postexposure Prophylaxis (nPEP)

Use of ART within 72 hours of exposure to HIV outside of the workplace, such as through sexual assault, unprotected sexual intercourse, sharing needles during injection drug use, etc., is a method that has never been studied in clinical trials, but is employed to prevent HIV infection. Each case should be considered individually, to assess if the source is HIV negative (nPEP not recommended), unknown (consider nPEP), or HIV positive (nPEP recommended). As with occupational PEP, the preferred regimen is tenofovir/emtricitabine plus raltegravir for 28 days.

Preexposure Prophylaxis

Use of daily preexposure prophylaxis (PrEP) with tenofovir/emtricitabine in sexually active adults at risk of becoming infected with HIV has helped to decrease transmission. The largest clinical trial assessing the efficacy of this approach, known as the iPrEX study, demonstrated a 44% relative risk reduction in HIV infection incidence in HIV-negative men who have sex with men (Grant et al., 2010). Studies in heterosexual populations also show that this strategy is effective in reducing incidence of HIV infection. The decision to use PrEP must be considered carefully. Since the effectiveness of the regimen is linked with adherence, it is crucial to emphasize the importance of taking the regimen every day, not just on days when sexual intercourse would occur. Per recommendations from the U.S. Public Health Service, individuals must test negative for HIV infection within 1 week of PrEP initiation and every 3 months during treatment, to prevent the development of resistance in the presence of HIV infection (U.S. Public Health Service, 2014). Additionally, patients should receive safer sexual practices counseling at each visit, to further reduce the risk of transmission. No more than a 90-day supply of PrEP should be prescribed, and patients should be seen every 3 months for lab work and adherence assessments.

Monitoring Patient Response

The $CD4^+$ T-cell counts are important not only because they indicate the risk of development of opportunistic infections before treatment but also because they help the health care provider initiate or discontinue opportunistic infection prophylaxis during ART. Once ART is started, a $CD4^+$ count should be checked at baseline and after 3 months to assess reconstitution of the immune system. It is important to check $CD4^+$ counts every 3 to 6 months in order to assess response to ART during the first 2 years of treatment and to determine the necessity of opportunistic infection prophylaxis. $CD4^+$ counts may be obtained once yearly in those individuals who are receiving suppressive ART and have $CD4^+$ counts well above the threshold for risk of opportunistic infections, consistently ranging between 300 and 500 cells/mL or higher. More frequent monitoring would be required in patients with changes in clinical status, those who are unable to achieve virologic suppression on ART, or in those initiating treatment with interferon, steroids, or cancer chemotherapeutic agents.

Viral load indicates both initial and sustained responses to treatment with ART, and decreases in viral load correlate with decreased risk of progression to AIDS and death. Viral load should be measured at baseline for all patients, to permit appropriate ART selection. Once therapy has been initiated or changed, viral load should be assessed immediately before treatment and again 2 to 8 weeks later. The viral load should be repeated every 4 to 8 weeks until it becomes undetectable. Subsequent testing should reveal an undetectable viral load by 8 to 12 weeks in those patients adherent to ART. At that point, viral load testing should be repeated every 3 to 4 months to determine continuing effectiveness of the regimen. This duration can be extended to 6 months in those patients who are stable and have fully suppressed viral loads for at least 2 years. If a patient exhibits a suboptimal response, it is important to review medication adherence, drug interactions, and resistance mutations to permit consideration of regimen changes.

Genotypic resistance testing is recommended for all patients at baseline, regardless of when treatment is initiated, in order to optimize regimen selection by determining which drugs still retain activity. It is also useful for patients with suboptimal viral load reduction and virologic failure. Resistance testing is not recommended for patients with viral loads of fewer than 500 copies/mL because the assays cannot consistently determine resistance patterns with such low-level viremia. Recommendations for genotypic resistance testing in pregnant patients include baseline testing prior to therapy as well as testing those with detectable viral loads while taking ART.

Patient Education

To minimize the likelihood of treatment regimen failure and development of drug resistance, the health care professional must be aware of who is at high risk for adherence issues as well as the most common reasons for poor adherence. Risk factors for poor adherence to antiretroviral regimens include active substance abuse, active mental illness, lack of disease and medication education, low levels of literacy, and stigma. Several treatment factors affect adherence, such as pill burden, frequency of dosing, food requirements, adverse effects, and treatment fatigue.

Strategies the practitioner can use to minimize the risk of failure due to nonadherence include encouraging the patient to develop a strong relationship with the health care team, taking an active role in his or her therapy, and involving the patient's family, friends, and peers in the therapy. In addition, counseling on HIV and the goals of achieving viral suppression (e.g., reduction in HIV-related morbidity and mortality, prevention of sexual transmission) may encourage an otherwise indifferent patient to adhere to a regimen.

Another strategy the practitioner should use to promote drug adherence is preparing the patient for adverse events. The patient needs to know which adverse events are likely to occur, how to minimize the risk of experiencing adverse events, and which adverse events demand discontinuation of therapy. The patient also needs to understand the importance of following the dosing schedule in addition to the food requirements for each agent (Panel, 2015). Table 49.1 provides information on dosing, diet, and fluid requirements of each agent.

Developing a plan for scheduling medications and carefully explaining to the patient how the medication should be taken is imperative. This plan should focus on daily pill taking as well as future events in a patient's life that threaten to interrupt the established schedule (e.g., holidays or vacations). This plan must consider lifestyle factors such as work schedule and privacy issues (e.g., taking medication at work or storage of medication at work). Regardless of how much or little assistance the patient needs in developing strategies for ensuring adherence, success is often determined by the patient's outlook. If the patient perceives that therapy will lead to an improved quality of life or increased length of life, chances for adherence are greater (Reynolds, 1998). Therefore, before attacking the logistics of a medication schedule, the health care provider must convince the patient of the benefits of continuing therapy.

Once the daily plan is developed, it should evolve into a long-term plan that allows the patient to adhere to therapy and allows the health care provider to monitor adherence. Aids for adherence include pill boxes that separate doses per day, alarms to remind patients of their doses, or something as simple as a calendar that lists dosing schedules. Whatever method is used, the patient must remain adherent and be checked for adherence. The simplest way to check for adherence is to ask the patient. However, a patient may not

confess to missed doses or may not be aware of missed doses. Pill counting is another option, but patients may remove missed doses to appear adherent. Testing the viral load may reveal adherence information, but if levels increase because of resistance, not nonadherence, the results will be misleading. Adherence counseling and effective engagement and retention in care are all closely linked to improving treatment success.

Case Study*

A.P. is a 36-year-old woman who was diagnosed with HIV infection 2 weeks ago at a community outreach clinic. She has been feeling well for the past 2 years, and she maintains a healthy, active lifestyle by exercising three to four times a week and eating a balanced diet. Her medications include a multiple vitamin and occasional antacids for heartburn, and she does not consistently use birth control methods. She has never received ART. She comes to your office for an initial physical exam and blood work in preparation for treatment initiation. The physical examination is unremarkable, and the laboratory results are as follows:

Electrolytes, serum creatinine, liver function tests: within normal limits
Complete blood count with differential: within normal limits
$CD4^+$ T-cell count: 400 cells/mm^3
Viral load: 110,000 copies/mL
Genotype: No resistance mutations detected

Diagnosis: Asymptomatic HIV Infection

1. List specific goals for treatment for this patient.
2. What drug therapy would you prescribe? Why?
3. What are the parameters for monitoring success of the therapy?
4. Discuss specific patient education based on the prescribed therapy.
5. List one or two adverse reactions for the selected agents that would cause you to change therapy.
6. What would be the choice for the second-line therapy?
7. What over-the-counter and/or alternative medications would be appropriate for A.P.?
8. What dietary and lifestyle changes should be recommended for this patient?
9. Describe one or two drug–drug or drug–food interactions for the selected agents.

* Answers can be found online.

UNIT 12
Pharmacotherapy for Hematologic Disorders

50 Pharmacotherapy for Venous Thromboembolism Prevention and Treatment, Stroke Prevention in Atrial Fibrillation, and Thromboembolism Prevention with Mechanical Heart Valves

Sarah A. Spinler

Thromboembolic disease and patients with risk factors for thromboemboli are frequently encountered in the ambulatory population, and an understanding of the pathogenesis of these conditions and underlying patient risk factors, along with the clotting cascade, is essential for determining appropriate treatment. The indications for anticoagulation continue to expand, and treatment for some conditions has now shifted to the outpatient setting. Several disorders warrant anticoagulant therapy, including venous thromboembolism (VTE) prevention and treatment, stroke prevention in atrial fibrillation (SPAF), ischemic stroke, prosthetic cardiac valves, coronary and peripheral vascular disease, and hypercoagulable conditions. Recognizing when prophylaxis for clotting events is appropriate is also important, including during orthopedic surgery and during hospitalization in patients with multiple risk factors for VTE. Anticoagulation practices are an important component of quality metrics and patient safety practices for hospitalized patients. Anticoagulation management strategies for the prevention and treatment of VTE and SPAF and the prevention of systemic thromboembolism in patients with prosthetic heart valves are discussed in this chapter.

Disorders Requiring Anticoagulation and Their Causes

Venous Thromboembolism

VTE is a thromboembolic event occurring in the venous system, and it is manifested as either deep vein thrombosis (DVT) or pulmonary embolism (PE). VTE contributes significantly to patient morbidity and mortality and is considered a major global disease burden (Raskob et al., 2014). Venous thrombus formation occurs in the setting of venous stasis (sluggish blood flow), vascular endothelial wall injury, and hypercoagulability (propensity for increased blood clotting); these three features are classically referred to as *Virchow triad* (Merli, 2008).

The components of Virchow triad can assist with categorizing the most common causes and risk factors for VTE. Venous stasis, which results in pooling of blood in the lower extremity veins, is precipitated by prolonged immobility occurring during hospitalization, surgery, spinal cord injury, or paralyzing stroke; in conditions that increase venous pressure, including varicose veins or venous insufficiency from the postthrombotic syndrome; or, less frequently, in obesity or pregnancy. Vascular intimal injury is often related to recent surgery, especially abdominal and orthopedic surgery, recent trauma or fracture to the pelvis or lower extremities, childbirth, and previous venous thrombosis. Imbalances between the body's regulatory mechanisms of procoagulant and anticoagulant proteins can result in hypercoagulable conditions. Hypercoagulability may be present secondary to inherited abnormalities of coagulation (thrombophilia), malignancy, oral contraceptive use, and estrogen therapy (Merli, 2008). In addition, central venous catheters and age older than 40 years also increase the risk of venous thromboembolic disease (Ortel, 2010). The incidence of VTE is approximately 0.75 to 2.69 per 1,000 individuals in the general population and is increased to between 2 and 7 per 1,000 among those ages ≥70 years and to 1 in 200 in patients with active cancer (Easaw et al., 2015; Raskob et al., 2014). Risk factors for VTE should be identified and corrected, if possible (Heit, 2006). Inherited thrombophilia is the most common risk factor in patients presenting with VTE under the age of 50 years (Kreidy, 2014). See Box 50.1 for more information on predisposing risk factors for VTE.

In DVT, the characteristic symptom of lower extremity swelling is due to the thrombus partially or completely occluding the vein. Proximal DVT develops in the popliteal, femoral, or iliac veins above the knee, while calf vein DVT is isolated below the knee. Calf vein DVT may extend proximally in 40% to 50% of patients without anticoagulation.

BOX 50.1 Risk Factors for Deep Vein Thrombosis

and Pulmonary Embolism

Reversible

Trauma,[§] surgery,[*] pregnancy, estrogen therapy,[±] chemotherapy, prolonged or transient immobility, fractures, central venous catheters, obesity, long-haul air travel[˜]

Acquired

Increasing age >40 years, malignancy,[†] previous venous thromboembolism, hematologic disease, heart failure, stroke, inflammatory bowel disease, nephrotic syndrome, spinal cord injury, varicose veins, superficial vein thrombosis, antiphospholipid antibodies, lupus anticoagulant[˜]

Inherited Disorders

Activated protein C resistance, antithrombin III deficiency, protein C deficiency, protein S deficiency, anticardiolipin antibodies,[‡] factor V Leiden, prothrombin gene mutation

*Especially orthopedic, gynecologic, neurosurgical, or urologic procedures.

[§]Especially major or lower extremity injury

[±]Oral contraceptives or hormone replacement therapy

[†]Especially of the lung, breast, or viscera

[‡]May also be acquired

[˜]Considered weak factor

Data from Geerts, W. H., Bergqvist, D., Pineo, G. F., et al. (2008). Prevention of venous thromboembolism: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines (8th ed.). *Chest*, 133(6 Suppl.), 381S–453S; and Osinbowale, O., Ali, L., & Chi, Y. W. (2010). Venous thromboembolism: A clinical review. *Postgraduate Medicine*, 122(2), 54–65.

The major complication of proximal DVT is thrombus dislodgment and extension into the pulmonary circulation. PE is a life-threatening emergency, with an associated mortality rate of 25%. Lower extremity DVTs are the source of 90% of PEs (Piazza & Goldhaber, 2006). Distal DVT isolated to the calf veins has a lower risk of long-term complications. In hospitalized patients, proximal DVT accounts for 80% of cases, with distal DVT comprising 20% (Righini & Bounameaux, 2008).

Nearly 50% of patients experiencing DVT develop chronic venous insufficiency or postphlebitic (postthrombotic) syndrome. The acute thrombus and accompanying inflammation lead to valvular incompetence and venous stasis, with resultant chronic lower extremity edema, ulceration, and chronic pain (Vazquez et al., 2009). These symptoms are frequently debilitating to the patient's quality of life. The lower extremities should be assessed for edema, skin pigmentation changes, spider veins, varicosities, and scarring from previous ulcers to assist with recognizing chronic venous insufficiency and implementing

preventive measures if possible (Kelechi & Bonham, 2008).

Patients with a proximal DVT have a higher risk of recurrence than those with a distal DVT, and patients with PE have a higher recurrent VTE risk than those with isolated DVT. Patients presenting with provoked VTE have a lower risk of recurrence than those with idiopathic (unprovoked VTE). Other risk factors for recurrent VTE include malignancy (recurrence rates exceed 20% at 1 year), antiphospholipid (aPL) antibody syndrome, male sex, persistent positive D-dimer (checked 3 weeks to 2 months following cessation of anticoagulation), and residual thrombosis. Several paper score sheets and web-based risk prediction models are available to estimate a patient's risk of recurrent VTE (http://cemsiis.meduniwien.ac.at/en/kb/science-research/software/clinical-software/recurrent-vte/, http://www.mdcalc.com/dash-prediction-score-for-recurrent-vte/, Barnes et al., 2015).

Atrial Fibrillation

Atrial fibrillation is a cardiac arrhythmia characterized by loss of coordination of electrical and mechanical activity in the atria. Thrombi can form in the left atrial appendage due to impaired ventricular filling and incomplete emptying of the atria. Atrial fibrillation may initially present with the embolic complication of stroke, when atrial thrombi dislodge and travel through the bloodstream to the brain. Other major complications of AF include heart failure, dementia, and death (January et al., 2014). Patients with AF caused by conditions other than valvular problems (e.g., nonvalvular AF [NVAF]) have a fivefold risk of ischemic stroke compared with those in sinus rhythm (January et al., 2014). NVAF is defined as AF in the absence of a mechanical or bioprosthetic heart valve, mitral stenoses, or a history of mitral valve repair surgery (January et al., 2014).

Atrial fibrillation is the most common cardiac rhythm disturbance seen in clinical practice. Hospitalization for this arrhythmia is increasing, accounted for by the aging of the population and an increased incidence of chronic heart disease (Mozaffarian et al., 2015). The incidence increases with advancing age and is highest in those older than age 65 or in younger patients with comorbidities of hypertension or underlying heart disease. Other underlying cardiovascular conditions that can cause AF include hypertension with left ventricular hypertrophy, coronary artery disease, heart failure (HF), and rheumatic valvular disease, especially mitral valve disease. Additional cardiac causes include atrial enlargement, atrial septal defect, and coronary artery bypass graft surgery. Noncardiac etiologies include thyrotoxicosis, hypothermia, fever, stroke, chronic pulmonary disease, electrolyte disorders, PE, alcohol intoxication, obesity, and genetic predisposition (Mozaffarian et al., 2015).

The three key components to managing AF include preventing transient ischemic attack (TIA) and stroke with anticoagulant drugs, restoring and maintaining sinus rhythm in selected patients, and controlling the ventricular heart rate. The patient's risk of stroke determines the need for anticoagulation. Patients with a history of stroke or TIA have the highest risk of a recurrent event. Other independent risk factors for stroke in AF are increasing age, hypertension (HTN), HF with impaired systolic function, and diabetes mellitus. Patients older than age 75 comprise over half of AF-associated strokes; thus, the elderly represent a population in which stroke prophylaxis is essential (Fuster et al., 2006). Anticoagulation therapy is the cornerstone for SPAF.

Prosthetic Valvular Heart Disease

Prosthetic heart valves confer a high risk of systemic embolism, and antithrombotic therapy, antiplatelet therapy, anticoagulation, or a combination of antiplatelet and anticoagulation, is warranted in most patients. Valvular heart disease is most commonly caused by degenerative valve disease due to increasing life spans and rheumatic heart disease. Indications for prosthetic heart valve replacement include mitral stenosis, mitral regurgitation, aortic stenosis, and aortic regurgitation, as progressive deterioration of the native valve can lead to syncope, dyspnea, angina, and HF. There are two main types of prosthetic heart valves: mechanical, made from synthetic materials, or bioprosthetic, of porcine or bovine origin. Mechanical prosthetic valves are more thrombogenic than bioprosthetic valves and require lifelong anticoagulation, but they are more durable. Factors contributing to thrombus formation with mechanical valve replacement include disruption of the vessel wall during surgery, leading to altered blood flow and activation of hemostasis, or exposure of circulating blood to the artificial surfaces of the valve prosthesis (Sun et al., 2010).

Prosthetic valves in the mitral position are more thrombogenic than those in the aortic position. In the mitral position, shear stress is low, blood flow is stagnant, and stasis occurs. In the aortic position, blood flow is rapid and shear stress is high, which causes red blood cell hemolysis and activation of platelets and coagulation factors (Sun et al., 2010).

The risk of thromboembolism in native valvular heart disease is influenced by the position of the valve, for example, mitral versus aortic, heart chamber dimension, ventricular performance, and concomitant risk factors such as prior thromboembolism and AF. In native valvular disease, individuals with rheumatic mitral valve disease have the greatest incidence of systemic embolism. Thromboembolism in aortic valve disease has been noted but is uncommon. Without the coexistence of mitral valve disease or AF, anticoagulation is not indicated in these patients (Salem et al., 2008).

Anticoagulant therapy for thromboprophylaxis is recommended in all patients having prosthetic valve replacement. The rate of embolism reported with mechanical valves (St. Jude bileaflet valve) when antithrombotic prophylaxis was not administered ranged from 12%/year with aortic valves to 22%/year with mitral valves (Salem et al., 2008). Bioprosthetic tissue valves present a much lower risk of thromboembolism, averaging 1%/year; the risk of thromboembolic events is highest in the first 3 months following surgery, after which anticoagulant therapy is usually discontinued (Sun et al., 2010).

Pathophysiology of Coagulation and Clotting Disorders

Disrupting the body's normal system of checks and balances for hemostasis will lead to either excessive bleeding or inappropriate clotting. The three major components of the coagulation system—endothelial cells, platelets, and coagulation proteins—preserve hemostasis by promoting clot formation in response to vascular injury. The intact vessel wall of the vascular endothelium maintains blood fluidity by inhibiting blood coagulation and platelet aggregation while promoting fibrinolysis. When the vessel wall is injured, substances in the endothelial cell lining stimulate the formation of a hemostatic plug by promoting platelet adhesion and aggregation and by activating blood coagulation, resulting in a fibrin clot (Colman et al., 2006).

Role of Clotting Cascade

In response to tissue injury, a series of complex enzymatic reactions (the clotting cascade, Figure 50.1) is initiated that leads to the formation of a stable fibrin clot. Circulating inactive coagulation factors are sequentially converted into activated coagulation factor complexes. The final step in the cascade is the formation of thrombin (factor IIa), which leads to the conversion of fibrinogen to fibrin and the formation of a fibrin clot (Colman et al., 2006).

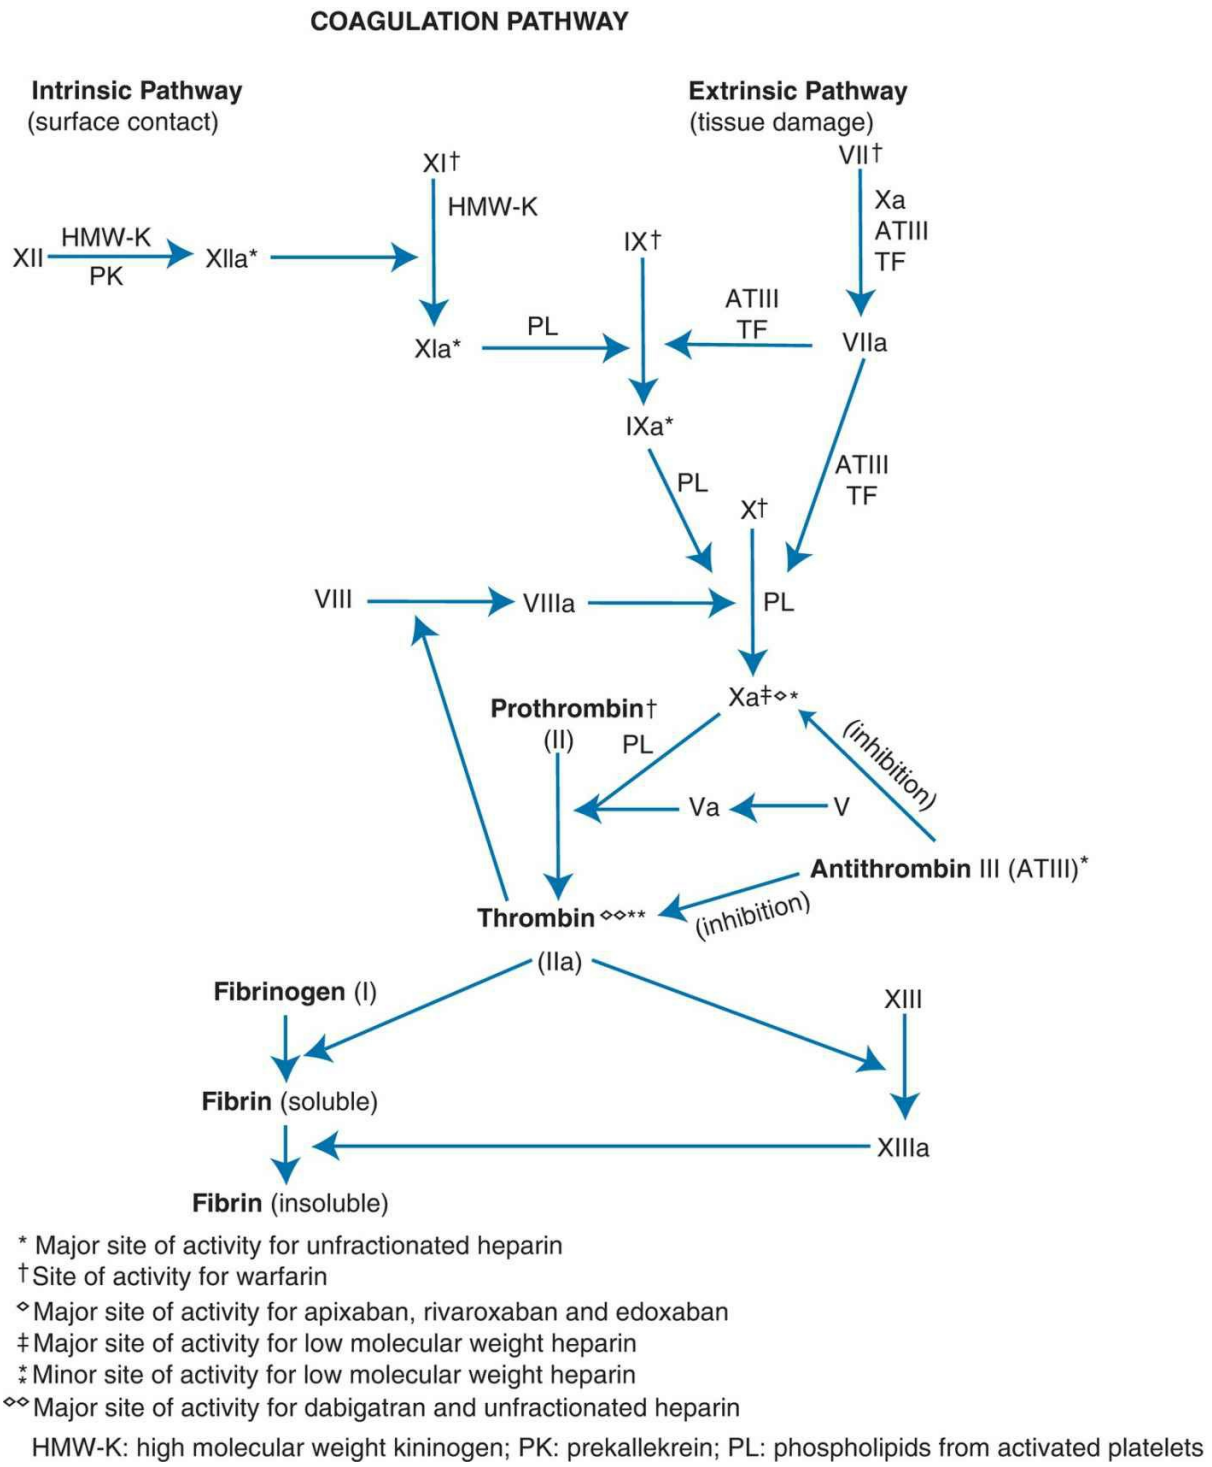

FIGURE 50.1 The coagulation system.

Platelets also participate in repairing tissue injury by adhering to the site of injured blood vessels, attracting other platelets to the site, and forming large platelet aggregates that help stabilize the platelet–fibrin clot. When platelets are activated, receptors for clotting factors are exposed. This also provides a stable environment for the initiation of the clotting cascade (Colman et al., 2006).

The coagulation system is traditionally divided into the intrinsic and extrinsic pathways. Activity through the extrinsic pathway is initiated by components from the blood and vasculature, with factor VII as the major initiating factor. Activation occurs when procoagulant components migrate to sites of vascular damage or when blood is exposed to substances released as a result of vascular wall damage. In contrast, activity through the intrinsic coagulation pathway is initiated by activation of factor XII when blood comes in contact with a foreign surface (such as a prosthetic device) or damaged endothelial blood vessels. Once factor X is activated in either the extrinsic or intrinsic pathways, the two pathways merge to form a final common pathway for clot formation by converting prothrombin to thrombin (Colman et al., 2006). (See Figure 50.1.)

Several inhibitory processes limit the clotting process. One of the main regulatory proteins of the clotting cascade is antithrombin III, which inhibits the activated clotting factors Xa, VIIa, IXa, XIa, XIIa, and IIa (thrombin). Three other regulatory proteins, proteins C, S, and Z must be present in sufficient amounts because they prevent excessive clot formation by inactivating factors Va and VIIIa (activated protein C with its cofactor protein S), and preventing the degradation of factor Xa (protein Z). Deficiency in any of these proteins creates a predisposition to pathologic thrombosis (Colman et al., 2006).

Thrombotic Process

Thrombi can form in any part of the cardiovascular system—the veins and arteries (including those of the brain) as well as the heart. Thrombi can cause local complications by obstructing vessels or by breaking off and traveling to a distant site (embolization). Arterial thrombi often form in the setting of preexisting atherosclerosis or other vascular diseases, especially at the sites of ruptured atherosclerotic plaques. In the heart, thrombi can develop on damaged cardiac valves, in a dilated or dyskinetic heart chamber, or on prosthetic valves. Although most intracardiac thrombi cause no symptoms, serious consequences can arise if the thrombi migrate to the systemic circulation, especially the brain. In the venous system, thrombi usually occur in the lower extremities as DVT or in the pulmonary circulation as PE. Venous thrombi form in areas of sluggish blood flow (venous stasis) and contain primarily red cells held together with fibrin, with only small amounts of platelets. In contrast, arterial thrombi form in areas of high blood flow and are composed primarily of platelets bound with fibrin strands (Colman et al., 2006). The type of thrombus will dictate whether treatment is most appropriate with anticoagulant drugs or antiplatelet drugs.

Hypercoagulable States

Patients with thrombophilia, or hypercoagulable conditions, have an increased tendency to develop thrombosis, most often venous thrombosis. Hypercoagulability may be inherited or acquired. The two most common genetic risk factors for VTE are factor V Leiden mutation and the prothrombin gene mutation 20210. The aPL antibody syndrome is the most common nongenetically acquired thrombophilia. Genetic risk factors increase the likelihood of an initial VTE but don't impact the risk of a recurrent event (Goldhaber, 2010).

A mutation in coagulation factor V, one of the key proteins in the coagulation cascade, occurs with factor V Leiden. Normally, activated protein C and S will inactivate factor V; in individuals with factor V Leiden, activated factor V is not degraded as efficiently, resulting in increased coagulability (Varga, 2008). Factor V Leiden occurs in 2% to 10% of whites in the United States and increases the risk of VTE two- to fivefold (Coppola et al., 2009).

Another genetic mutation that causes an increased risk of thrombosis is prothrombin gene mutation 20210 or 20210A. Some patients will have increased prothrombin activity, which is thought to contribute to thrombosis. The incidence in the population and the risk of VTE is similar to factor V Leiden. Both the factor V Leiden and prothrombin gene mutation are uncommon in Blacks and Asians (Merli, 2008).

Antithrombin III, activated protein C, and activated protein S are natural anticoagulants, so deficiencies in these clotting factors, although very rare, will also induce a prothrombotic state, corresponding to a 5- to 10-fold increase in VTE risk.

Homocysteine is an amino acid formed when the essential amino acid methionine is metabolized. Genetic defects (polymorphism) in the enzymes that regulate homocysteine metabolism can lead to elevated levels (hyperhomocysteinemia), but the exact association between this defect and resultant VTE is still uncertain. Hyperhomocysteinemia has been linked to an increased risk of stroke (Goldstein et al., 2011). Hyperhomocysteinemia is likely due to genetic and acquired causes (e.g., dietary deficiencies of folate, vitamin B_6, or vitamin B_{12}) (Coppola et al., 2009).

The presence of a genetic risk factor superimposed with an acquired risk factor significantly increases the risk of VTE (Coppola et al., 2009). Clues that a patient with VTE has an underlying inherited hypercoagulable condition include thrombosis in patients younger than age 50, a positive family history of VTE, idiopathic or unprovoked thrombosis, recurrent thrombosis, and thrombosis in unusual locations, such as the adrenal glands, renal veins, or upper extremities (Merli, 2008).

A wide spectrum of acquired hypercoagulable states exist, including aPL antibody syndrome, malignancy, hematologic disorders, and nephrotic syndrome. For the purposes of this chapter, only aPL antibody syndrome will be discussed. aPLs are autoantibodies that

bind to membrane phospholipid proteins, which are thought to cause the proteins to be antigenic and initiate thrombosis. Several aPLs have been identified, but the two most common are lupus anticoagulant and anticardiolipin antibodies. Lupus anticoagulant is often found in patients with systemic lupus erythematosus, but can occur in other diseases, including syphilis. Lupus anticoagulant is a strong predictor of thrombotic risk for arterial and venous thrombosis. The hallmark characteristics of aPL antibody syndrome are recurrent arterial or venous thrombosis, unexplained fetal loss, and thrombocytopenia with the presence of circulating aPLs. Ischemic stroke is a well-established criterion for the diagnosis of aPL antibody syndrome (Dafer & Biler, 2008).

A workup for thrombophilia is usually deferred until after the acute thrombosis phase because diagnosis does not impact treatment (Goldhaber, 2010). Widespread screening for inherited disorders is not recommended unless it is expected to change clinical management. A hematologist referral is required to determine what, if any, laboratory testing is required and whether wider testing of family members is warranted. The presence of certain anticoagulant drugs, in particular warfarin, will dictate the best timing for laboratory testing because warfarin treatment will affect protein C, Z, and S (Merli, 2008).

Although inherited thrombophilia increases the risk of VTE, prophylaxis with long-term anticoagulation is not necessary because the risk of bleeding, including fatal bleeding, outweighs the benefits of prophylaxis. However, in the setting of a potential triggering risk factor (e.g., surgery), anticoagulation prophylaxis is beneficial during the period of exposure (Coppola et al., 2009).

Diagnostic Criteria

Venous Thromboembolism

Erythema, pain, swelling, venous distention, and warmth in the affected leg are common presenting symptoms of DVT. Other conditions, such as muscle strain, cellulitis, and postphlebitic syndrome, may mimic symptoms of DVT. Approximately 50% of patients with DVT have no symptoms. Diagnosing VTE based on clinical factors is often unreliable because only 20% of patients who present with suspected VTE actually have a thrombosis. Therefore, objective confirmatory tests are required (Merli, 2008).

First, the laboratory blood test D-dimer may be measured. D-dimer is the major degradation product released into the circulation when cross-linked fibrin undergoes fibrinolysis. Levels of D-dimer are elevated (>500 μg/L) in most patients with ongoing thrombosis. Current assays for D-dimer are over 95% sensitive but not specific. Therefore, a negative D-dimer (<500 μg/L) test helps to rule out DVT or PE. Clinical prediction models that divide patients into low-, moderate-, or high-risk categories for DVT/PE have been validated. For a first-time DVT, the Wells Score may be calculated to determine the pretest probability of DVT or PE (see http://www.qxmd.com/calculate-online/hematology/wells-dvt-deep-vein-thrombosis and http://www.mdcalc.com/wells-criteria-for-pulmonary-embolism-pe/). Using clinical judgment along with D-dimer assays may decrease the need for unnecessary testing and patient exposure to radiation and contrast dye (Merli, 2008).

The methods used for detecting DVT are contrast-enhanced venography, compression ultrasonography (CUS), and magnetic resonance imaging (MRI). Contrast-enhanced venography is the gold standard for confirming DVT because it is nearly 100% sensitive and specific and can visualize the distal and proximal venous system. However, it is no longer used in the initial diagnosis of DVT due to high cost, invasiveness, and risk of contrast dye–induced allergic reactions and renal impairment. CUS measures the rate and direction of blood flow and can visualize clot formation in the proximal leg veins. CUS is the diagnostic method of choice because it is noninvasive, can be conducted at the bedside, and is relatively easy to perform. In CUS, DVT is diagnosed if the common femoral or popliteal veins cannot be compressed. For CUS, the sensitivity is 95% and specificity is 96% with a first episode of symptomatic proximal DVT. Disadvantages of CUS include decreased accuracy for detecting calf vein thrombi (73% sensitivity), operator variability, and limitations caused by obesity, casts, and immobilization devices. Although MRI is useful for examining pelvic veins, it has limited usefulness for diagnosing DVT because it is expensive and requires the presence of an experienced radiologist (Merli, 2008).

PE is the most serious complication of DVT. The PE mortality rate is related to the size of the thrombus. A massive PE obstructs 50% of the pulmonary vasculature. The term *submassive* is used when less than 50% of the pulmonary circulation is affected. Death occurs from acute right-sided HF in untreated patients. The diagnosis of PE is difficult

when based on symptoms because presenting symptoms are not specific. For patients presenting with PE, shortness of breath with or without leg pain may be the first symptom. Other physical findings include sudden onset of dyspnea, pleuritic chest pain, cough, tachycardia, and tachypnea; these symptoms also occur in HF, interstitial lung disease, and pneumonia, so thorough examination and further testing is important. Suspicion of PE is based on symptoms along with such risk factors as immobility, recent trauma or surgery, underlying malignancy, and oral contraceptive use. Baseline tests for evaluating PE include a chest x-ray, an electrocardiogram (ECG) to differentiate between PE and MI, and arterial blood gas evaluations (to assess the severity of hypoxemia). Chest x-ray is often normal, so it is most useful in excluding the diagnosis of other conditions with similar symptoms of PE, including pneumothorax (Merli, 2008).

For PE, ventilation/perfusion (V/Q) lung scanning is used to measure the distribution of blood and air flow in the lungs. The results are reported as high, intermediate, or low probability or normal. A normal scan excludes clinically important PE and is sufficient evidence to withhold anticoagulant therapy. An abnormal scan, even though it might suggest PE, can result from other disease states. V/Q lung scanning previously was the major test for diagnosing PE. However, the combination of clinical suspicion and V/Q scan results is nondiagnostic in 72% of patients. Thus, additional confirmatory testing is required. Pulmonary angiography is the gold standard for confirming PE, but it is invasive and expensive, uses contrast dye, and is not always readily available. It is reserved for patients when noninvasive tests are inconclusive (Merli, 2008). A V/Q scan is reserved for patients with acute kidney injury, chronic kidney disease, or dye allergy who have a relative or absolute contraindication to contrast.

Computed tomography pulmonary angiography (CTPA) has replaced the pulmonary angiogram as the preferred test for diagnosing PE, and it has largely replaced V/Q lung scanning due to higher sensitivity. With CTPA, the sensitivity is 92%, and its specificity is 94%. Disadvantages to CTPA include radiation exposure and the need for injected contrast agent and subsequent risk of renal impairment; V/Q lung scanning is preferred in this setting. CTPA and V/Q lung scanning can reliably exclude the diagnosis of PE (Weitz, 2009).

Imaging of the chest and vascular structures is possible with MRI. In magnetic resonance angiography (MRA), the contrast agent gadolinium is used, which has a lower risk of renal toxicity than the contrast agents used in computed tomography (CT) scans. Disadvantages to MRA include cost and patient physical limitations (e.g., implanted metallic devices and cardiac pacemakers, claustrophobia, obesity) (Merli, 2008).

Atrial Fibrillation

Symptoms associated with AF include palpitations, chest discomfort, shortness of breath, weakness, hypotension, dizziness, and syncope. Clinical signs of AF include acute HF, pulmonary edema, dyspnea, and possibly hemodynamic instability (Fuster et al., 2006). On physical examination, findings of an irregular pulse, irregular jugular venous pulsations, or variations in the intensity of the first heart sound (S_1) can guide the practitioner in suspecting AF (Bentz, 2006). The ECG is used to confirm the diagnosis; an irregularly irregular rhythm is the hallmark of AF. Other ECG characteristics include the absence of P waves and ventricular response rates of 100 to 180 beats/minute. A thorough history and physical examination is needed to rule out underlying causes of AF. Other baseline assessments include evaluation of electrolytes, thyroid function tests, complete blood count (CBC), and chest x-ray. The diagnostic workup also includes a transthoracic echocardiogram, which can detect left ventricular dysfunction, left ventricular hypertrophy, valvular heart disease, and atrial enlargement. In some cases, a stress test is ordered to rule out the presence of ischemic heart disease. Transesophageal echocardiography (TEE) is frequently used to identify left atrial thrombi in preparation for electrical cardioversion, which attempts to restore normal sinus rhythm (Fuster et al., 2006).

Nurses and physician assistants can assist with the initial management of AF by remembering the mnemonic *SALTE*—stabilize (monitor heart rate, blood pressure, respiratory status, and medication), assess (fluid and electrolyte status, medication management, risk factor identification and modification), label/treat (arrhythmia management, reducing anxiety, anticoagulation management), and educate (disease process, anticoagulation teaching, prescribed medications) (McCabe, 2005). Patients with stroke or TIA or risk factors for stroke should be taught the acronym FAST, a mnemonic that stands for facial drooping, arm weakness, speech difficulty, and time to call 911 (http://www.strokeassociation.org/STROKEORG/WarningSigns/Stroke-Warning-Signs-and-Symptoms_UCM_308528_SubHomePage.jsp).

Atrial fibrillation may be classified as "valvular" or "nonvalvular" AF (NVAF). NVAF is defined by the American College of Cardiology (ACC)/American Heart Association (AHA)/Heart Rhythm Society of America (HRSA) AF practice guidelines as "AF in the absence of rheumatic mitral stenosis, a mechanical or bioprosthetic heart valve, or mitral valve repair" (January et al., 2014). Antithrombotic therapy selection for the prevention of stroke is based upon a discussion with the patient about the risk of stroke and the benefits/risks of antithrombotic therapy. Patients with valvular heart disease and AF are at high risk of stroke. For patients with NVAF, an annual risk of stroke is estimated using the $CHAS_2DS_2$-Vasc Score (http://www.mdcalc.com/cha2ds2-vasc-score-for-atrial-fibrillation-stroke-risk/ or via a mobile phone app AnticoagEvaluator available from the ACC at http://www.acc.org/tools-and-practice-support/mobile-resources). Risk factors included in this estimate are age, female gender, HF, HTN, prior history of stroke or TIA, diabetes

mellitus, and presence of concomitant vascular disease, such as myocardial infarction (MI), peripheral arterial disease, or aortic plaque.

Ischemic Stroke

Ischemic stroke is characterized by a sudden or progressive onset of focal neurologic signs due to an inadequate blood supply to the brain. The resulting neurologic deficits depend on the location of cerebral infarction. Most often, the deficits are confined to one side of the body, right or left. The most common presenting stroke symptom is tingling, numbness, and weakness or paralysis on one side of the body. Incoordination, aphasia, dysarthria, and visual disturbances also can occur. Other manifestations include changes in mental status or loss of consciousness. The time of onset of symptoms is a key piece of historical information to determine from the patient or family members because it will dictate treatment. Neurologic signs or symptoms may progress in approximately 25% of patients in the first 24 to 48 hours. Approximately 50% of patients are left with a permanent disability (Adams et al., 2007).

The physical examination may show signs of trauma or seizures (e.g., contusions, tongue lacerations) or carotid disease (bruits). A comprehensive neurological exam is necessary to determine the extent of neurological deficit, identify the possible location of the thrombus, and help determine the most appropriate intervention (Adams et al., 2007).

All patients presenting with suspected ischemic stroke require several diagnostic tests, including blood glucose, electrolytes, CBC with platelets, ECG, cardiac enzymes, prothrombin time (PT), international normalized ratio (INR), activated partial thromboplastin time (aPTT), and oxygen saturation (Adams et al., 2007).

Brain imaging studies, including noncontrast CT scan and MRI, are used to detect the presence, extent, and progression of a cerebral infarction and if there is intracranial bleeding. Several tests can help detect the source of a presumed thromboembolic ischemic stroke. Noninvasive carotid ultrasound will show occlusion or stenosis. An ECG differentiates between AF and MI. Transthoracic and transesophageal echocardiograms visualize cardiac function and the presence of an atrial thrombus. Carotid cerebral angiography can be performed to examine the arteries and veins of the brain and neck. This provides the most accurate visualization to detect abnormalities such as stenosis or occlusion that may have caused the ischemic event (Adams et al., 2007).

Native and Prosthetic Valvular Heart Disease

Signs and symptoms of valvular heart disease vary depending on the valve that is affected. In aortic stenosis, the cardinal symptoms are dyspnea, angina, syncope, and HF. Aortic regurgitation is often asymptomatic. Dyspnea is the hallmark symptom of mitral stenosis, although this usually is present with exertion and has a gradual onset over approximately 20 years. Mitral regurgitation also progresses slowly and may be asymptomatic for many years. The initial symptoms may be fatigue, dyspnea on exertion, and palpitations that, in severe cases, may lead to pulmonary edema. Each valvular disorder is associated with a characteristic murmur, but the intensity of the murmur does not always correlate with the severity of the valvular disorder (Maganti et al., 2010).

Findings on physical examination also vary with the severity of the valve calcification, severity of stenosis, and left ventricular dysfunction. The chest x-ray will show cardiomegaly, which can occur with aortic stenosis. An ECG is used to determine the possible cardiac effects of valve incompetence or stenosis such as left ventricular hypertrophy in mitral and aortic regurgitation. Confirmation of the diagnosis of valvular disease is best accomplished by an echocardiogram, which will also give an estimate of disease severity. Cardiac catheterization and angiography are used when noninvasive tests are inconclusive. When physical symptoms of valvular disease lead to limitations in daily activities or if cardiac decompensation occurs despite medical treatment, surgical intervention either with surgical repair, surgical valve replacement or minimally invasive transcatheter aortic valve replacement are recommended (Maganti et al., 2010).

Goals of Drug Therapy

Preventing the development of a stroke is the primary goal of antithrombotic therapy in patients with AF and prosthetic heart valves and in those with a history of cardioembolic stroke. Anticoagulation treatment in patients with existing DVT/PE is initiated to prevent extension of the thrombus; thromboembolic complications, including postthrombotic syndrome; and development of a new thrombus. Anticoagulation prophylaxis after orthopedic surgery is initiated with aspirin or anticoagulation to decrease the risk of DVT or PE. The goals of antiplatelet therapy are to prevent and treat ischemic strokes from noncardioembolic sources. Other indications for antiplatelet therapy for primary or secondary prevention of CVD events will not be discussed in this chapter.

Anticoagulants: Indications

A valid indication for anticoagulation is essential before starting anticoagulant therapy. Unfractionated heparin (UFH) and low molecular weight heparins (LMWHs) are used for treatment and secondary prevention of VTE and treatment of acute coronary syndromes. In addition, UFH is used in hospitalized patients undergoing procedures such as cardiothoracic surgery, electrophysiology arrhythmia catheter ablation, cardioversion for atrial fibrillation, and percutaneous coronary intervention as well as in patients undergoing hemodialysis. Warfarin is used in the prevention of valve thrombosis in patients with mechanical heart valves as well as for SPAF, prevention of VTE in patients undergoing orthopedic surgery, and treatment and secondary prevention of VTE. FDA-approved indications for direct-acting oral anticoagulants (DOACs) are described in Table 50.1.

TABLE 50.1 FDA-Approved Indications for DOACs

Drug	Dabigatran	Rivaroxaban	Apixaban	Edoxaban
Stroke and systemic thromboembolism prevention in NVAF	X	X	X	X
Prophylaxis of DVT following hip and knee orthopedic surgery	X	X	X	
Treatment of DVT and PE	X*	X	X	X*
To reduce risk of recurrence of DVT and PE in patients previously treated	X	X	X	

*In patients who have been treated with a parenteral anticoagulant for 5–10 d.

NVAF, nonvalvular atrial fibrillation; DVT, deep vein thrombosis; PE, pulmonary embolism.

Contraindictions to Anticoagulation

Absolute contraindications to anticoagulation are as follows: recent hemorrhagic stroke, active major bleeding, recent trauma or traumatic surgery, use in the immediate postoperative period after CNS or ocular surgery, or the presence of spinal catheters and aneurysms or CNS tumors with a high bleeding risk (Bristol-Myers Squibb, 2010). Warfarin is contraindicated in pregnancy, and there are no data with DOACs in pregnancy. Therefore, UFH or LMWH, which does not cross the placenta, is preferred. Active or a recent (within 100 days) history of heparin-induced thrombocytopenia (HIT) is a contraindication to UFH and LMWHs. Neuraxial anesthesia with spinal or epidural catheter placement or removal poses a risk of spinal hematoma in the anticoagulated patient. Therefore, the American Society of Regional Anesthesia and Pain Medicine released guidelines regarding timing for neuraxial needle placement and removal relative to UFH, LMWH, and DOAC dose were published (Horlocker et al., 2010).

Anticoagulants: Considerations Before Starting Therapy

In addition to a valid indication, several patient factors also warrant consideration to determine if the risk of hemorrhage outweighs the benefit of therapy.

Baseline laboratory values including PT, INR, aPTT, urinalysis, CBC (with platelet count), and a liver profile are recommended before initiating anticoagulation. In women of childbearing age, laboratory testing for β-human chorionic gonadotropin is strongly encouraged to rule out pregnancy. Obtaining the patient's telephone number and an alternative contact, such as a responsible family member or neighbor (obtain consent to contact others per HIPAA guidelines), is also advised. In addition, rule out any active major bleeding from the central nervous system (CNS) or gastrointestinal (GI) tract. A digital rectal examination or guaiac test to detect blood in the stool is recommended. A detailed medical, surgical, and medication history, including over-the-counter (OTC) medications and dietary supplements, is needed to assess the patient's risk of bleeding events or inadequate anticoagulation. It is also important to document the indication for anticoagulation, which determines the duration of therapy, and, if warfarin is selected, to define the corresponding target INR, which defines the intensity of anticoagulation. When all these issues are addressed, anticoagulation is initiated (Witt, 2010). For patients receiving an LMWH or DOAC, body weight (kg), serum creatinine, and estimation of renal function creatinine clearance (CrCl) should be calculated. For patient receiving UFH, body weight (kg) should also be obtained. Although not currently recommended as a routine practice, a bleeding risk estimate for patients with AF may be obtained from calculating the HAS-BLED score and is discussed later in this chapter (http://www.mdcalc.com/has-bled-score-for-major-bleeding-risk/ or via a mobile phone app AnticoagEvaluator available from the ACC at http://www.acc.org/tools-and-practice-support/mobile-resources). The HAS-BLED score has only been validated in patients taking vitamin K antagonists (VKAs) and not in patients receiving parenteral anticoagulants or DOACs.

Anticoagulants: Mechanism of Action and Time Frame for Response, Dosing Selection, Drug–Drug Interactions, and Monitoring

Anticoagulants include the injectable agents unfractionated heparin (UFH) and low-molecular-weight heparins (LMWHs) (e.g., enoxaparin), oral vitamin K antagonist (VKA) warfarin, and the direct-acting oral anticoagulants (DOACs) dabigatran etexilate (a direct thrombin inhibitors), and oral factor Xa inhibitors (rivaroxaban, apixaban, and edoxaban). (See Figure 50.1.)

Parenteral Anticoagulants: Unfractionated Heparin and Low Molecular Weight Heparin

UFH and LMWH are used for the treatment of acute venous or arterial thrombosis and prophylaxis of VTE.

Unfractionated Heparin

UFH inhibits reactions that lead to clotting, but it does not alter the concentration of the normal clotting factors of the blood. When UFH binds to antithrombin III, the shape of the structure changes, which increases the inactivation rate of the intrinsic clotting cascade pathway, including activated clotting factors XII, XI, X, and IX and thrombin (factor II). Once active thrombosis has developed, UFH inhibits further coagulation by inactivating thrombin and preventing the conversion of fibrinogen to fibrin. UFH is a very large molecule (i.e., it has an average molecular weight of 15,000 Da with chains of 18 to 50 saccharide units), but only a small portion of the entire structure is necessary for binding with antithrombin III. Because the structure is so large, UFH can bind to both factor Xa and thrombin. Heparin derivatives with smaller structures cannot bind to thrombin, but can bind to and inhibit factor Xa (Hirsh et al., 2008). One disadvantage of heparin's large size is that it cannot inactivate clot-bound thrombin or activated factor X that is bound to platelets. Clot-bound thrombin can continue to generate more thrombin, activate platelets, and convert fibrinogen into fibrin, promoting clotting. In contrast to UFH, direct thrombin inhibitors do not activate platelets (Spyropoulos, 2008).

Heparin is not absorbed from the GI tract, so it must be administered parenterally. UFH has an immediate onset of action and is administered by intravenous (IV) infusion when rapid anticoagulation is needed, as in acute DVT, PE, or unstable angina. UFH may also be administered subcutaneously with peak levels occurring 2 to 4 hours after administration, depending on the dose. Subcutaneous dosing must be at a sufficient amount to overcome the lower bioavailability, approximately 30%, associated with this route of administration. The duration of action and half-life are dose dependent. The average half-life is 30 to 180 minutes, which may be significantly prolonged at high doses. UFH is metabolized by liver heparinase and the reticuloendothelial system and possibly secondarily in the kidneys. It is then excreted in urine as unchanged drug.

Limitations of UFH include variability in its size, anticoagulant activity, and pharmacokinetic profile. UFH can range in size from 5,000 to 30,000 Da. Agents with higher molecular weights are cleared from the circulation more rapidly than agents with lower molecular weights. UFH is highly bound to plasma proteins and cellular components, including endothelial cells and macrophages, which reduces its therapeutic effect and increases the incidence of immunologic reactions (e.g., HIT). Furthermore, some patients exhibit heparin resistance. This is characterized by no measurable change in anticoagulant effect despite receiving large doses (35,000 units) of heparin daily. UFH also

has a nonlinear dose response, so that small changes in dosage can result in large changes in anticoagulant effect (Hirsh et al., 2008).

Before initiating UFH therapy, define the target aPTT, establish the frequency of aPTT monitoring, and determine the duration of therapy. UFH treatment dosing is based on weight. Initial dosing for treatment of VTE is 80 units/kg as an IV bolus and then 18 units/kg/hour as a continuous IV infusion. UFH's effect is monitored by aPTT. Dosage changes should be made based on aPTT levels monitored every 6 hours until the patient is stable and then every 12 to 24 hours. Each individual hospital defines a regent-specific aPTT therapeutic range depending upon an antifactor Xa concentration—aPTT curve. Hospitals construct a dosing algorithm for dose adjustment depending on the resultant aPTT or utilize heparin anti-Xa activity measures directly. One popular method is the weight-based nomogram (Hirsh et al., 2008) shown in Table 50.2. Anticoagulation may be subtherapeutic or supratherapeutic despite the use of validated dosing protocols. UFH in a fixed low dose of 5,000 units subcutaneously every 8 to 12 hours is used for VTE prophylaxis. This regimen may be used in postoperative patients and medical patients with decreased mobility (Hirsh et al., 2008).

TABLE 50.2 Weight-Based Heparin Dosing Nomogram

Activated Partial Thromboplastin Time	Rate Change
Initial dose	80 U/kg bolus, then 18 U/kg/h
<35 s	80 U/kg bolus, then increase infusion by 4 U/kg/h
35–45 s	40 U/kg/h bolus, then increase infusion by 2 U/kg/h
46–70 s	No change (Therapeutic range determined by anti-Xa calibration curve 0.3–0.7 IU/mL)
71–90 s	Decrease infusion rate by 2 U/kg/h
>90 s	Hold infusion for 1 h; then decrease infusion rate by 3 U/kg/h

Low Molecular Weight Heparins

LMWHs are fragments of UFH, prepared by the depolymerization of porcine heparin. Like

UFH, LMWHs produce their major anticoagulant effect via thrombin and factor Xa. LMWHs are used for prophylaxis of VTE in patients after orthopedic and abdominal surgery, in medical patients with decreased mobility or increased risk of VTE, and for treatment of DVT/PE. As with UFH, most patients need subsequent treatment with warfarin, depending on the indication for anticoagulation. Other uses that will not be discussed in this chapter include the treatment of acute coronary syndromes. Three LMWHs are available in the United States: dalteparin (Fragmin), enoxaparin (Lovenox), and tinzaparin (Innohep), but the most commonly used in enoxaparin.

LMWHs preferentially inhibit the activation of factor X but have minimal effects on thrombin (factor II) because of their small size. The average molecular weight of LMWHs ranges from 4,000 to 6,500 Da with 13 to 22 saccharide units. (UFH has a mean molecular weight of 12,000 to 15,000 Da with 18 to 50 saccharide units.) Only the LMWHs with saccharide chains having 18 or more units can bind to and inhibit thrombin. UFH has a ratio of anti-Xa to anti-IIa activity of 1:1, and the anti-Xa to anti-IIa activity of LMWHs ranges from 2:1 to 4:1 (Hirsh et al., 2008).

LMWHs given by the subcutaneous route have a bioavailability of greater than 90% of the given dose. In contrast to UFH, LMWHs have minimal binding to cells or plasma proteins, which results in the persistence of free drug in the circulation and a longer half-life of activity. The half-lives of LMWHs range from 108 to 252 minutes. Dosing is fixed in prophylaxis, but is based on weight for treatment. The peak effect occurs at approximately 4 hours following a subcutaneous dose.

As previously noted, the major antithrombotic and bleeding effects of LMWHs arise through their ability to inactivate factor Xa. UFH is monitored using aPTT, which primarily reflects antiactivated factor II (IIa) activity, but LMWHs have minimal effects on the aPTT. Theoretically, LMWHs may be monitored by anti-Xa activity, with a target range for treatment regimens of a chromogenic anti-Xa peak of 0.5 to 1.2 units/mL measured 3 to 4 hours after a subcutaneous dose. Studies have demonstrated that the anti-Xa effect of LMWHs is linearly related to the dose administered. Therefore, plasma levels are predictable, and anti-Xa activity monitoring is not routinely performed. Monitoring may be considered in selected patients, such as those with renal dysfunction because LMWHs are cleared primarily by the renal route, morbidly obese patients (>150 kg) because weight-adjusted dosing has not been evaluated in patients with severe obesity, and pregnant patients because their weight changes, volume shifts occur, and clearance changes as pregnancy progresses. In addition to the recommendation for monitoring anti-Xa levels in patients with renal dysfunction, a dosing reduction is recommended for enoxaparin. UFH is recommended over LMWH for patients with CrCl < 30 mL/min in the 2012 American College of Chest Physicians Guidelines (Hirsh et al., 2008).

Advantages of LMWHs over UFH include greater bioavailability with subcutaneous administration; longer duration of anticoagulant effect, allowing for once-daily or twice-daily dosing; high degree of correlation between anti-Xa and body weight, allowing for fixed dosing; less intensive nursing care; and less intensive laboratory monitoring and more

predictable anticoagulant response, permitting use in the outpatient setting (Hull & Pineo, 2004).

Each LMWH has a unique dosing regimen because of its unique chemical properties and the relative proportions of anti-Xa to anti-IIa activity. Because of differences in the manufacturing process, molecular weight, half-life, ratio of anti-Xa to anti-IIa activity, and dose, the FDA does not consider these agents therapeutically interchangeable (Hirsh et al., 2008). Enoxaparin at 30 mg every 12 hours or 40 mg daily is currently approved for prophylaxis in medical inpatients and patients after hip, knee, and abdominal surgery. Dalteparin at 2,500 units every 12 hours or 5,000 units daily is approved for prophylaxis in patients after hip and abdominal surgery. For VTE treatment, current FDA-approved dosing for enoxaparin is 1 mg/kg subcutaneous every 12 hours or 1.5 mg/kg daily subcutaneous for inpatients with acute DVT with and without PE when administered in conjunction with warfarin and for outpatients with acute DVT without PE when administered in conjunction with warfarin. Dosing adjustment is required for enoxaparin in patients with CrCl <30 mL/min. Dalteparin is dosed at 100 international units/kg subcutaneous every 12 hours or 200 international units/kg every 24 hours for patients with acute DVT with or without PE. Tinzaparin 175 international units/kg subcutaneous daily is FDA approved for inpatient treatment of acute DVT with and without PE when administered in conjunction with warfarin. When LMWHs are used in the outpatient setting, patient education regarding subcutaneous injection is necessary. Establish that the patient or their caregiver can reliably and accurately administer the subcutaneous injection, or consider arranging for home health care visits (www.lovenox.com/docs/pdf/At-Home-With-Lovenox_p.pdf). The use of UFH and LMWH for acute coronary syndromes will not be discussed in this chapter.

Patients are carefully assessed for bleeding including hematuria and GI bleeding/blood in stools or hemoptysis. Monitoring UFH and LMWHs for HIT is the section on Other Adverse Effects below.

Vitamin K Antagonist (Warfarin)

Warfarin inhibits activation of the clotting factors in the liver that depend on vitamin K for synthesis—factors II, VII, IX, and X and the coagulation inhibitor proteins C, Z and S. Warfarin interferes with the conversion of vitamin K from its inactive form to active vitamin K. Vitamin K is depleted, and the rate of clotting factor formation is decreased, which ultimately prevents clot formation and extension. Warfarin does not affect the function of existing clotting factors and has no effect on an existing thrombus (Ansell et al., 2008).

A significant limitation to warfarin is its long onset of effect. The half-lives of clotting factors range from 6 hours (factor VII) to 60 hours (factor II) (Tran & Ginsberg, 2006). The average half-life of warfarin is 36 to 42 hours. The onset of anticoagulant effect depends on both the half-life of warfarin and the time required to deplete the vitamin K–

dependent clotting factors. The anticoagulant effect of warfarin is monitored with the INR, which is derived from the PT (Table 50.3 and Box 50.2). The INR will show an initial prolongation 1 to 3 days after warfarin is first administered, which is due to the rapid depletion of factor VII. However, the full antithrombotic effect of warfarin won't be seen for 8 to 14 days, when factor II (prothrombin) is depleted. In cases of acute DVT or PE, UFH or LMWHs is often given with warfarin when rapid anticoagulation is needed or in hypercoagulable patients (protein C or S deficiency). Warfarin causes a quick fall in protein C (half-life of 8 to 10 hours), which can induce a temporary hypercoagulable state, putting patients at risk for thrombosis. The injectable anticoagulant is continued until the INR is stable for at least 2 days, which allows for additional reductions in the levels of factors X and II (Ansell et al., 2008). During therapy in hospitalized patients, daily CBCs and platelet counts are usually obtained and daily INRs with warfarin to determine the dose.

TABLE 50.3 Relationship between the Prothrombin Time Ratio and the International Normalized Ratio for Thromboplastins with Varying International Sensitivity Index Values

Hospital	ISI	Control PT (s)	PT (s)	PT ratio	INR
A	1.3	14.8	33.9	2.3	2.9
B	2.3	11.4	18.2	1.6	2.9

The INR takes into account the differences in thromboplastin sensitivity, thus giving a more accurate reflection of the level of anticoagulation.

PT, prothrombin time; PT ratio, observed PT divided by control PT; ISI, International Sensitivity Index; INR, international normalized ratio (INR = PT ratio^{ISI}).

BOX 50.2 International Normalized Ratio: Sensitive Test for Clotting Time

The international normalized ratio (INR is the universally accepted laboratory test for monitoring anticoagulation therapy with the vitamin K antagonists. The INR has replaced the previously used prothrombin time (PT) ratio.

PT is the time in seconds for a blood sample to clot after the addition of laboratory reagents, including specific plasma proteins (tissue thromboplastins) that aid in coagulation. PT measures the reduction in three of the four vitamin K–dependent clotting factors (II, VII, and X) of the extrinsic coagulation cascade. The PT ratio is simply the patient's individual PT divided by a laboratory's control PT. A change in the tissue thromboplastin source from human brain to rabbit brain 40 years ago resulted in a reduced sensitivity in the PT test, leading to lower PT values, and accordingly higher PT

ratio goals, with subsequent increased bleeding risk. The International Sensitivity Index (ISI) was developed by the World Health Organization (WHO) as a reference standard to correct this problem.

Mathematically, the INR is the PT ratio raised to the power of the ISI, or INR = PT ratio^{ISI}. The ISI for commercially available tissue thromboplastins varies between individual lots and manufacturers. The WHO reference standard was assigned an ISI of 1.0, although most commercial laboratories use tissue thromboplastins with ISIs ranging from 1.0 to 2.88. The ISI for a particular reagent is identified in the package insert. The INR can be determined using a calculator, if needed.

Most laboratories commonly report PT and INR. However, only the INR should be used for dosing changes. Relying on the INR minimizes variability in reported results if different laboratories, with different thromboplastin preparations, are used (Table 50.1). The INR represents the best method for standardizing results from different thromboplastin reagents. The American College of Chest Physicians has standardized the desired target INR goal for anticoagulation therapy for each clinical indication. Current guidelines recommend an INR range of 2 to 3 for most indications of anticoagulation. INRs of 2.5 to 3.5 are reserved for patients with prosthetic heart valves or hypercoagulable conditions.

Data from Ansell, J., Hirsh, J., Hylek, E., et al. (2008). Pharmacology and management of the VKAs. American College of Chest Physicians Evidence-Based Clinical Practice Guidelines (8th ed.). *Chest*, 133(6 Suppl.), 160S–198S.

Currently, warfarin (Coumadin) is the most widely used oral anticoagulant in the United States. However, it has numerous drug–drug interactions (Table 50.4), a very narrow therapeutic index, and requires routine laboratory monitoring of the INR at least every 4 to 6 weeks. Warfarin is metabolized by the liver isoenzymes CYP2C9, CYP3A4, and CYP1A2. Medications that inhibitor or are a substrate for these isoenzymes may decrease warfarin metabolism and increase the INR. Medications that induce these isoenzymes increase the clearance of warfarin and decrease the INR.

TABLE 50.4 Common Warfarin Drug Interactions

Increase the INR	Decrease the INR
Amiodarone	Carbamazepine
Cimetidine	Methimazole
Ciprofloxacin	Nelfinavir
Clarithromycin	Nevirapine
Cyclosporine	Phenobarbital
Efavirenz	Phenytoin
Erythromycin	Rifampin
Fenofibric acid	Ritonavir, Ritonavir/Lopinavir
Fluconazole	
Fluorouracil	
Fluvastatin	
Fluvoxamine	
Itraconazole	
Ketoconazole	
Levofloxacin	
Lovastatin	
Metronidazole	
Miconazole	
Nelfinavir	
Phenytoin	
Prednisone	
Rosuvastatin	
Saquinavir	
Simvastatin	
Sulfamethoxazole	
Tamoxifen	

Several herbal preparations can potentially interfere with the anticoagulant effect of warfarin. Although stringently performed clinical trials are lacking, bilberry, feverfew, garlic, and ginger have limited data that show an increased anticoagulant effect when used with warfarin (Nutescu et al., 2006). Fish oil has been noted to increase the INR (Jacobs, 2008). Garlic has platelet inhibitory effects that can increase bleeding risk, and there are

anecdotal reports of increases in the PT/INR in patients receiving warfarin. Herbal products that can decrease the effect of warfarin include ginseng and green tea, due to its vitamin K content (Holbrook et al., 2005). Literature and regulatory actions on herbal supplements can be accessed through the U.S. Department of Agriculture Food and Nutrition Information Center Web site at http://fnic.nal.usda.gov. Supplements containing multiple ingredients are a concern because there may be variations in the amount and purity of the substances comprising the product (Wittkowsky, 2008).

Because of its long half-life, warfarin is administered once daily. Warfarin is completely absorbed after oral administration and is metabolized to inactive metabolites by the liver. Warfarin has a narrow therapeutic window; therefore, the dose needed to exert clinical efficacy is similar to the dose that causes adverse effects (Ansell et al., 2008). Individual patients vary widely in their ability to absorb and eliminate warfarin (pharmacokinetic variations) and in their rate of clinical response and dosage requirements (pharmacodynamic variations). Patient variability in the dose response to warfarin is not related to weight or sex but is influenced by age, comorbid disease states, concomitant medications, and one's genetically predetermined rate of metabolism (Ansell et al., 2008; Garcia et al., 2008).

Gene variants have been identified affecting CYP2C9 (warfarin metabolism) as well as vitamin K epoxide reductase complex 1 (VKORC1) (an enzyme involved in the conversion of vitamin K from active to inactive forms affecting the body's sensitivity to warfarin). The prescribing information contains recommended initial doses of warfarin for warfarin-naive patients based upon selected genotypes combinations of CYP2C9 and VCORC1. However, since many other factors affect warfarin clearance and thus INR, and there are no strong scientific data supporting improved outcomes from knowing this pharmacogenetic information prior to starting warfarin, pharmacogenetic testing for these genetic variants prior to starting warfarin is currently not recommended by any professional organization (Kimmel, 2015).

An increased warfarin response can occur in patients with hepatic dysfunction, in which there is impaired synthesis of clotting factors and decreased warfarin metabolism. Likewise, lower warfarin doses may be needed in patients with low serum albumin or those with significant congestive HF (Jacobs, 2008). Other pharmacodynamic factors that may potentiate warfarin response include hypermetabolic states, such as hyperthyroidism, and febrile states when there is an increased catabolic rate of vitamin K–dependent clotting factors. The elderly also seem to be more sensitive to warfarin, possibly because of altered pharmacodynamic parameters, but the etiology is unknown (Jacobs, 2008).

If the patient receives a prescription for warfarin, the prescriber needs to choose among nine different dosage strengths and colors (e.g., a 1-mg tablet is pink, whereas a 5-mg tablet is peach). For safety's sake and to avoid confusing the patient, prescribe only one warfarin tablet strength (e.g., 2.5- or 5-mg tablets, but not both). Patients also need to be taught to remember the tablet color, shape, and tablet strength with each new prescription and refill.

The goal INR for various indications is described in Box 50.3. It is difficult to predict an individual's warfarin requirement needed to reach the INR range that is considered therapeutic for the disease state. The initial dose of warfarin is typically 5 to 10 mg/d orally administered for 1 to 3 days. Certain patient populations, such as the elderly, patients with congestive heart failure, those with underlying malignancy, those with severely impaired renal or hepatic function, or those taking interacting drugs that increase warfarin's effect, are at high risk for bleeding and should receive a lower initial dose. Larger starting doses, such as 7.5 to 10 mg, may be used in younger patients without comorbid conditions if rapid effect is urgently needed, but this is unnecessary for most patients. During the initial titration phase, daily dosage increases or decreases are commonly made in 2- to 2.5-mg increments based on INR values. Administering warfarin at the same time daily is recommended to reduce variability in effects (Ansell et al., 2008). Warfarin is overlapped with an injectable anticoagulant in patients with acute VTE and in patients at higher risk of stroke or recently cardioverted patients with AF (Jacobs, 2008).

BOX 50.3 Target INRs for Thrombosis Prevention

INR Goal 2.0 to 2.5

Patients with a disease-specific anticoagulation goal of 2.0 to 3.0 (see below) who also are taking concomitant aspirin and a P2Y12 inhibitor

INR Goal 2 to 3

Prophylaxis of venous thrombosis
Treatment of deep vein thrombosis
Treatment of pulmonary embolism
Stroke prevention in atrial fibrillation
Tissue (bioprosthetic) heart valves with other risk factors for stroke
Mechanical prosthetic heart valves (bileaflet valves; St. Jude Medical, Medtronic Hall) in the aortic position
Hypercoagulable conditions (antiphospholipid antibodies with lupus anticoagulant)—certain patients with thromboembolism

INR Goal 2.5 to 3.5

Mechanical prosthetic heart valves (caged ball, tilting disk) in the mitral position or in the aortic position for patients with additional stroke risk factors (e.g. AF)
Hypercoagulable conditions (antiphospholipid antibodies with lupus anticoagulant)—if a history of thromboembolic events with INR of 2 to 3

Target INRs for various anticoagulation indications are described in Box 50.3. The relationship between the warfarin dosage and the INR is not linear. Therefore, minor changes in dose can result in greater than expected changes in the INR. The maintenance warfarin dose varies widely among individuals, and there are no widely accepted patient characteristics that reliably predict the necessary maintenance dose. Warfarin-dosing algorithms for initiation and maintenance therapy can also assist with determining warfarin doses (Witt, 2010). Questions to ask to help determine the cause of an out-of-range INR in a patient previously stabilized on warfarin are described in Box 50.4.

BOX 50.4 Questions to Ask When INR Results Are Unexpected

- Have any warfarin doses been missed in the past 3 to 5 days?
- Have extra warfarin tablets been ingested?
- Is the patient taking a warfarin regimen other than prescribed?
- Is the patient experiencing bleeding problems?
- Is the patient experiencing thromboembolic complications?
- Have any new medications (prescription, over the counter, herbal) been started, deleted, or changed from the patient's medication regimen?
- Has the patient's underlying condition changed, as in acute congestive heart failure exacerbation or worsening renal or hepatic impairment?
- Has the patient had a recent acute febrile or GI illness?
- Has thyroid status changed or has a malignancy been diagnosed?

For maintenance therapy changes, calculating the total weekly warfarin dose and then increasing or decreasing the weekly regimen by only 10% to 20%, spread over the course of the week, can cause measurable changes in the INR. Some clinicians advocate administering the same dosage daily, whereas others agree that giving varying doses on alternate days is rational. Patients with low educational levels and cognitive impairments or those receiving several other medications may benefit from a simple dosing schedule. If an alternating-day regimen is chosen, defining the actual dosage for each day of the week is recommended (e.g., 5 mg administered on Tuesdays, Thursdays, Saturdays, and Sundays and 7.5 mg on Mondays, Wednesday, and Fridays, rather than 5 mg alternating with 7.5 mg every other day). This helps to reduce patient confusion and avoid fluctuations in the INR. Sensitive patients with reduced requirements should receive warfarin daily rather than alternating between drug and drug-free days, for example, 1.5 mg given every day, rather than 2 mg alternating with 1 mg every other day (Ansell et al., 2008). Once a patient has reached a therapeutic INR with a consistent warfarin dose, INR monitoring should continue at least every 4 weeks (Witt, 2010). Patients using vitamin K supplementation

will require frequent INR value checks to avoid the INR dropping below the therapeutic range. Patients also need to be cautioned to not abruptly discontinue the vitamin K supplement due to the risk of excessive anticoagulation (Ansell et al., 2008).

Several dosing nomograms are available that assist in rapidly achieving therapeutic INR values when warfarin is started, and computer software programs are also used (Jacobson, 2008; Witt, 2010 also see www.cfp.ca/content/suppl/2013/08/13/59.8.856…/Warfarin_Tips.pdf). It is important to note that these nomograms were developed in patients who were not taking interacting medications. The addition or subtraction of an interacting medication requires more frequent INR monitoring. If possible, patients taking warfarin should be managed by specialized anticoagulation clinics as the clinic reported patient time spent in the therapeutic INR range is higher than "usual" care and bleeding events lower (Garcia and Hylek, 2008).

Direct-Acting Oral Anticoagulants

Dabigatran etexilate (Pradaxa), rivaroxaban (Xarelto), apixaban (Eliquis), and edoxaban (Savaysa) are DOACs. FDA-approved indications of DOACs are described in Table 50.1. Dabigatran etexilate is a prodrug that is metabolized by blood esterases to dabigatran, which binds to and inhibits thrombin that prevents the conversion of fibrinogen to fibrin. Thrombin is also the most potent stimulator of platelet aggregation. (See Figure 50.1.) Blocking thrombin is an effective method of inhibiting coagulation since thrombin is needed for fibrin formation and to activate factors V, VII, VIII, IX, and XIII. Dabigatran directly inhibits free and clot-bound thrombin. The direct-acting agents, rivaroxaban, apixaban, and edoxaban, bind directly to factor Xa and do not require antithrombin like LMWHs do. Intravenous direct thrombin inhibitors are available (e.g., bivalirudin, and argatroban) and are administered via infusion in the hospital and used primarily for percutaneous coronary intervention (bivalirudin) or treatment of HIT (argatroban and bivalirudin).

One of the most important advantages of the DOACs over warfarin is that the DOACs have a faster onset of action. The time to anticoagulant effect of a DOAC depends on the time to maximum plasma concentration, which typically occurs within 2 to 4 hours of first dose administration. Therefore, bridging between an injectable anticoagulant and a DOAC is not necessary. Other advantages compared to warfarin include fixed dosing, no dietary interactions, and few indications for coagulation intensity monitoring. The DOACs have fewer drug–drug interactions compared to warfarin (Table 50.5). In contrast to warfarin, these agents have fixed dosing and a predictable anticoagulant response; therefore, dosing adjustments are not necessary.

TABLE 50.5 DOAC Drug Interactions

Type of Interaction and Outcome	Dabigatran	Rivaroxaban	Apixaban	Edoxaban
Pharmacokinetic (increase of at least 50% in AUC plasma concentrations)	Amiodarone Dronedarone Ketoconazole Quinidine Ticagrelor Verapamil	Clarithromycin Itraconazole Ketoconazole Posaconazole Voriconazole Ritonavir	Itraconazole Ketoconazole Posaconazole Voriconazole Ritonavir	No dose reduction for P-gp inhibitors
Pharmacokinetic (decrease of at least 50% in AUC plasma concentrations)	Carbamazepine Rifampin St. John's wort	Carbamazepine Rifampin St. John's wort Phenobarbital Phenytoin	Carbamazepine Rifampin St. John's wort Phenytoin	Rifampin
Pharmacodynamic (increased risk of bleeding)	Aspirin NSAIDs Other antiplatelets (e.g., cilostazol, vorapaxar, dipyridamole) Other anticoagulants Thrombolytics			

Disadvantages of DOACs compared to warfarin include lack of a specific antidote for reversal of apixaban, edoxaban and rivaroxaban, a higher acquisition cost, and potentially a faster offset of action so that adherence is key to a sustained effect.

Determining a patient's past history of medication compliance is also recommended because dabigatran and apixaban require twice-daily dosing, and anticoagulant efficacy will be decreased if a patient misses one dose. Dabigatran cannot be crushed or put in weekly pillboxes to help with compliance because it is packaged in moisture-proof containers. Rivaroxaban must be taken with a meal to improve bioavailability. The dosing of rivaroxaban and apixaban for the treatment of NVAF and VTE differs (Tables 50.6 and 50.7). Apixaban has the least dependency on renal clearance, and edoxaban has the fewest labeled drug–drug interactions (Table 50.5). Edoxaban has a black box warning for stroke prevention in NVAF to avoid use in patients with CrCl >95 mL/min due to reduced efficacy for ischemic stroke. Reduced efficacy was not proportional to CrCl and was not apparent in the primary endpoint of stroke or systemic thromboembolism.

TABLE 50.6 Dosing and Renal Adjustment for DOACs for Stroke and Systemic Thromboembolism Prevention in Nonvalvular AF

	Dabigatran	Rivaroxaban*	Apixaban	Edoxaban
SPAF	150 mg bid	20 mg once daily	5 mg bid	60 mg once daily if CrCl 51–95 mL/min
Renal adjustment	75 mg bid if CrCl 15–30 mL/min No dosing recommendation if CrCl <15 mL/min	15 mg daily if CrCl 15–50 mL/min Avoid use if CrCl < 15 mL/min	2.5 mg bid if 2 of the following 3 are present: SCr ≥1.5 mg/dL, age ≥80 years or weight ≤60 kg*	Do not use if CrCl > 95 mL/min 30 mg once daily if CrCl 15–50 mL/min

NOTE: the 2014 AHA/ACC/HRS AF Guidelines note that warfarin is preferred for patients with CrCl <15 mL/min and NOACs are not recommended.

*For NVAF patients with end-stage renal disease, the recommended dose is 5 mg twice daily; reduce dose to 2.5 mg twice daily if one of the following patient characteristics (age ≥ 80 years or body weight ≤60 kg) is present; patients with ESRD with or without dialysis were not studied in clinical efficacy and safety studies; therefore, the dosing recommendations for patients with NVAF are based on pharmacokinetic and pharmacodynamic data in subjects maintained on dialysis.

SPAF, Stroke Prevention in Atrial Fibrillation; CrCl, creatinine clearance; *, taken with a meal.

1. Pradaxa (dabigatran etexilate mesylate) [prescribing information]. Ridgefield, CT: Boehringer Ingelheim Pharmaceuticals Inc.; 01/2015. 2. Xarelto (rivaroxaban) [prescribing information]. Titusville, NJ: Janssen Pharmaceuticals, Inc.; 01/2015. 3. Eliquis (apixaban) [prescribing information]. Princeton, NJ: Bristol-Myers Squibb Company; 6/2015. 4. Savaysa (edoxaban) [prescribing information]. Parsippany, NJ: Daiichi Sankyo, Inc; 01/2015.

TABLE 50.7 Dosing and Renal Adjustment for DOACs for VTE Treatment and Secondary Prevention of VTE

	Dabigatran	Rivaroxaban	Apixaban	Edoxaban
VTE Treatment				
VTE	150 mg bid (after parenteral therapy)	15 mg bid for 21 days, then 20 mg daily for months	10 mg bid for 7 days, then 5 mg bid	Following parenteral therapy, 50 mg once daily when weight is > 60 kg; 30 mg once daily if ≤ 60 kg
Renal Adjustment	No dosage recommendation if CrCl ≤ 30 mL/min	Avoid use if CrCl <30 mL/min	No adjustment required	30 mg once daily if CrCl ≤15–50 mL/min
VTE Secondary Prevention				
Long-term Secondary Prevention	150 mg bid	20 mg daily	2.5 mg bid	Not approved for this indication
Renal Adjustment	No dosage recommendations for CrCl ≤ 30 mL/min	Avoid use if CrCl < 30 mL/min	No adjustment required	Not approved for this indication

VTE, venous thromboembolism; CrCl, creatinine clearance.

1. Pradaxa (dabigatran etexilate mesylate) [prescribing information]. Ridgefield, CT: Boehringer Ingelheim Pharmaceuticals Inc.; 01/2015. 2. Xarelto (rivaroxaban) [prescribing information]. Titusville, NJ: Janssen Pharmaceuticals, Inc.; 01/2015. 3. Eliquis (apixaban) [prescribing information]. Princeton, NJ: Bristol-Myers Squibb Company; 6/2015. 4. Savaysa (edoxaban) [prescribing information]. Parsippany, NJ: Daiichi Sankyo, Inc; 01/2015.

In a patient transitioning from warfarin to a DOAC, warfarin should be discontinued and the DOAC should be started when the INR is at the lower end of the warfarin therapeutic range. In a patient transitioning from UFH to a DOAC, discontinue UFH at the time that the DOAC is administered. In a patient transitioning from LMWH to a DOAC, discontinue the LMWH and administer the DOAC at the time of the next scheduled LMWH dose. When switching between DOACs, give the first dose of the new DOAC at the time the previous DOAC scheduled dose was due.

Anticoagulants: Patient Education

Patient education is essential because patients must comply with laboratory follow-up and accurately follow dosing instructions. An assessment of any contraindications to therapy, including active bleeding and pregnancy, is necessary before starting therapy. The risk of bleeding may exceed the benefits of taking warfarin in patients with a previous history of medication nonadherence, falls, significant alcohol consumption, memory impairment, and lack of adequate support from family members or caregivers. Patients and caregivers must agree with the decision to initiate therapy (Witt, 2010). Common elements of anticoagulation patient education are described in Box 50.5.

BOX 50.5 Elements of Anticoagulation Patient Education

- Indicate the reason for initiating anticoagulation therapy and how it relates to clot formation.
- Review the name of anticoagulant drug(s) (generic and trade) and discuss how they work to reduce the risk of clotting complications.
- Discuss the potential duration of therapy.
- Describe the common signs/symptoms of bleeding and what to do if they occur.
- Describe the common signs/symptoms of clotting complications and what to do if they occur.
- Outline precautionary measures to minimize the risk of trauma or bleeding.
- Discuss potential drug interactions (prescription and in addition for warfarin over the counter, herbal) and what to do when normal medication regimens change.
- Clarify whether or not the patient may take concomitant low-dose aspirin and other NSAIDs.
- Discuss the need to avoid or limit alcohol consumption.
- Explain the need for birth control measures for women of childbearing age.
- Review the importance of notifying all health-care providers (e.g., physicians, dentist) of the use of anticoagulation therapy.
- Review the importance of notifying the anticoagulation provider when dental, surgical, or invasive procedures and hospitalization are scheduled.
- Explain when to take anticoagulant mediations and what to do if a dose is missed.
- Discuss the importance of carrying identification (ID card, medical alert bracelet/necklace).
- Document in the patient's medical record that the patient education session occurred.

For warfarin:

- Explain the meaning and significance of the INR.

Explain the need for frequent INR testing and target INR values appropriate for the patient's treatment.

Identify the laboratory location where the patient will go for the INR test and the date and time of the next test.

Identify the prescriber who will interpret the INR and the method of communicating those changes to the patient.

Discuss the narrow therapeutic index of warfarin and emphasize the importance of regular monitoring as a way to minimize the risk of bleeding/thrombosis.

Discuss the influence of dietary vitamin K use on the effects of VKA.

For rivaroxaban, apixaban, and edoxaban:

Explain the importance of periodic serum creatinine laboratory tests to monitor renal function.

Identify the prescriber or their designee as the individual to contact regarding questions, bleeding, and refills.

Review the date, time, and location of the patient's next follow-up appointment.

For rivaroxaban

Explain that the dose should be taken with a large meal.

For dabigatran:

Explain that the capsule cannot be crushed and cannot be removed from the original packaging.

Adapted from: Garcia, D. A., Witt, D. M., Hylek, E., et al. (2008). Delivery of optimized anticoagulant therapy: Consensus statement from the anticoagulation forum. *Annals of Pharmacotherapy*, 42, 979–988.

Education concerning food restrictions for patients taking warfarin is essential. Vitamin K_1, the antidote to warfarin, is naturally found in several plant foods. In contrast, vitamin K_2 is primarily synthesized by normal intestinal flora. The estimated necessary dietary intake of vitamin K_1 is 80 μg/d for men older than age 25 and 65 μg/d for women older than age 25. In the United States, typical American dietary vitamin K_1 intake is 300 to 500 μg (Suttie, 1992). Excessive amounts of dietary vitamin K_1 may antagonize warfarin's clinical effect and decrease the INR. Khan and coworkers (2004) found that for every 100-μg increase in vitamin K_1 intake in the 4 days before an INR measurement, the INR fell by 0.2. In another study, it was found that higher warfarin doses at 5.7 ± 1.7 mg/d were needed by those consuming 250 μg or more of vitamin K daily compared to that of 3.5 ± 1.0 mg/d by those consuming less than 250 μg of vitamin K daily (Khan et al., 2004).

Dark green leafy vegetables (spinach and turnip, collard, and mustard greens), broccoli, Brussels sprouts, and cabbage are the primary sources of vitamin K and contain high amounts, greater than 100 mg/100-g serving. Herbal and green teas may also contain large

quantities of vitamin K_1 (1,400 mg/100 g), and high levels of vitamin K_1 (50 mg/100 g) are found in soybean and soy products and olive oils, whereas peanut and corn oils contain minimal amounts. Vitamin K is also found in certain plant oils and prepared foods containing these oils, such as baked goods, margarine, and salad dressings. Food preparation with oils rich in vitamin K may also contribute to total vitamin K intake and affect warfarin action. The *Coumadin Cookbook* (available from amazon.com) is a great resource for patients taking warfarin because it provides tips for monitoring and maintaining a consistent vitamin K intake and provides many recipes with a low vitamin K content. Patients should be encouraged to eat a healthy diet, maintain consistency in their choice of foods, and avoid large fluctuations in dietary vitamin K_1 intake. Instructing patients to maintain a consistent intake of vitamin K–containing foods, rather than trying to eliminate all sources of dietary vitamin K_1, is essential. Patients must also be educated on portion sizes and their vitamin K content so that they are not only consistent with the frequency of intake of vitamin K foods but also consistent with the number of servings of vitamin K they consume. Fad diets, such as the "cabbage soup" diet, are discouraged, and if diets such as the Atkins diet or low-carbohydrate diets are to be started, the patient must notify the practitioner so that INRs can be monitored more often. These diets, when strictly followed, frequently lead to a change in the intake amount of vitamin K foods. Table 50.8 lists examples of vitamin K food content and serving sizes.

TABLE 50.8 Vitamin K Content of Common Foods

Description	Weight (g)	Common Measure	Vitamin K per Measure (mcg)
Asparagus, frozen, cooked, boiled, drained, without salt	180	1 cup	144
Beans, snap, green, canned, regular pack, drained solids	135	1 cup	53
Beet greens, cooked, boiled, drained, without salt	144	1 cup	697
Broccoli, cooked, boiled, drained, without salt	156	1 cup	220
Broccoli, raw	88	1 cup	89
Broccoli, cooked, boiled, drained, without salt	37	1 spear	52
Broccoli, frozen, chopped, cooked, boiled, drained, without salt	184	1 cup	162
Brussels sprouts, frozen, cooked, boiled, drained, without salt	155	1 cup	300
Brussels sprouts, cooked, boiled, drained, without salt	156	1 cup	219
Cabbage, raw	70	1 cup	53
Cabbage, cooked, boiled, drained, without salt	150	1 cup	163
Cabbage, Chinese (pak choi), cooked, boiled, drained, without salt	170	1 cup	58
Celery, cooked, boiled, drained, without salt	150	1 cup	57
Collards, frozen, chopped, cooked, boiled, drained, without salt	170	1 cup	1,059
Collards, cooked, boiled, drained, without salt	190	1 cup	836
Cowpeas (blackeyes), immature seeds, frozen, cooked, boiled, drained, without salt	170	1 cup	63
Cucumber, with peel, raw	301	1 large	49
Dandelion greens, cooked, boiled, drained, without salt	105	1 cup	579
Endive, raw	50	1 cup	116
Kale, frozen, cooked, boiled, drained, without salt	130	1 cup	1,147
Kale, cooked, boiled, drained, without salt	130	1 cup	1,062
Lettuce, iceberg (includes crisphead types), raw	539	1 head	130
Lettuce, green leaf, raw	56	1 cup	71
Lettuce, cos or romaine, raw	56	1 cup	57
Lettuce, butterhead (includes boston and bibb types), raw	163	1 head	167
Mustard greens, cooked, boiled, drained, without salt	140	1 cup	419
Onions, spring or scallions (includes tops and bulb), raw	100	1 cup	207
Okra, cooked, boiled, drained, without salt	160	1 cup	64
Okra, frozen, cooked, boiled, drained, without salt	184	1 cup	88
Parsley, fresh	10	10 sprigs	164
Peas, green (includes baby and lesuer types), canned, drained solids, unprepared	170	1 cup	63
Peas, edible-podded, frozen, cooked, boiled, drained, without salt	160	1 cup	48
Plums, dried (prunes), stewed, without added sugar	248	1 cup	65
Rhubarb, frozen, cooked, with sugar	240	1 cup	51
Spinach, frozen, chopped or leaf, cooked, boiled, drained, without salt	190	1 cup	1,027
Spinach, canned, regular pack, drained solids	214	1 cup	988
Spinach, cooked, boiled, drained, without salt	180	1 cup	888
Spinach souffle	136	1 cup	172
Spinach, raw	30	1 cup	145
Turnip greens, frozen, cooked, boiled, drained, without salt	164	1 cup	851
Turnip greens, cooked, boiled, drained, without salt	144	1 cup	529
Pie crust, cookie type, prepared from recipe, graham cracker, baked	239	1 pie shell	59
Noodles, egg, spinach, cooked, enriched	160	1 cup	162
Fast foods, coleslaw	99	3/4 cup	70
Bread crumbs, dry, grated, seasoned	120	1 cup	55

Adapted with permission from INRTracker: http://inrtracker.com/articles/diet/vitamin-k-foods

Hidden sources of excess vitamin K include enteral supplements, which can cause resistance to warfarin. Checking the amount of vitamin K in any nutritional supplement is advised because several of these preparations are now marketed directly to patients through the lay press. In addition, many OTC vitamin preparations contain vitamin K, and patients should be counseled to read the label or bring in all medication bottles to the practitioner. For example, one Viactiv calcium chew contains 40 mcg of vitamin K; this translates to 80 mcg of vitamin K daily if the recommended dose of two chews is ingested. Questioning patients regarding any changes in dietary habits may provide clues when the INR varies.

Managing Anticoagulation-Related Bleeding

Bleeding is the most worrisome adverse event associated with antithrombotic therapy. In patients with AF, the annual risk of major bleeding is approximately 2% to 3% with DOACs and 3% to 4% with warfarin with fatal bleeding occurring in up to 0.5% (Kovacs et al., 2015; Werth et al., 2015). In patients with VTE, the annual risk of major bleeding for warfarin and DOACs is approximately 1% to 2% (Werth et al., 2015). The highest risk of bleeding with warfarin, especially intracranial hemorrhage, occurs when the INR exceeds a 4 to 5 range. The frequency of major bleeding in patients with a target INR of 2 to 3 is half of that seen in patients with a target INR above 3. One of the greatest advantages of DOACs over warfarin for SPAF is that they reduce the risk of intracranial hemorrhage by more than 50% (Werth et al., 2015).

In addition to the intensity of anticoagulation, the other major factors that determine bleeding risk include individual patient characteristics such as elderly age, chronic kidney disease, liver disease, a prior history of stroke (for patients with AF), a labile INR (for patient taking warfarin), anemia, malignancy, uncontrolled HTN (for patients with AF), ethanol use, concomitant antiplatelets (such as aspirin, other NSAIDs, P2Y12 inhibitors such as clopidogrel, prasugrel, and ticagrelor) and concomitant use of selective serotonin reuptake inhibitors (such as sertraline, fluoxetine, and citalopram), ethanol intake, as well as a longer duration of therapy (Schulman et al., 2008). The greatest risk of bleeding occurs within the first months of therapy (Ansell et al., 2008). Coadministration of aspirin plus an anticoagulant increases a patient's bleed risk by about 50%, and therefore, indications for concomitant antiplatelet therapy should be scrutinized carefully (Goodman et al., 2014; Held et al., 2015; Lauffenburger et al., 2015).

Minor bleeding is defined as that which is self-terminating and does not require hospitalization or an office visit or treatment by a health-care provider. Clinically relevant nonmajor bleeding is defined as overt bleeding that does not meet the criteria for major bleeding but does require either hospitalization and prompt physician-guided medical or surgical care or change in antithrombotic therapy. Major bleeding involves bleeding into a major organ, intracranial or epidural bleeding, and pericardial, intraocular, retroperitoneal, intra-articular, or intramuscular with compartment syndrome bleeding. Bleeding that is overt with a 2 g/dL drop in hemoglobin, or requires transfusion of at least 2 units, or requires surgical correction or administration of intravenous vasoactive agents, is also described as major bleeding (Kovacs et al., 2015).

Common locations of antithrombotic bleeding include the oral or nasal mucosa, urine, stool, or soft tissues. Bleeding complications in order of frequency are epistaxis, purpura, hematuria, GI bleeding, and hemoptysis (Jacobs, 2008). Women are more likely to experience minor bleeding than men (Schulman et al., 2008). Minor bleeding is usually

managed by temporarily discontinuing warfarin therapy for 1 to 2 days and then restarting warfarin at a reduced dosage or reducing the target INR range.

Patients with a history of falling are commonly thought to have an increased risk of intracranial hemorrhage. One researcher evaluated the risk of elderly patients falling and subsequent development of a subdural hematoma, compared to the benefits of warfarin for stroke prevention in AF. Their conclusion was the risk of stroke if the patient did not receive warfarin (5% per year) was much larger than the risk of developing a subdural hematoma (0.0004 per patient-year). An elderly patient with AF would need to fall 300 times a year for the risk of subdural hematoma to outweigh the benefits of warfarin therapy (Man-Son-Hing et al., 1999).

Management of Warfarin-Associated Bleeding

When the INR is elevated, management depends on the patient's potential risk of bleeding, whether the patient is actively bleeding, and the INR level. Treatment options include simply omitting one or more warfarin doses with more frequent INR testing or administering vitamin K. In the inpatient setting, administering prothrombin concentrates can also be considered. Management of major bleeding focuses on reversing the anticoagulation effects of warfarin, which include administration of either intravenous or oral vitamin K with or without clotting factor replacement. The 2012 ACCP Guidelines for VKA reversal according to INR and presence or absence of bleeding are described in Box 50.6. Currently, administration of four factor prothrombin complex concentrates is recommended over fresh frozen plasma for warfarin reversal because of a more rapid and complete effect with similar incidence of thromboembolic events (Goldstein et al., 2015). Any bleeding event should be adequately investigated because an underlying comorbidity, such as malignancy, may be the cause.

BOX 50.6 2012 ACCP Guidelines for Reversing the Anticoagulant Effects of VKAs

The reason for bleeding should be evaluated. Consider discontinuing or holding 1–2 doses of VKA. Stop concomitant medications that predispose to bleeding as appropriate (e.g., aspirin). Consider restarting with a lower maintenance dose and monitor the INR more frequently.

INRs 4.5 to 10 and No Evidence of Bleeding. No Administration of Vitamin K

For patients with INRs above 4.5 but less than or equal to 10 who are not experiencing significant bleeding, omitting the next one to two doses, monitoring the INR more frequently, and resuming therapy at a lower dose is one approach.

INRs > 10

Patients with INRs above 10 who are not experiencing significant bleeding should have their warfarin held and receive oral vitamin K (2.5 to 5 mg). The INR will fall substantially in 24 to 48 hours. Frequent INR checks are necessary, and additional doses of oral vitamin K can be given if the INR is still elevated. Once the INR falls within the target range, warfarin can be resumed at a lower dose.

Significant Bleeding

Patients experiencing significant bleeding, regardless of how high the INR is elevated, or patients with life-threatening bleeding need immediate reversal of the INR and should have their warfarin temporarily discontinued; administration of four-factor prothrombin complex concentrate should be administered (e.g., KCentra; see dosing information based on INR at Kcentra.com), as well as intravenous vitamin K 5–10 mg should be administered via slow intravenous (IV) infusion over 1 hour. Depending on the INR, repeat doses of vitamin K can be given every 12 hours.

Recommendations from Holbrook, A., Schulman, S., Witt, D. M., et al. (2012). Evidence-based management of anticoagulant therapy: Antithrombotic therapy and prevention of thrombosis. American College of Chest Physicians Evidence-Based Clinical Practice Guidelines (9th ed.) *Chest*, 141(2 Suppl.), e152S–e184S.

Management of DOAC-Associated Bleeding

Currently, there are no available antidotes for apixaban-, edoxaban- or rivaroxaban-associated bleeding. Idarucizumab, a humanized monoclonal antibody fragment against dabigatran was recently approved in October 2015, and andexanet alpha, a recombinant inactive factor Xa derivative against factor Xa inhibitors including apixaban, edoxaban, rivaroxaban, and LMWHs (Gomez-Outes et al., 2014; Pollack et al., 2015) is anticipated to be available in late 2016.

For minor bleeding, the bleeding site should be manually compressed. Rarely should a dose be held given the short half-life and risk of thromboembolic event. The situations should be evaluated to determine whether or not the DOAC should be continued, dose adjusted, or changed to a different DOAC or warfarin.

For major bleeding, the DOAC should be discontinued and manual or mechanical compression of the bleeding site should be performed. If the last administered dose was within 3 hours, administer activated charcoal. For dabigatran, administer idarucizumab 5 g by rapid IV bolus or infusion. In patients with chronic kidney disease or acute kidney injury, the DOAC half-life may be prolonged and the patient should be monitored for a longer period of time. In the absence of a direct-acting antidote and clinical trials, experts have advocated discontinuation and administration of four-factor prothrombin complex concentrate to treat major bleeding associated with apixaban, rivaroxaban, and edoxaban (Nutescu et al., 2013). Administration of recombinant factor VIIa is reserved for serious bleeding with either warfarin apixaban, edoxaban, or rivaroxaban when other hemostatic products fail (Nutescu et al., 2013).

Management of Unfractionated Heparin-Associated Bleeding

Excessive anticoagulation with UFH can be reversed with IV protamine sulfate, which is high in arginine and is cationic binding tightly to heparin, which is highly anionic, thus reversing the anticoagulant effect (Hirsh et al., 2008). Unfortunately, protamine has other undesirable effects in some patients, including immediate and delayed allergic response.

Management of LMWH-Associated Bleeding

There is no proven method for reversing excessive anticoagulation occurring with LMWHs, although consensus guidelines provide dosing recommendations for using protamine and it has been found useful in some, but not all, coagulopathic patients (Van Veen et al., 2011).

Other Anticoagulant Adverse Effects

Heparin-Induced Thrombocytopenia

Platelet counts should be closely monitored during UFH and LMWH therapy because a drop in platelet count below 150×10^9/L or greater than 50% of baseline necessitates an evaluation for HIT, antibody-mediated prothrombotic reaction. This immune-mediated thrombocytopenia, HIT, has been reported in less than 1% of patients. The incidence of thrombocytopenia is much lower with LMWH than with UFH. Clinical effects of HIT can result in DVT, PE, MI, limb ischemia, gangrene requiring limb amputation, cerebral thrombosis, and death. Suspected HIT should be evaluated using the "4Ts" score: thrombocytopenia, Timing, Thrombosis, and oTher where scores above three require that all sources of heparin or LMWH such as heparin flushes and heparin-coated catheters, infusions, and injections are required for platelet counts to normalize. In patients in which HIT is strongly suspected or confirmed, an alternative anticoagulant such as an intravenously administered direct thrombin inhibitor (argatroban and bivalirudin) should be administered. The diagnosis is confirmed using an ELISA antibody test (sensitive but not specific for HIT) and/or the heparin antibody serotonin release assay. The patient should be carefully monitored for the development of thrombosis, and argatroban is administered until platelet counts are above 150×10^9/L (Warkentin, 2010).

Antiplatelet Agents

Clinical Uses

Antiplatelet agents that have been used in the prevention and treatment of ischemic stroke are aspirin, aspirin/dipyridamole (Aggrenox), and the P2Y12 inhibitor clopidogrel (Plavix). Aspirin has been studied in primary and secondary prevention of VTE. Aspirin has been studied as a sole therapy for stroke prevention in patients with bioprosthetic heart valves and as add-on therapy to warfarin for stroke prevention in patients with mechanical heart valves. Aspirin has been shown to be inferior to warfarin and apixaban for SPAF. Two other P2Y12 inhibitors, prasugrel (Effient) and ticagrelor (Brilinta), as well as clopidogrel are used to prevent CV death, MI, or stroke following acute coronary syndrome and to prevent stent thrombosis following percutaneous coronary intervention. The use of P2Y12 inhibitors for secondary coronary heart disease indications will not be discussed in this chapter.

Mechanism of Action, Dosing, and Adverse Effects of Antiplatelets

Aspirin

Aspirin prevents prostaglandin synthesis in platelets and other tissues by irreversibly modifying and inhibiting the enzyme COX, which catalyzes the conversion of arachidonic acid to thromboxane A_2, a prostaglandin derivative, which is a potent vasoconstrictor and promoter of platelet aggregation. The onset of antiplatelet effects is within 5 min of oral administration. After discontinuing aspirin, platelets are impaired for their normal life span of 7 to 10 days because of the irreversible inhibition of COX. Every 24 hours, 10% of platelets are replaced; 5 to 6 days after aspirin ingestion, approximately 50% of platelets function normally (Patrono et al., 2008).

The optimal aspirin dosage for thrombotic disorders is still controversial because doses ranging from 30 to 1,500 mg/d are effective (Adams et al., 2008; Albers et al., 2008). Inhibition of platelet aggregation can be shown at doses as low as 20 mg/d given over several days. Randomized trials have found lower aspirin doses ranging between 50 and 100 mg/d effective as an antithrombotic agent (Patrono et al., 2008). There is no benefit to higher doses over low-dose aspirin for CVD prevention. Because higher doses may be associated with increased risk for GI bleeding, a lower dose, such as 81 mg orally daily, is preferred (Antiplatelet Trialists' Collaboration, 2009).

Aspirin's contraindications are active GI bleeding (unless a recent coronary stent has been placed) or aspirin allergy or hypersensitivity. The most common adverse effects of aspirin are GI upset, such as nausea, dyspepsia, heartburn, epigastric discomfort, anorexia, and bleeding. These effects are dose related and are more likely to occur at doses greater than 325 mg/d. Although lower aspirin doses cause fewer GI symptoms, they still can cause significant GI bleeding. Aspirin may also potentiate peptic ulcer disease. Caution should be exercised when using aspirin with other drugs that affect platelet function (e.g., NSAIDs, P2Y12 inhibitors, and SSRI antidepressants) or anticoagulants because the bleeding potential will be increased.

Aspirin/Dipyridamole

A combination product containing 25-mg aspirin and 200-mg extended-release dipyridamole (Aggrenox) administered twice daily is available for preventing recurrent stroke in patients who have experienced a TIA or previous ischemic stroke. Dipyridamole inhibits platelet adhesion, but its full mechanism of action is unknown. A European trial conducted in 6,000 patients (ESPS2) was the basis for FDA approval of this agent. Efficacy was also confirmed in a second trial (ESPRIT). The most common adverse effects include GI complaints, diarrhea, and headache. Elevations in hepatic enzymes have also been reported. Contraindications for aspirin with dipyridamole include hypersensitivity or

allergy to aspirin or NSAIDs and active peptic ulcer disease.

Clopidogrel

Clopidogrel inhibits adenosine diphosphate (ADP), a promoter of platelet receptor binding (Patrono et al., 2008). A clopidogrel dose of 75 mg/d irreversibly inhibits ADP-mediated platelet aggregation. Dose-dependent inhibition of platelet aggregation is seen 2 hours after a single oral dose with a peak effect about 6 hours after the dose, and platelet aggregation and bleeding time return to baseline approximately 7 days after discontinuing clopidogrel.

Clopidogrel is a prodrug and must be activated (biotransformed) to inhibit platelet aggregation. Clopidogrel is extensively metabolized by the liver primarily by CYP2C19, and moderate or stroke CYP2C19 inhibitors, such as omeprazole, decrease the antiplatelet effect of clopidogrel. Patients vary in their ability to biotransform clopidogrel because the activity of CYP2C19 is controlled genetically. An early communication from the FDA in January 2009 acknowledged that clopidogrel was less effective in some patients and that genetic differences in drug metabolism likely accounted for the reduced effectiveness. Another mechanism for reduced clopidogrel activity is via inhibition of CYP2C19 by interacting drugs. PPIs are frequently given with clopidogrel plus aspirin to protect against GI bleeding. Omeprazole is a strong inhibitor of CYP2C19 and reduces the conversion of clopidogrel to the active form. An FDA public health advisory in November 2009 recommended against using clopidogrel with both omeprazole and esomeprazole. Several retrospective reviews of pharmacy claims databases reported that patients receiving a PPI, most commonly omeprazole, with clopidogrel had reduced effectiveness of the antiplatelet drug, shown by an increase in cardiovascular events, including MI, hospitalization for acute coronary syndrome, and all-cause mortality (Abraham et al., 2010). Only one randomized trial has prospectively examined cardiovascular event rates in patients receiving clopidogrel 75 mg/d with omeprazole 20 mg/d (Bhatt et al., 2010). The study was terminated early due to the manufacturer going into bankruptcy, but an interim analysis showed no significant difference in the incidence of cardiovascular death, MI, or stroke in patients receiving clopidogrel with omeprazole compared to a placebo. The combination did protect against GI bleeding; the number of GI events was similar between a placebo and the antiplatelet/PPI combination. Limitations to the trial include that it was not powered to detect differences in cardiovascular events, and it was terminated early after a median duration of 133 days, which may not have been long enough to show a difference in outcomes. There is ongoing controversy regarding the clinical impact of this drug interaction. Current joint consensus from leading cardiology and gastroenterology groups is that PPIs are appropriate in patients with multiple risk factors for GI bleeding (e.g., history of ulcer disease or prior GI bleeding, dual antiplatelet therapy, concomitant anticoagulant therapy, advanced age) who require antiplatelet therapy (Abraham et al., 2010).

Bruising and bleeding are the primary risks of clopidogrel therapy, and the risk is increased in the setting of dual antiplatelet therapy with aspirin. In the CAPRIE trial, there was no major difference between clopidogrel and aspirin monotherapy in terms of safety,

although there was a slightly higher rate of serious hemorrhage in the patients receiving aspirin. Clopidogrel is considered to have a safety profile similar to that of 325 mg/d dose of aspirin (Patrono et al., 2008). Contraindications to clopidogrel are active major bleeding, including from peptic ulcer or intracranial hemorrhage. Diarrhea is relatively common, occurring in approximately 5%. Rash and thrombotic thrombocytopenic purpura are rare adverse effects of clopidogrel.

Selecting the Most Appropriate Agent

Treatment of Deep Vein Thrombosis or Pulmonary Embolism

Treatment options for VTE are shown in Table 50.9. All patients with a diagnostically confirmed DVT of the proximal leg veins or diagnostically confirmed PE should receive a bolus of IV UFH followed by a continuous IV infusion of UFH, subcutaneous LMWHs, and oral rivaroxaban or oral apixaban as initial therapy. Injectable UFH/LMWH is followed by warfarin, apixaban, dabigatran, edoxaban, or rivaroxaban for at least 3 months. A decision on duration of therapy for treating DVT or PE depends on whether or not the VTE event was considered to be caused by a reversible risk factor ("provoked") or when no reversible risk factor can be identified ("unprovoked"). For patients with a provoked DVT, the recurrence rate is less than 5% at year 1 and less than 15% at 5 years. A 3-month course of warfarin is sufficient in patients with reversible risk factors, if the provoking risk factor has resolved. Patients with idiopathic VTE are more likely to experience recurrent DVT than provoked events (10% recurrence rate at 1 year and 30% recurrence rate at 5 years); extended warfarin therapy is recommended (Kearon et al., 2008). Provoked VTEs are treated for 3 months and unprovoked VTEs for a minimum of 3 months and often longer than 12 months depending on patient tolerability, continued presence of the clot on ultrasound or CT, or continued elevation of D-dimer measured 3 months off anticoagulation (and then anticoagulation may resume) (Wells et al., 2014). If warfarin is selected, it should be overlapped with UFH or LMWHs for approximately 4 to 5 days while warfarin reaches a therapeutic level (Kearon et al., 2008).

TABLE 50.9 Treatment options for VTE

Agent	Initial Dosing or Lead In	Maintenance Dosing
Preferred for Renal Insufficiency (<30 mL/min)		
UFH[1]	Weight-based bolus followed by weight-based continuous infusion Fixed subcutaneous: 333 U/kg followed by 250 U/kg bid	
Ideal for Normal Renal Clearance		
LMWH[1]	**Dalteparin:** 200 IU/kg every 24 h or 100 IU/kg bid **Enoxaparin:** 1 mg/kg bid or 1.5 mg/kg every 24 h **Nadroparin:** 86 IU/kg bid or 171 IU/kg every 24 h **Tinzaparin:** 175 IU/kg every 24 h	
Warfarin	Bridge with LMWH or UFH ≥5 d 0.5–10 mg/d	• 0.5–6 mg/d, individualized to INR 2.0–3.0
Apixaban	10 mg bid for 7 d ***Coadministration with strong dual CYP3A4 and P-gp inhibitors:*** For patients receiving apixaban >2.5 mg bid, reduce the dose by 50% when apixaban is coadministered with drugs that are strong dual inhibitors of cytochrome P450 3A4 (CYP3A4) and P-glycoprotein (P-gp) (e.g., ketoconazole, itraconazole, ritonavir, clarithromycin)	• 5 mg bid • 2.5 mg bid for secondary prevention
Dabigatran	5–10 d parenteral anticoagulant	• 150 mg bid (CrCL >30 mL/min)
Edoxaban	5–10 d parenteral anticoagulant	• 60 mg/d • 30 mg/d (CrCL 15–50 mL/min, ≤60 kg, or with some P-gp inhibitors)
Rivaroxaban	15 mg bid for 21 d with food	• 20 mg/d with food (CrCL >30 mL/min)

[1]Bridged to a DOAC or warfarin.

In clinical trials, DOACs have similar efficacy and reduced bleeding compared to warfarin for treatment of VTE (van der Hulle et al., 2014). One area that requires further study is the use of DOACs for treating VTE associated with malignancy, and at this time, LMWH remains the preferred agent (Streiff, 2010; Vedovati et al., 2015).

Nondrug Therapy

An inferior vena cava (IVC) filter or umbrella filter (Greenfield filter) is inserted percutaneously into the IVC and traps thrombi in the leg veins to prevent migration to the lungs (Anderson & Bussey, 2006). IVC filter placement is recommended in patients with proximal DVT or PE in which anticoagulants are contraindicated due to the risk of bleeding. However, the routine use of IVC filters in addition to anticoagulation is not recommended for patients with DVT or PE. If the patient's bleeding risk resolves, a conventional course of anticoagulation should be initiated (Kearon et al., 2008). Vena cava filters have not been shown to decrease mortality. Complications of IVC filters include thrombosis, migration of the filter (rarely to the heart), and obstruction of the vena cava.

Prophylaxis of Deep Vein Thrombosis and Pulmonary

Patients undergoing total hip replacement (THR), total knee replacement (TKR), or hip fracture surgery should receive anticoagulation prophylaxis to reduce the high risk of DVT or PE. Several studies have found the prevalence of total DVT at 7 to 14 days after THR, TKR, and hip fracture surgery to be approximately 50% to 60%. The incidence of PE is less certain, but in studies in which a V/Q scan was performed, about 7% to 11% of THR and TKR patients had a high probability scan within 7 to 14 days after surgery. It has also been found that total DVT rate is greater in TKR than THR. Overall, the data suggest that asymptomatic VTE is common after orthopedic surgery and, in the absence of prophylaxis, will affect at least half of these patients (Geerts et al., 2008). Numerous pharmacologic and nonpharmacologic agents have been used in the postoperative setting to decrease the risk of DVT or PE. According to the ACCP 2012 guidelines, effective drugs for prophylaxis of VTE following orthopedic surgery include LMWHs (example enoxaparin 40 mg subcutaneous daily), fondaparinux, warfarin, apixaban (2.5 mg twice daily), rivaroxaban (10 mg daily), and aspirin (Falck-Ytter et al., 2012) Recently, dabigatran at an initial dose of 110 mg on day 1 followed by 220 mg daily was FDA-approved for VTE prophylaxis following orthopedic surgery.

For the hospitalized medical patient, LMWH, fondaparinux, or UFH is considered efficacious (Kahn et al., 2012).

VTE prophylaxis is a Joint Commission Core Measure for hospitalized medical and surgical patients at risk (VTE-1), and the incidence of hospital-acquired potentially preventable VTE events is also reported for hospitals (http://www.jointcommission.org/venous_thromboembolism/). The proportion of patients undergoing surgery receiving VTE prophylaxis within 24 hours before to 24 hours after surgery is also a reported quality measure (SCIP-VTE-2) (https://manual.jointcommission.org/pub/Manual/MIF0061/SCIPVTE2).

Nondrug Therapy

Nondrug therapies help prevent or treat the complications of DVT, including venous stasis ulcers and the postthrombotic syndrome. Mechanical measures, including IPC devices and graduated compression stockings, offer the advantage of carrying no risk of bleeding compared to anticoagulants. IPC sleeves applied to the lower extremities periodically inflate and deflate, to squeeze the calf and prevent venous stasis and pooling of blood in the leg veins. Nonambulatory patients can have IPC devices applied to reduce the risk of VTE. Use of IPC alone is recommended in patients with a high risk of bleeding following general orthopedic or general surgery, until the bleeding risk resolves (Geerts et al., 2008).

Secondary Prevention of Noncardioembolic Ischemic Stroke and Transient Ischemic Attack

Pharmacotherapy for secondary prevention of stroke/TIA is described in the 2014 AHA/ASA guidelines (Kernan et al., 2014). Antiplatelet therapy reduces the relative risk of death, MI, or recurrent stroke by 22% (Kernan et al., 2014). These guidelines recommend treatment with either aspirin (50 to 325 mg/d) or aspirin plus dipyridamole (25 mg/200 mg twice daily) as first-line class I indications. Second-line class II agents are either clopidogrel monotherapy (75 mg daily) (class IIa) or clopidogrel plus aspirin (class IIb) combination therapy. If clopidogrel is combined with aspirin for stroke, it should be started within 24 hours poststroke and only continued for 90 days (CHANCE trial). If used later, the combination is associated with an increased risk of hemorrhagic stroke (Kernan et al., 2014).

Although not directly compared in a head-to-head trial, the efficacy of clopidogrel alone (CAPRIE trial) seems comparable to aspirin/dipyridamole (PRoFESS trial) and by inference aspirin (comparable to clopidogrel in CAPRIE). Because of cost, low-dose aspirin, 81 mg, is often preferred. Side effects may also influence drug selection with aspirin/dipyridamole associated with headache as well as GI intolerance. Aspirin plus clopidogrel may be preferred in patients with acute coronary syndrome or coronary artery stents (Kernan et al., 2014).

Stroke Prevention in Nonvalvular Atrial Fibrillation

Antithrombotic therapy for stroke prevention in NVAF is outlined in the 2014 AHA/ACC/HRS guidelines (January et al., 2014).

The risk of thromboembolic stroke in patients with NVAF should be estimated using the CHA_2DS_2-Vasc score. Patients with a CHA_2DS_2-Vasc Score of 0 have an annual stroke risk of less than 1% and do not require antithrombotic therapy for SPAF. There is controversy with respect to drug selection for patients with a CHA_2DS_2-Vasc Score of 1 who have an annual risk of 1 to 2%, and no therapy, aspirin (81 mg to 325 mg/d) or oral anticoagulation is recommended. Patients with a CHA_2DS_2-Vasc Score of 2 or greater have an annual risk of stroke of 2% to 15%, and anticoagulation is recommended (January et al., 2014). Either warfarin or a DOAC may be selected with warfarin preferred in patients with creatinine clearance less than 30 mL/min.

DOACs have been found to have superior or similar efficacy to warfarin for the prevention of stroke or systemic thromboembolism with similar or lower major bleeding and an approximate 50% reduction in intracranial hemorrhage (Chan et al., 2014; Ruff et al., 2014). Drug selection is often made by patient preference based upon cost (insurance copay) or convenience (dosing frequency, lack of INR monitoring).

Prophylaxis Against Systemic Embolism in Patients with Prosthetic Heart Valves

Antithrombotic therapy for patients with prosthetic heart valves is described in the 2014 AHA/ACC guideline for the management of patients with valvular heart disease (Nishimura et al., 2014). Long-term anticoagulation with warfarin alone or in combination with aspirin is required in patients with mechanical heart valves because the valve itself is thrombogenic and because of the high risk of thromboembolism (Sun et al., 2010). The rate of major thrombotic events in patients who have mechanical heart valves and who are not receiving anticoagulation is 8%; anticoagulation therapy decreases this risk by 75% (Carnetiger et al., 1995). Refer to the professional guidelines for information on anticoagulation in patients with native valvular disease (rheumatic mitral valve disease, mitral stenosis) and other conditions.

Both the position and type of the mechanical valve influence the risk of embolism. The prevalence of thromboembolism is higher with a valve in the mitral position than in the aortic position. Caged ball valves like the Starr–Edwards valves, which are rarely seen today, have the highest risk of thromboembolism, followed by tilting-disk valves (Bjork–Shiley valves) and then bileaflet valves (St. Jude Medical valves, which are most commonly used today, or Medtronic Hall valves). Patients with double mechanical valves (i.e., aortic and mitral valve replacement) have a higher risk of thromboembolism compared with those with only one prosthetic valve. The risk of thromboembolism is highest in the 3 months following valve replacement surgery, until the valve becomes covered with endothelial tissue. Immediately after surgery, LMWH or UFH is used short term until the INR with warfarin is therapeutic (Sun et al., 2010). Individual patient risk factors that increase the risk of embolic events include AF, previous thromboembolic event, impaired left ventricular systolic function, and concomitant hypercoagulable conditions.

Patients with mechanical valves in the (1) mitral position or (2) patients with aortic valves with additional risk factors such as AF, previous thromboembolism, left ventricular ejection fraction less than 40%, as well as those with older caged ball valves require lifelong therapy with warfarin maintained at a target INR of 2.5 to 3.5 (target INR 3.0). A lower INR of 2 to 3 (target 2.5) is recommended for patients with mechanical bileaflet or Medtronic Hall valves in the aortic position because studies show there is not an increased risk of thromboembolism and the bleeding risk is lower than with a higher target INR (Nishimura et al., 2014).

With warfarin therapy, the risk of thromboembolism is still 1% to 2% per year. Therefore, adding 100 mg/d of aspirin to warfarin therapy is recommended and has been shown to reduce mortality and thromboembolic events without increasing the risk of major bleeding (Nishimura et al., 2014).

For bioprosthetic (e.g., porcine heart valves), warfarin with an INR of 2 to 3 (target 2.5) for the first 3 months for aortic valves and an INR of 2.5 to 3.5 (target 3.0) for the

first 3 months following surgery is recommended. Only 3 months of anticoagulation is warranted because after that time frame, the risk of bleeding outweighs the risk of thrombosis. Aspirin monotherapy 75 to 100 mg/d is then recommended lifelong after the first 3 months regardless of the valve position (Nishimura et al., 2014). Following transaortic valve replacement (TAVR), 6 months of aspirin 81 mg/d plus clopidogrel 75 mg/d is recommended (Nishimura et al., 2014).

Patients with mechanical heart valves can experience thromboembolic events even if antithrombotic therapy is administered appropriately; the risk is 0.5% to 1.7%/patient-year. Options in these cases from expert consensus are to increase the target INR for patients on warfarin, to add aspirin to patients not already receiving warfarin, or to add warfarin if the patient is receiving aspirin (Sun et al., 2010).

Dabigatran has been shown to be less effective than warfarin for patients with mechanical heart valves, and therefore, at this time, DOACs are not recommended for use in patients with mechanical heart valves (Eikelboom et al., 2013; Nishimura et al., 2014). Few patients with AF and bioprosthetic heart valves have been included in clinical trials at this time. Product prescribing information for dabigatran, apixaban, and rivaroxaban recommends against their use, while no recommendation is made for edoxaban.

Case Study*

D.G. is a 74-year-old woman who arrives at the emergency room complaining of shortness of breath, palpitations (for 2 days), and lower extremity edema. Her medical history includes diabetes mellitus, hypertension, heart failure with reduced ejection fraction, and osteoarthritis. She had a left heart catheterization and coronary angiography last year and has no significant coronary artery disease. She has a biventricular pacemaker/implantable defibrillator for heart failure symptom treatment and sudden cardiac death prevention. The patient's current medications are losartan 100 mg/d, metoprolol succinate 50 mg/d, metformin 500 mg twice daily, spironolactone 25 mg/d, furosemide 40 mg/d, and naproxen 500 mg twice daily.

Vital signs are as follows: blood pressure of 140/80 mm Hg, respiratory rate of 30 bpm, and heart rate of 120 bpm. ECG shows atrial fibrillation with a rapid ventricular response. Echocardiography reveals a moderately dilated left atrium, left ventricular systolic ejection fraction of 35% (unchanged), chronic kidney disease (baseline serum creatinine 1.01 mg/dL), and moderate mitral regurgitation.

Pertinent laboratory values include the following: hemoglobin 12 g/dL, hematocrit 36%, platelets 300,000/microliter, and serum creatinine 1.20 mg/dL (estimated creatinine clearance 39 mL/min). Her weight is 60 kg (increased from 55 kg), and height is 5 ft 3 inches. She does not smoke and does not drink alcohol. Dietary habits include one can of Ensure daily, with other meals provided by a social service agency (Meals on

Wheels). Social concerns include the fact she lives alone, but a son visits every 1 to 2 weeks and transports her to physician appointments. She is living on a limited budget. With regard to her medication adherence, her son states that she occasionally forgets to take her afternoon medications, but overall, she is considered to be reasonably adherent with her drug regimens.

Diagnosis: Atrial Fibrillation, Acute Onset

1. List specific goals of treatment for D.G.
2. What drug therapy would you prescribe for stroke prevention in atrial fibrillation? Why?
3. What are the parameters for monitoring success of the anticoagulant therapy?
4. Discuss specific patient education based on the prescribed therapy.
5. List one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What would be the choice for the second-line therapy?
7. What OTC or alternative medications would be appropriate for D.G.?
8. What lifestyle changes would you recommend to D.G.?
9. Describe one or two drug–drug or drug–food interactions for the selected agent.

* Answers can be found online.

51 Anemias

Kelly Barranger

Anemia is a condition in which there is a decrease in the number of red blood cells (RBCs) or hemoglobin in the blood. Anemia can also be defined as a reduced ability to carry oxygen to meet physiologic needs, which varies by age, sex, altitude, and pregnancy status. There is not one set of "normal ranges" for hemoglobin, hematocrit, and RBCs. In general, anemia can be defined as values that are more than two standard deviations below the mean. The World Health Organization (WHO) criteria for anemia in men and women are less than 13.0 and less than 12.0 g/dL, respectively (Table 51.1). These values are also supported in the second National Health and Nutrition Examination Survey (Centers for Disease Control and Prevention, 2012).

TABLE 51.1 Hemoglobin Thresholds

Age or Gender Group	Hemoglobin Thresholds (g/dL)
Children (0.5–4.99 y)	11.0
Children (5.00–11.99 y)	11.5
Children (12.0–14.99 y)	12.0
Nonpregnant women (15.00 y)	12.0
Pregnant women	11.0
Men (15.00 y)	13.0

Causes

Anemia may develop through blood loss, nutritional deficiency, or malabsorption syndromes, or concurrently with inflammation or malignancy, or be inherited as in sickle cell disease (SCD), thalassemia, or hemoglobinopathy. Anemia may also occur from the treatment of diseases such as cancer, human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome, or hepatitis C.

Pathophysiology

RBCs, also known as *erythrocytes*, are formed in the marrow of the ribs, sternum, clavicle, vertebrae, pelvis, and proximal epiphyses of the humerus and femur. RBCs play a vital role in the support of metabolism by transporting oxygen to and removing carbon dioxide from tissue. To maintain proper tissue oxygenation and sustain a normal acid–base balance, an adequate number of RBCs must be available and they must be in specific shape and size. The average adult blood cell concentration for mean corpuscular volume (MCV) is 80 to 96 fL. These values may vary slightly from laboratory to laboratory.

RBCs develop from a pluripotent cell, which differentiates into an erythroid precursor. The cells shed their nuclei and obtain hemoglobin. The production of RBCs is initiated by the hormone erythropoietin (EPO), which is produced by the kidneys in response to a decrease in tissue oxygen concentration. Decreased tissue oxygen then signals the kidneys to increase production and release EPO. This EPO stimulates the stem cell to differentiate into proerythroblasts. EPO also increases the rate of mitosis and increases the release of reticulocytes from the marrow and induces hemoglobin formation. When hemoglobin synthesis is accelerated, the critical hemoglobin concentration necessary for maturity is reached more rapidly, causing an earlier release of reticulocytes. The appearance of reticulocytes in peripheral circulation indicates that RBC production is being stimulated. The maturation process takes about 1 week. Several days are then required for the reticulocyte to become an erythrocyte (Figure 51.1). The normal RBC survival time is 120 days; the survival time can be decreased to 18 to 20 days before occurrence of an anemia if the bone marrow functions at maximal capacity. When hemolytic destruction of RBCs exceeds marrow production, anemia will develop, causing the hemoglobin value to decrease.

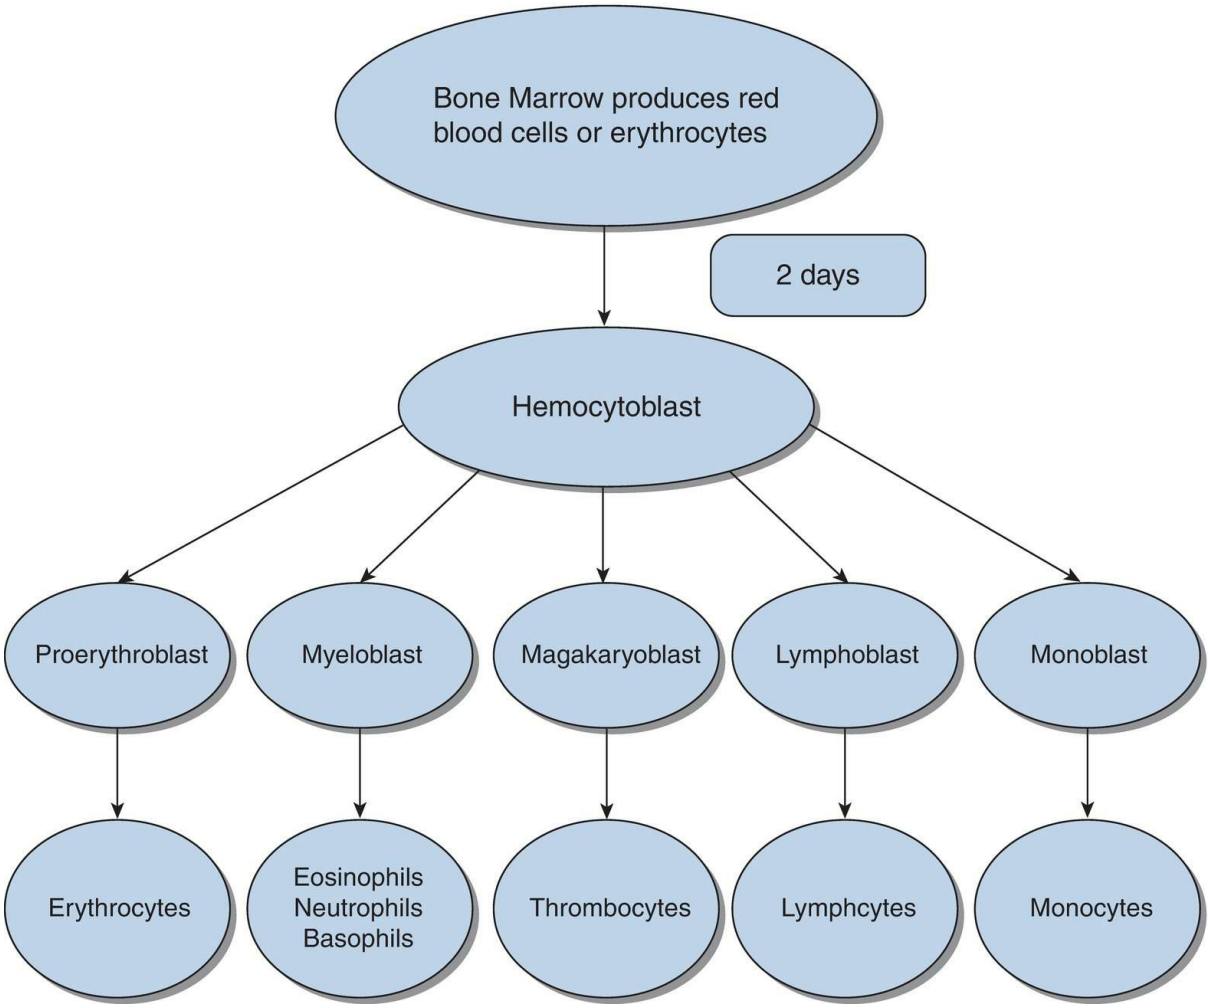

FIGURE 51.1 Hematopoiesis.

Diagnostic Criteria

Anemia is a reduction in the number of circulating RBCs (the hemoglobin concentration) or the volume of packed RBCs (hematocrit) in the blood. Anemias are classified according to their pathophysiologic basis and occur due to decreased production or increased destruction of RBCs. They are also classified according to cell size using the MCV (Figure 51.2). Microcytic anemias are those anemias due to RBCs with a lower than normal size. These include iron deficiency anemia, thalassemia, and anemia of chronic disease, infection, inflammation, or malignancy. In contrast, macrocytic anemia may be megaloblastic such as folate or vitamin B_{12} deficiency or nonmegaloblastic causes such as myelodysplasia, liver disease, or reticulocytosis (Box 51.1).

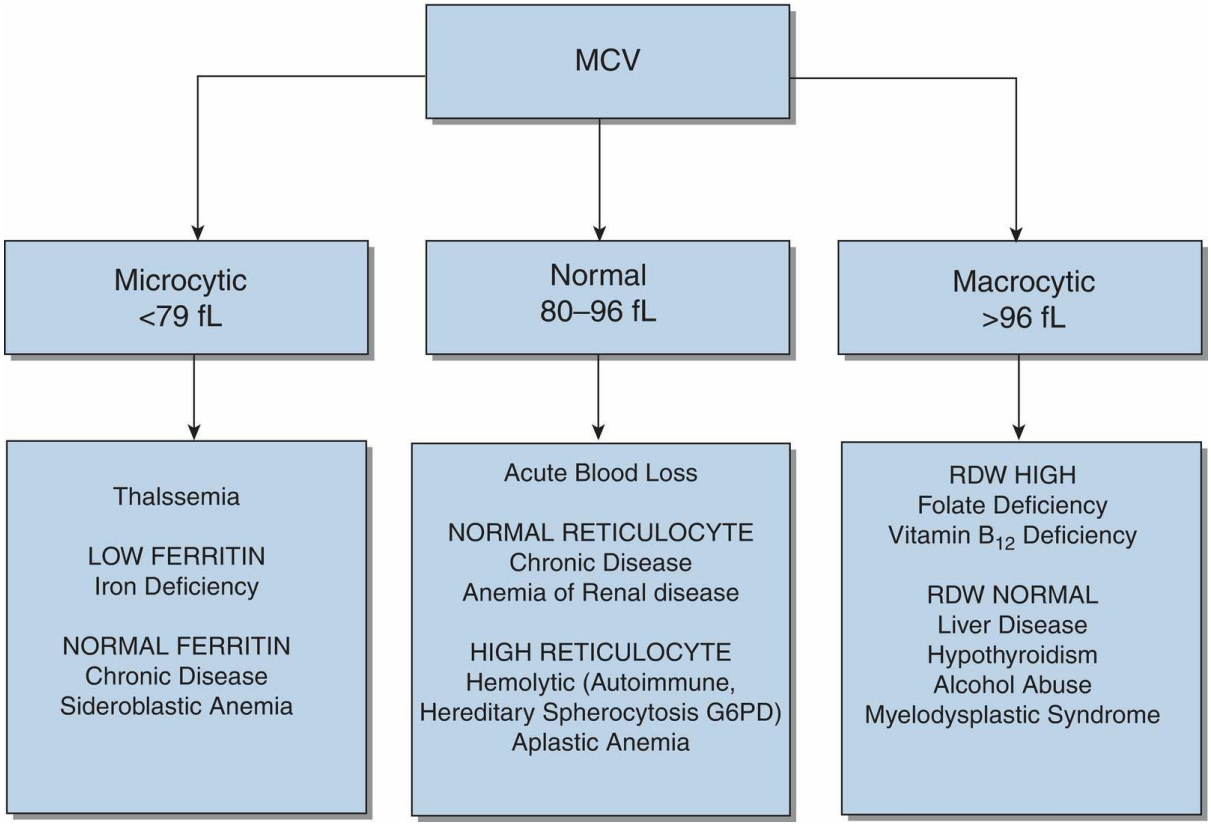

FIGURE 51.2 Anemias classified by mean corpuscular volume (MCV).

BOX 51.1 Classification of Anemias by Pathophysiology

Increased destruction
- Blood loss

Hemolysis
Sickle cell disease
G6PD deficiency
Thrombotic thrombocytopenic purpura
Hemolytic–uremic syndrome
Clostridial infection
- Hypersplenism

Decreased production
- Iron deficiency

Thalassemia
Anemia of chronic disease
Aplastic anemia
- Myeloproliferative leukemia

G6PD, glucose-6-phosphate dehydrogenase.

The signs and symptoms of anemia depend on the rate of development, age, and cardiovascular status of the patient. Rapid onset of anemia is most likely to present with cardiorespiratory symptoms (tachycardia, light-headedness, breathlessness). Anemia of a chronic nature may present with vague symptoms including fatigue, weakness, headache, vertigo, faintness, sensitivity to cold, pallor, and loss of skin tone.

Normal ranges may not be appropriate for all populations. Patients living at high altitude have values higher than those living at sea level. Smokers or those who have a significant exposure to secondary smoke have higher than normal levels. African Americans of both sexes have lower values than compared to the Caucasian population.

Evaluation

Anemia is never normal. A history, physical examination, and simple laboratory testing are useful in evaluating patients with anemia. The first thing to consider in evaluating anemia is the stability of the patient. Secondly, consider whether it is recent or lifelong. Recent anemia is almost always acquired, whereas lifelong anemia is likely inherited (hemoglobinopathies, thalassemia hereditary spherocytosis). Next, obtain a thorough history including recent and past infections, malignancy, renal disease, and a history of autoimmune disease. The review of systems should include weight loss or weight gain, fever, chills or night sweats, change in bowel habits, and black tarry stools.

The goal of the physical examination is to assess the patient's condition and to find signs of organ or multisystem involvement. During the physical examination, note the presence or absence of tachycardia, dyspnea, fever, or postural hypotension. Also, note the presence or absence of lymphadenopathy, hepatosplenomegaly, and bone tenderness, especially over the sternum (chronic myeloid leukemia) or lytic lesion (multiple myeloma or metastatic cancer). Assess the skin for signs of petechiae due to thrombocytopenia, ecchymosis, or coagulation abnormalities. During the physical examination, a stool examination for occult blood should be performed.

Laboratory evaluation should be performed and include a complete blood count (CBC), including differential and reticulocytes.

A low WBC count (leukopenia) may be associated with hypersplenism, cobalamin deficiencies, or bone marrow suppression or replacement, whereas high WBC count may be associated with a primary hematologic malignancy, inflammation, or infection.

The WBC differential, in conjunction with the total WBC count, may show absolute number of various cell types:

- Absolute neutrophil count may be elevated due to infection and may be decreased after having chemotherapy.
- Absolute monocyte count may be elevated in myelodysplasia.
- Absolute eosinophil count may be elevated in certain infection.
- Absolute lymphocyte count may be decreased in HIV infection or following treatment with glucocorticoids.

Pancytopenia is the combination of anemia, thrombocytopenia, and neutropenia. Mild pancytopenia is seen in patients with splenomegaly and splenic trapping. The presence of severe pancytopenia is associated with disorders such as aplastic anemia, folate or cobalamin deficiency, hematologic malignancy, and marrow ablation from chemotherapy or radiation.

Hemolysis should be considered in patients with a rapid fall in hemoglobin concentration, reticulocytosis, and/or abnormally shaped RBC (spherocytes or fragmented RBC) in the absence of blood loss.

An important principle in the treatment of anemia is to initiate treatment only when a specific diagnosis is made. In the acute setting, anemia may be severe and a red cell transfusion is required, but this is rare. Frequently, the cause of anemia is multifactorial. In most cases, it is important to evaluate a patient's iron status before and during the treatment for anemia. Moreover, treatment modalities for anemia are based on the underlying cause and are discussed separately further in the chapter.

Anemias Caused By Increased Destruction

Acute Posthemorrhagic Anemia/Chronic Blood Loss

Posthemorrhagic anemia results from massive hemorrhage associated with spontaneous or traumatic rupture or incision of a large blood vessel. It can also be from an erosion of an artery by a lesion (peptic ulcer, neoplasm) or failure to maintain normal hemostasis. The sudden loss of one third of blood volume may be fatal, whereas a two-thirds loss of blood volume slowly over 24 hours is without immediate risk. During and immediately after hemorrhage, the RBC count, hemoglobin value, and hematocrit may be high due to vasoconstriction. Fluid from tissue enters the circulation within a few hours resulting in hemodilution causing a drop in the RBC count and hemoglobin value. This result is proportional to the severity of bleeding. Signs of vascular instability (hypotension and decreased organ perfusion) appear with acute losses of 10% to 15% of the total blood volume. When more than 30% of blood volume is lost suddenly, hypotension and tachycardia occur. When more than 40% of blood volume is lost, signs of hypovolemic shock (confusion, dyspnea, diaphoresis, hypotension, and tachycardia) appear.

Diagnostic Criteria

Initial evaluation of anemia includes a careful history and physical examination. Laboratory evaluation includes CBC, reticulocyte index, iron studies, examination of the peripheral blood smear, and a stool sample for occult blood (Table 51.2). Further studies are indicated based on the results of the preliminary evaluation.

TABLE 51.2 Laboratory Values

	Reference Range*
Hemoglobin	
Adult male	13.3–16.2 g/dL
Adult female	12.0–15.8 g/dL
Hematocrit	
Adult male	38.8%–46.4%
Adult female	35.4%–44.4%
Reticulocyte count	
Adult male	0.8%–2.3% RBCs
Adult female	0.8%–2.0% RBCs
WBC (leukocyte)	3.54–9.06 L
Mean corpuscular hemoglobin (MCH)	26.7–31.9 pg
Mean corpuscular volume (MCV)	79–93 fL
Mean platelet volume (MPV)	9.0–12.95 fL
Mean corpuscular hemoglobin concentration (MCHC)	32.3–35.9 g/dL
Platelet	165–415 mn
Ferritin	
Adult male	15–400 ng/mL
Adult female	10–200 ng/mL
Vitamin B_{12}	200–600 pg/mL
Folate	3–16 ng/mL

*These values may vary from laboratory to laboratory.

Initiating Therapy

Immediate therapy consists of hemostasis, restoration of blood volume, and treatment of shock. In many cases, the blood lost needs to be replaced promptly. Blood transfusion is the only means of rapidly restoring blood volume.

Sickle Cell Anemia

Sickle cell anemia is an autosomal recessive disorder in which abnormal hemoglobin leads to chronic hemolytic anemia with numerous clinical consequences. It most commonly affects African Americans and, to a lesser extent, Hispanics.

Pathophysiology

Patients with SCD predominantly make hemoglobin S that is present in RBCs. Normal adult hemoglobin is made up of hemoglobin A. When the erythrocyte in patient with SCD becomes stressed, the erythrocyte loses its oxygen causing the cell integrity to be lost. These cells form long, stiff rod-like structures that bend the erythrocyte into a sickle shape. This causes the cells to get stuck in the blood vessels and cut off blood supply to organs. This vasoocclusion and blockage of microvasculature causes significant damage to the endothelium of the arterial and venous circulation, which leads to a sickle cell crisis. Crisis occurs when patients are physically stressed (exercise), exposed to high altitude or cold temperatures, or have a high fever or infection. The underlying cause includes hypoxia, dehydration, and acidosis. Sickle cell crises last about a week but may not resolve for several weeks to months. Pain typically occurs in the back, ribs, and limbs. Patients with sickle cell anemia are susceptible to infection, particularly *Streptococcus pneumoniae* and *Haemophilus influenzae*, and are prone to gallstones and renal failure. Other complications include chronic leg ulcer, priapism, aseptic necrosis of the humoral and femoral heads, and chronic osteomyelitis. Long-term effects include stroke, heart failure, and death. Patients should be screened for renal disease, pulmonary hypertension, hypertension, retinopathy, risk of stroke, and pulmonary disease and should receive reproductive and contraception counseling.

Therapeutic transfusion therapy is reserved for individuals with acute stroke, acute chest syndrome, acute multiorgan failure, and acute symptomatic anemia. A lifelong cure for SCD is available through an HLA-matched sibling donor hematopoietic stem cell transplant. However, this treatment is limited to individuals who are younger than age 16 due to toxicities and adverse outcomes including stroke, acute chest syndrome, osteonecrosis, and osteomyelitis and a mortality rate of 10% (Bernaudin et al., 1997).

Diagnostic Criteria

Examination of a peripheral blood smears for sickling and checking a reticulocyte count can provide supportive data for the diagnosis of SCD. Hemoglobin electrophoresis or a sickle cell preparation can also be useful in the diagnosis of SCD. Laboratory findings also show reduced hemoglobin and an RBC count between 2 and 3 million/μL.

For those at risk, techniques such as chorionic biopsy have been used during early gestation (6 to 8 weeks of pregnancy) to identify SCD. Genetic counseling and education must also be offered. Risk of the procedure to mother and fetus, risks of false-positive and false-negative results, and the acceptability of therapeutic abortion should also be discussed.

Initiating Drug Therapy

The management of SCD focuses on primary prevention and treatment of the complication as well as a potential cure. Children with SCD should be immunized against *S. pneumoniae*, *H. influenzae* type B, hepatitis B virus, and influenza. All individuals should be immunized as recommended by the Advisory Committee on Immunization Practices (ACIP). The immunization schedule can be found online and is updated up to four times a year (National Heart, Lung, and Blood Institute, 2014). Infants are at increased risk for pneumococcal disease and should receive 13-valent conjugate pneumococcal vaccine (PCV13) shortly after birth and 23-valent pneumococcal polysaccharide (PPSV23) vaccine at 2 years of age. A second dose should be given at 5 years of age. Other immunizations include hepatitis B and meningococcal vaccine.

Patients are maintained on folic acid supplementation, 1 mg/d, because of accelerated erythropoiesis.

Hydroxyurea

In selected patients, hydroxyurea is used for prophylaxis treatment to reduce the number of crises (acute chest syndrome or greater than three crises per year) in adult and children. The effects of hydroxyurea on RBCs include increasing hemoglobin F levels, increasing water content of RBCs, increasing deformability of sickled cells, and altering the adhesion of RBCs to endothelium. Evidence suggests that hydroxyurea reduces the number of chest syndromes and transfusions and may reverse organ dysfunction (Wong et al., 2014).

The starting dose of hydroxyurea for adults is 15 mg/kg/d (round up to the nearest 500 mg). For patient with chronic kidney disease (CKD), the dose is adjusted to 5 to 10 mg/kg/d. Starting dosage for infants and children is 20 mg/kg/d. While adjusting the dose of hydroxyurea, a CBC with differential and reticulocyte count should be done every 4 weeks. The goal of therapy is for an absolute neutrophil count ≥2,000/μL and a platelet count ≥80,000/μL. In younger patients, an absolute neutrophil count down to 1,250/μL may be safely tolerated. If neutropenia or thrombocytopenia occurs, hydroxyurea should be held and a CBC with differential should be performed weekly. Once blood counts have recovered, reinstitute hydroxyurea at a dose 5 mg/kg/d lower than the dose given before onset of cytopenias. The dose of hydroxyurea should be increased by 5 mg/kg/d every 8 weeks until mild myelosuppression (absolute neutrophil count 2,000 to 4,000/μL) is achieved, up to a maximum of 35 mg/kg/d. Laboratory studies including a CBC with differential, reticulocyte count, and platelet count should be performed every 2 to 3 months. The effectiveness of hydroxyurea depends on adherence, and patients should be counseled not to miss a dose and not to double up on doses. Keep in mind that it may take 3 to 6 months of treatment with hydroxyurea to see a clinical response. Patients should be maintained on a maximum tolerated dose for 6 months before considering discontinuation or treatment failure. During hospitalizations, patients should be continued on hydroxyurea

(National Heart, Lung, and Blood Institute, 2014).

Hydroxyurea should not be used in patients likely to become pregnant or those unwilling or unable to follow instructions regarding treatment. Patients should be monitored for myelotoxicity. Serious adverse reactions include myelosuppression and the risk of cancer. Side effects include cutaneous hyperpigmentation, alopecia, xerosis, nail pigmentation, and leg ulcers.

Pain Management

Management of acute painful episodes consists of exclusion of causes (infection), hydration by oral or intravenous (IV) fluid resuscitation, and aggressive pain relief, including analgesics and opiates. Acetaminophen has analgesic and antipyretic effects. The 24-hour maximum daily dose of acetaminophen in four divided dose should not exceed 4 g for healthy individuals and 3 g in individuals with liver disease or who are pregnant. High dosages of acetaminophen can damage the liver and could be fatal (Ballas, 2005).

Nonsteroidal anti-inflammatory agents (NSAIDs) have anti-inflammatory effects in addition to pain and antipyretic proprieties. NSAIDs have potentially serious adverse effects, including gastritis and gastrointestinal (GI) bleeding, which may result in anemia. NSAIDs are contraindicated in patients with history of GI bleed and renal disease (Ballas, 2005).The management of acute painful crisis includes aggressive narcotic analgesia, such as morphine or hydromorphone (see Chapter 7). Adverse effects of opioid analgesics include severe sedation and respiratory depression. Side effects include itching, nausea, and vomiting. Opioid analgesics should be used carefully in patients with asthma, impaired ventilation, liver failure, renal failure, and increased intracranial pressure.

Meperidine should be used with caution in the treatment of acute SCD because multiple doses are associated with the accumulation of its major metabolite, normeperidine, and central toxicity, including twitching, multifocal clonus, and seizures. Coadministration with antipsychotics may cause neuromuscular disorders, including dystonia, tardive dyskinesia, akathisia, and neuroleptic malignant syndrome. Meperidine in combination with monoamine oxidase inhibitors may cause severe adverse reactions, including excitation, hyperpyrexia, convulsions, and death.

Patients with chronic sickle cell pain are managed with long-acting opioids and short-acting opioids for breakthrough pain according to the National Heart, Lung, and Blood Institute's guidelines.

Anemias Caused by Diminished Production of Red Blood Cells

Iron Deficiency Anemia

Iron deficiency anemia is the most common nutritional deficiency worldwide. The diagnosis of iron deficiency anemia is made by low hemoglobin and iron stores, whereas iron deficiency is made by low iron stores without anemia. According to the WHO, iron deficiency is most prevalent in young children and women of childbearing age. The goal of treatment is to identify the underlying causes and administer the appropriate therapy.

Causes

The cause of iron deficiency is related to insufficient iron intake, inadequate absorption from the GI tract, and increased iron demands and is exacerbated by chronic intestinal blood loss due to parasitic and malarial infections.

A vegetarian diet and a diet low in consumption of animal protein contribute to inadequate intake of iron. Inadequate absorption from the GI tract is usually related to malabsorption syndromes (celiac disease, Whipple disease, bacterial overgrowth), postgastrectomy, gastric bypass and the presence of certain foods (dietary fiber, coffee, tea, eggs, or milk) or drugs (quinolones, tetracycline, H2 blockers, proton pump inhibitors, calcium supplements), or unrelenting diarrhea. Iron demands are increased in menstrual blood loss, pregnancy, and lactation. Iron requirements are highest during infancy and pregnancy. Iron deficiency in pregnancy has been implicated as a cause of perinatal complications such as low birth weight and premature delivery in affected mothers. In children, long-term findings include increased susceptibility to infection, poor growth, developmental and behavioral delays, and low mental and motor test scores. Pregnant women should routinely receive iron supplementation and continue into postpartum.

The consequence of chronic alcoholism, food faddism, prolonged illness with anorexia, or poor nutrition also contributes to iron deficiency (Box 51.2). Interventions such as foods fortified with iron and iron supplementation are in place to prevent and correct iron deficiency.

BOX 51.2 Causes of Iron Deficiency

Deficient diet
Decreased absorption
Increased requirements
  Pregnancy
  Lactation
Blood loss
  GI
Menstrual
  Blood donation
Hemoglobinuria
Iron sequestration

Pathophysiology

The predominant use of iron is for the creation of heme groups that are incorporated into hemoglobin and myoglobin. Additionally, iron is involved in the production of cytochromes and other enzymes. Immediately bioavailable, iron is bound in the bloodstream to a specific carrier protein, transferrin. Excess of immediate iron needs is stored in the liver, spleen, and bone marrow as ferritin. Patients with iron deficiency anemia may be asymptomatic or have vague symptoms. Other manifestations include koilonychia (spoon nail), angular stomatitis, glossitis, and pica (eating dirt, paint, clay, ice, or cornstarch).

Diagnostic Criteria

Laboratory findings are critical for the diagnosis. The classic criteria for iron deficiency anemia include low serum iron and ferritin concentrations and a high total iron-binding capacity (TIBC). In mild iron deficiency, the hemoglobin, hematocrit, and RBC indices remain normal. In the later stages, the hemoglobin and hematocrit levels fall below normal values (Table 51.2).

A low concentration of ferritin (less than 0 to 120 ng/L) is the earliest and most sensitive indication of iron deficiency. However, patients with renal or liver disease, malignancies, or infectious or inflammatory processes may have elevated ferritin levels that may not correlate with iron stores in the bone marrow. Transferrin saturation (serum iron divided by TIBC) is also used to assess iron deficiency anemia. Low values (less than 15%) indicate iron deficiency anemia, although low serum transferrin saturation values may also be present in inflammatory disorders. In this case, TIBC helps to differentiate the diagnosis. A TIBC over 400 mcg/dL suggests iron deficiency anemia, whereas values below 200 mcg/dL usually represent inflammatory disease. Free erythrocyte protoporphyrin (FEP) can also be used to distinguish between iron deficiency anemia and thalassemia minor. Iron binds with protoporphyrin to form heme. The serum concentration of protoporphyrin not bound to iron is elevated when iron levels are low. Thus, FEP is elevated in patients with iron deficiency anemia, inflammatory disorders, and lead poisoning. Rarely, a bone marrow examination is performed to assess iron stores.

Initiating Drug Therapy

The successful treatment of iron deficiency anemia depends on identifying the underlying cause. The treatment of iron deficiency anemia consists of dietary supplementation and iron preparations (Table 51.3). Oral iron is inexpensive and effective in the treatment of anemia. Iron is best absorbed from red meat, fish, and poultry. Plant-based foods are good sources of iron, although they are less easily absorbed. Whole-grain or iron-fortified cereals, breads, and pastas are among the best. Beverages such as tea or milk will reduce the absorption of iron and should be consumed in moderation between meals. Medications such as antacids, proton pump inhibitors, and histamine-2 (H_2) antagonists reduce absorption and should be avoided if possible. Vitamin C (500 mg daily), as well as orange juice, increases the absorption of iron due to increased stomach acidity. They should be given together and are recommended with meals. Transfusion should be considered for patients with iron deficiency anemia complaining of fatigue or dyspnea on exertion.

TABLE 51.3 Elemental Iron Content of Various Iron Salts

Iron Salt	% Iron
Ferrous fumarate	33
Ferrous gluconate	11.6
Ferrous sulfate	20
Ferrous sulfate, anhydrous	30

Indications for the use of IV iron include chronic bleeding, intestinal malabsorption, intolerance to oral iron, nonadherence, or hemoglobin of less than 6 g/dL with signs of poor perfusion.

Goals of Drug Therapy

The goal of therapy is based on how the anemia affects the patient's quality of life, activities of daily living, and general well-being. Treatment with oral iron may take 6 to 8 weeks for the hemoglobin to improve and as long as 6 months to replete iron stores.Minimization of the impact chronic iron deficiency anemia has on adequate iron replacement has typically occurred when the serum ferritin level reaches 500 ng/L and when the hemoglobin and hematocrit have returned to normal levels.

Iron Replacement Therapy

Dosage

Treatment of iron deficiency anemia in adults should start with 100 to 200 mg of elementary iron (Adamson, 2012). For children, treatment is 3 to 6 mg/kg. Supplemental iron should be administered in divided doses without food. The addition of vitamin C may improve absorption.

Non–enteric-coated ferrous salts containing ferrous sulfate are the least expensive and provide adequate elemental iron. Typically, a dose of 325 mg ferrous sulfate three times daily provides sufficient iron replacement (195-mg elemental iron or about 2.7 mg/kg for a 70-kg adult). Slow-release or sustained-release iron preparations do not dissolve until reaching the small intestines, significantly reducing iron absorption.

Iron dextran is administered intravenously in one large dose of 200 to 500 mg. Safer alternatives include sodium ferric gluconate and iron sucrose. Sodium ferric gluconate is administered intravenously in eight weekly 125-mg doses for a total of 1,000 mg, and iron sucrose is administered intravenously five times over 2 weeks in 200-mg doses. Side effects of intravenous iron supplementation include nausea, vomiting, pruritus, headache, and flushing. Myalgia, arthralgia, and back and chest pain usually resolve in 48 hours.

Blood transfusion should be reserved for those patients who are hemodynamically unstable or show signs of end-organ ischemia from acute GI bleeding.

Time Frame for Response

Therapeutic doses of iron should increase hemoglobin value by 0.7 to 1 g/wk. Reticulocytosis occurs within 7 to 10 days after initiation of iron therapy. Iron therapy should be continued for at least 3 to 6 months. Common causes of treatment failure include noncompliance with therapy, malabsorption, and blood loss equal to the rate of production. Malabsorption can be ruled out by the iron test, which is rarely use, in which plasma iron levels are measured 1 to 2 hours afterward. Refractory responses to treatment may be due to patient with *Helicobacter pylori* infection or celiac disease. By eradicating *H. pylori* or following a gluten-free diet may eliminate the need for iron supplementation.

Adverse Events

Adverse reactions to iron are primarily GI difficulties, consisting of discolored feces, anorexia, constipation or diarrhea, nausea, and vomiting. To minimize the GI side effects, iron supplements should be taken with food. However, the impact of this on bioavailability of agents may be as high as a 66% decrease in iron absorption. Changing to a different iron salt or to a controlled-release preparation may reduce side effects.

A major adverse reaction of iron dextran is the risk of anaphylaxis, which can be fatal.

Delayed reactions include myalgias, headache, and arthralgias.

Interactions

There is a host of drug–drug interactions with iron preparations. Many antibiotics, such as tetracyclines and fluoroquinolones, have a decrease in absorption due to the formation of a chelation product with the ferrous ions. The absorption of iron may be decreased when it is given with products containing aluminum, calcium, or magnesium. This effect may be as much as 30% to 40% reduction in absorption. The theory is that the reduced stomach acidity secondary to the antacid-like properties of products reduces the iron absorption. Similarly, patients taking proton pump inhibitors or H_2 antagonists may also have decreased iron absorption due to the lowered stomach acid. If the patient is taking both medications, space them at least 1 to 2 hours apart. In contrast, acidifying agents such as ascorbic acid (vitamin C) may enhance the absorption of iron-containing salts.

Anemia of Chronic Renal Failure

Anemia is a common complication of chronic renal failure and is primarily due to reduced EPO production by the kidney. Anemia occurs when the glomerular filtration rate (GFR) declines below 60 mL/min. Stages of CKD are defined according to the estimated GFR (Table 51.4) based on National Kidney Foundation guidelines (Kidney Dialysis Outcomes Quality Initiative [KDOQI, 2007]). Risk factors that increase the risk of CKD include hypertension, diabetes mellitus, autoimmune disease, older age, African ancestry, a family history of renal disease, a previous episode of acute renal failure, and the presence of proteinuria, abnormal urinary sediment, or structural abnormalities of the urinary tract. Measurement of albuminuria is a good test for early detection of renal disease; a 24-hour urine collection is the "gold standard." A first-morning urine sample is often more practical and correlates well, but not perfectly. Persistence in the urine of greater than 17 mg of albumin per gram of creatinine in adult males and 25 mg of albumin per gram of creatinine in adult females usually signifies chronic renal damage.

TABLE 51.4 Classification of Chronic Kidney Disease

Stage	GFR, mL/min/1.73 m^2
0	>90*
1	>90†
2	60–89
3	30–59
4	15–29
5	<15

*With risk factors for CKD.

†With demonstrated kidney damage (e.g., persistent proteinuria, abnormal urine sediments, abnormal blood and urine chemistry, and abnormal imaging studies).

Progressive renal impairment is associated with worsening systemic inflammation as seen with elevated levels of C-reactive protein, which contributes to the acceleration of vascular disease and comorbidities associated with advanced renal disease. As renal impairment advances, metabolic and endocrine functions are impaired and result in anemia, malnutrition, and abnormal metabolism of carbohydrates, fats, and proteins. Plasma levels of hormones, including parathyroid hormone (PTH), insulin, glucagon, sex hormones, and prolactin, change with renal failure as a result of urinary retention, decreased degradation, and abnormal regulation. Calciphylaxis is a devastating condition seen in patients with

advanced kidney disease. It is heralded by livedo reticularis and advances to patches of ischemic necrosis, especially on the legs, thighs, abdomen, and breasts.

Pathophysiology

CKD is characterized by the progressive loss of functioning nephrons. With a reduction in nephron mass, renal vasodilation occurs and leads to hyperperfusion of the remaining glomeruli. Nephrons exposed to prolonged hyperperfusion begin to leak protein, become sclerotic, and eventually are destroyed. Substances that are filtered that are neither secreted nor resorbed by the tubule, such as urea, begin to rise early in the course of renal impairment.

Serum concentration of phosphorus, which is under the influence of PTH, is kept within the normal range until more than 80% of real function is lost. This is because increased PTH reduces the amount of phosphorus resorbed by the tubule. Failure of the kidney to fulfill its excretory, endocrine, and metabolic function results in inadequate quantities of EPO and 1,25-dihydroxy-vitamin D_3. Other hormones, such as PTH, insulin, and prolactin, are present in excess. The primary cause of anemia in patients with CKD is insufficient EPO production by the diseased kidneys. The mechanisms impairing renal EPO production are not well understood.

Initiating Drug Therapy

Patients should be placed on a multivitamin to replace the vitamins lacking in restrictive diets. Adequate bone marrow iron stores should be available before EPO treatment is initiated. Iron supplementation is usually essential to ensure an adequate response to EPO because the demand for iron by the marrow frequently exceeds the amount of iron immediately available for erythropoiesis (measured by percentage of transferring saturation) as well as the amount of iron stores (measured by serum ferritin). Current practice is to target a hemoglobin concentration of 10 to 12 g/dL.

The treatment of anemia caused by chronic renal failure begins with treating reversible causes of deteriorating renal function. Disorders of mineral metabolism (calcium, phosphorus, and bone) are common in CKD. Oral phosphorus-binding agents, calcium carbonate, and calcium acetate are used to treat hyperphosphatemia. Phosphorus-binding agents that do not contain calcium are sevelamer and lanthanum. Vitamin D or vitamin D analogs (calcitriol, paricalcitol) are given to treat secondary hyperparathyroidism.

Many of the immunologically mediated renal diseases (e.g., membranous nephropathy, Wegener disease, Goodpasture syndrome, lupus nephritis) respond to treatment with corticosteroids, cytotoxic agents, or plasmapheresis. This will not be discussed here. These patients should be under the care of a rheumatologist and/or a nephrologist.

When renal disease is associated with a metabolic disorder such as diabetes (Chapter 46) or gout (not discussed here), the treatment is directed at metabolic control to slow the course of renal deterioration.

When a drug (methicillin, indomethacin, NSAID, metformin, meperidine, and oral hypoglycemics) or other toxic substance is identified as the cause of renal failure, the offending agent should be withheld or avoided. Many antibiotics, antihypertensives, and antiarrhythmics require a reduced dosage or a change in the dose interval in patients with kidney disease.

Kidney Disease: Improving Global Outcomes (KDIGO) 2012 recommendations for erythropoiesis-stimulating agents (ESA) therapy in nondialysis and dialysis patient follow the recommendation from the FDA (Kliger et al., 2013). That is, a hemoglobin target range of 10 to 12 g/dL should be replaced by using the lowest possible dose of ESA to prevent transfusion. The concern is that increased blood transfusions will expose eligible kidney transplant recipients to allosensitizing effects of blood transfusions. Furthermore, ESA dose should be reduced or interrupted if the hemoglobin exceeds 11 g/dL. The ESA dosing strategy should be individualized for each patient considering the risks and benefits. KDIGO guidelines add an additional goal to avoid hemoglobin levels of less than 9 g/dL. The Normal Hematocrit Study reported worse outcomes in patients with hemoglobin 13 to 15 g/dL compared to 9 to 11 g/dL. While the FDA removed quality-of-life benefits in the use of ESA, the KDIGO recommendation is that it is still reasonable to start ESA in some patients with a hemoglobin level above 10 g/dL. The disagreement falls in

interpreting quality of life.

For the naive pediatric patient with anemia, not on iron or ESA, the KDIGO recommendation is for oral iron when the transferrin is less than 20% and ferritin is less than 100 ng/mL. For pediatric patients on dialysis, oral or IV iron is recommended.

Goals of Drug Therapy

The goals of therapy are to (1) treat the underlying renal disease; (2) slow the progression of renal deterioration by modifying the known or suspected factors that are thought to aggravate the primary process and avoid factors that may aggravate existing renal failure; and (3) treat the specific complications of renal disease and prevent long-term complications of uremia. Correction of anemia decreases morbidity and reduces hospitalization and mortality among patients with CKD. Benefits of correcting anemia include improvements in quality of life, exercise capacity, cognitive function, and sexual function.

Epoetin and Darbepoetin

The KDOQI anemia guidelines 2007 recommend individualizing the risks and benefits of ESA therapy. The goal is to avoid transfusion and for a hemoglobin target of 11.0 to 12.0 g/dL and should not be above 13.0 g/dL.

Recombinant EPO (epoetin, Epogen, Procrit) is indicated for the treatment of anemia due to chronic renal failure, zidovudine administration (in HIV-infected patients), and chemotherapy administration. Other indications include a reduction in blood transfusions in anemic patients undergoing elective, noncardiac, nonvascular surgery. Similarly, darbepoetin is indicated for patients with chronic renal failure and patients receiving chemotherapy. Recombinant EPO is indicated in chronic renal failure to elevate the hemoglobin when the hemoglobin is less than 10.0 g/dL and to decrease the need for transfusion. Epogen should be avoided for a hemoglobin greater than 12.0 g/dL.

Mechanism of Action

Epoetin and darbepoetin are recombinant hormones that stimulate the production of RBCs from the erythroid tissues in the bone marrow. Epoetin also stimulates the division and differentiation of erythroid progenitors in bone marrow. Darbepoetin is a longer-acting erythropoietic agent than epoetin (serum half-life of 25 vs. 8.5 hours).

Dosage

The starting dose of epoetin is 50 to 100 units/kg given subcutaneously three times a week for a hemoglobin less than 10 g/dL for anemia due to CKD (Epogen, 2005). For patient on dialysis, this should be administered intravenously. Dosing should be individualized and the lowest dose used to reduce the need for transfusion. The dose should be reduced or interrupted for a hemoglobin greater than 10 g/dL or if the hemoglobin rises greater than 1 g/dL in a 2-week period. In the latter case, the dose should be reduced by 25% or more.

The recommended starting dose for darbepoetin is 0.45 mcg/kg body weight, administered as a single IV or subcutaneous injection once weekly (Aranesp, 2013). Dosing

is the same whether it is given subcutaneously or intravenously. Treat to a target hemoglobin concentration of 10 to 11 g/dL. After initiating therapy, the hemoglobin level should be monitored weekly for at least 4 weeks until the hemoglobin value has stabilized.

All patients receiving erythropoietic stimulation should receive iron supplementation unless iron stores are already in excess. Iron supplementation should be initiated no later than the beginning of treatment and continue throughout the course of therapy. Oral therapy with ferrous sulfate 325 mg once to three times daily is adequate. Monitor the patient's hematocrit, ferritin, transferrin, vitamin B_{12} and folate levels, blood pressure, clotting times, platelet counts, blood urea nitrogen level, and serum creatinine concentration.

Time Frame for Response

Two to 6 weeks may be required to evaluate the effectiveness of epoetin. If the response is not satisfactory in terms of reduced transfusion requirements or increased hematocrit after 8 weeks of therapy, the dose may be increased up to 300 units/kg three times a week. If patients do not respond, it is unlikely that they will respond to higher doses. Maintenance doses are individualized for each patient.

With once-weekly dosing, steady-state serum levels are achieved within 4 weeks with darbepoetin. Dose adjustment should not be increased more frequently than once a month. If the hemoglobin is increasing and approaching 11 g/dL, the dose should be reduced by 25%. If the hemoglobin continues to increase, the dose is withheld temporarily until the hemoglobin begins to stabilize.

Contraindications

Epoetin and darbepoetin are contraindicated in patients with uncontrolled hypertension or hypersensitivity to mammalian cell–derived products or human albumin. In 2011, the Food and Drug Administration (FDA) revised the labeling of ESA warning that the risks may outweigh the benefits in patient who have current malignancy and had previous stoke. The KDIGO 2012 guidelines agree about using caution when using ESA. ESA is not intended for patients with chronic renal failure who require correction of severe anemia or in patients with iron folate deficiencies or GI bleeding.

Adverse Events

Epoetin and darbepoetin are generally well tolerated. Adverse reactions may include hypertension, headache, seizure, arthralgia, nausea, edema, fatigue, diarrhea, vomiting, chest pain, asthenia, and dizziness. Other adverse reactions include infection, hypertension, hypotension, and myalgia. Serious adverse reactions include vascular access thrombosis, heart failure, sepsis, and cardiac arrhythmia. There are no significant drug interactions.

Anemia of Chronic Disease

Anemia of chronic disease is a hypoproliferative anemia and is associated with infection, organ failure, trauma, inflammation, and neoplasia (Box 51.3).

BOX 51.3 Causes of Anemia of Chronic Disease

Common Causes
Chronic infections
  Tuberculosis
Subacute bacterial endocarditis
  Osteomyelitis
Chronic inflammation
  Rheumatoid arthritis and inflammatory osteoarthritis
Systemic lupus erythematosus
Collagen vascular diseases
  Gout
Malignancies
Less Common Causes
Alcoholic liver disease
Heart failure
Thrombophlebitis
Chronic obstructive lung disease
Ischemic heart disease

Pathophysiology

Anemia of chronic disease typically occurs despite adequate reticuloendothelial iron stores and is characterized by reduced concentrations of serum iron, transferrin, and TIBC; normal or raised ferritin levels; and high erythrocyte sedimentation rate. RBCs are often normochromic and normocytic. In patients with rheumatoid arthritis and Crohn disease, RBCs are similar to the effects of iron deficiency, with hypochromic and microcytic indices.

Diagnostic Criteria

In anemia of chronic disease, the hematocrit rarely falls below 60% of baseline. The MCV is usually normal or slightly reduced. Serum iron values may be unmeasurable, and transferrin saturation may be extremely low. Serum ferritin values should be normal or increased. A serum ferritin value lower than 300 ng/L suggests coexistent iron deficiency.

Initiating Drug Therapy

Treatment is directed at the underlying cause and at eliminating exacerbating factors such as nutritional deficiencies and marrow-suppressive drugs. Other causes of anemia should be treated before initiating therapy.

Doses of recombinant epoetin are higher than those in renal anemia. Epoetin is administered subcutaneously, and doses may vary from 150 to 1,500 units/kg/wk.

Goals of Drug Therapy

A good response is likely if, after 2 weeks of therapy, the hemoglobin increases more than 0.5 g/dL. If no response has been observed at 900 units/kg/wk, further escalation is unlikely to be effective. Iron supplements are required to ensure an adequate epoetin response.

Thalassemia

The thalassemias are hereditary disorders of hemoglobin synthesis, which are considered among the hypoproliferative anemias. The α-thalassemia syndromes are seen primarily in persons from India and China and are less commonly seen in African Americans. The β-thalassemia syndrome affects primarily persons of Mediterranean origin (Italian, Greek). Every year, more than 200,000 babies are born with thalassemia major. They have a life expectancy of less than 30 years and are dependent on blood transfusions. Repeated transfusions result in cirrhosis of the liver, cardiomyopathy, endocrinopathies, and death due to hemosiderosis (Savulescu, 2004).

Pathophysiology

Normal adult hemoglobin is primarily hemoglobin A. Hemoglobin A consists of equal quantities of α- and β-globin chains. Thalassemia is present when a hemoglobinopathy is associated with a decreased production of either the α- or β-globins or a structurally abnormal globin chain. In α-thalassemia, the production of α-globin chains is controlled by four genes. Mutation of all four genes is incompatible with life (hydrops fetalis). Mutation of only one of the four is considered a silent carrier. Mutations of two of the four genes result in both microcytosis and mild anemia. Mutations of three of the four genes allow excess β-chains to form tetramers (hemoglobin H) and result in severe anemia in addition to microcytosis. Physical examination will reveal pallor and splenomegaly. β-Thalassemia is commonly classified by the severity of anemia; many genotypes exist for each phenotype. In β-thalassemia, β-globin chain is controlled by two genes. Mutations of one of two genes results in β-thalassemia trait (β-thalassemia minor). Thalassemia intermedia is associated with dysfunction of both β-globin genes. Clinical severity is intermediate (hemoglobin level of 7 to 10 g/dL), and patients are usually not dependent on transfusions. Thalassemia major (Cooley anemia) results from mutations of both genes and reveals a majority of hemoglobin F, which results in severe anemia, and RBC transfusions are required to sustain life. Clinical problems include growth failure, bony deformities (abnormal facial structure, pathologic fractures), hepatosplenomegaly, jaundice, leg ulcers, and cholelithiasis. As a result of transfusion dependency, iron overload results because of the body's inability to excrete iron from the transfused RBCs. This results in hemochromatosis, heart failure, cirrhosis, and endocrinopathies typically after more than 100 units.

Diagnostic Criteria

α-Thalassemia Trait

Patients with mild anemia have a hematocrit between 28% and 40%. The MCV is low despite modest anemia, and the RBC bound is normal or increased. Peripheral blood smear shows microcytic, hypochromia, target cell and acanthocytes (cell with irregularly spaced bulbous projections). The reticulocyte and iron parameters are normal.

Hemoglobin H

Patients have marked hemolytic anemia with a hematocrit between 22% and 32%. The MCV is low. The peripheral blood smear reveals hypochromia, microcytosis, target cells, and poikilocytosis. The reticulocyte count is elevated. A peripheral blood smear demonstrates the presence of hemoglobin.

β-Thalassemia Minor

Patients have modest anemia with a hematocrit between 28% and 40%. The MCV ranges from 50 to 75 fL, and the RBC count is normal or increased. The peripheral blood smear reveals hypochromia, microcytosis, and target cells, and basophilic stippling may be present. The reticulocyte count is normal or slightly elevated.

β-Thalassemia Major

Patients have severe anemia, and the hematocrit may fall to less than 10%. The peripheral blood smear is bizarre, revealing severe poikilocytosis, hypochromia, microcytosis, target cells, basophilic stippling, and nucleated RBCs.

Initiating Drug Therapy

Patients with mild thalassemia (α-thalassemia trait or β-thalassemia minor) require no treatment. Patients should be identified so that they will not be subjected to repeated evaluation and treatment for iron deficiency. Patients with hemoglobin H should take folate supplements and avoid iron and oxidative drugs such as sulfonamides. Patients with severe thalassemia are maintained on a regular transfusion schedule and receive folate supplementation. Iron chelation therapy with deferoxamine mesylate may be used when transfusions result in tissue iron overload. Deferoxamine is administered by continuous subcutaneous infusion for 10 to 24 hours/day. Adverse reactions include local irritation at the injection site, pruritus, hypotension, tachycardia, abdominal discomfort, diarrhea, nausea, and vomiting. Ocular and auditory disturbances may occur, and patients should have baseline and annual vision and hearing examinations.

Vitamin B12 Deficiency

Vitamin B_{12} (cyanocobalamin) deficiency, or pernicious anemia, is a disorder of impaired DNA synthesis. Vitamin B_{12} deficiency is considered a macrocytic anemia and may arise because of genetic or acquired abnormalities. Special populations, such as older adults, alcoholics, patients with malnutrition, strict vegans, and patient who had weight loss surgery, namely, Roux-en-Y anastomosis, are at high risk for developing vitamin B_{12} deficiency. Vitamin B_{12} is essential in maintaining the integrity of the neurologic system.

Pathophysiology

Vitamin B_{12} deficiency has several causes, including lack of intrinsic factor, inadequate intake, decreased absorption, and inadequate utilization. Other causes include fish tapeworm infestation, *H. pylori* infection, malignancy, pancreatitis, gluten enteropathy, sprue, and small bowel bacterial overgrowth (Box 51.4). More recently, the increased incidence of obesity and the option of gastric bypass surgery raise greater concerns about vitamin B_{12} deficiency. Vitamin B_{12} is water soluble and obtained by ingestion of fish, meat (beef, pork, organ meat), and dairy products. Its absorption occurs in the terminal ileum and requires intrinsic factor (found in gastric mucosa) for transport across the intestinal mucosa. Ileal absorptive sites may be congenitally absent or destroyed by inflammation or surgical resection. Other causes of decreased absorption include chronic pancreatitis, malabsorption syndromes, and drugs (oral calcium-chelating drugs, aminosalicylic acid, and biguanides).

BOX 51.4 Causes of Vitamin B_{12} Deficiency

Dietary deficiency
Decreased production of intrinsic factor
Pernicious anemia
Gastrectomy
Helicobacter pylori infection
Fish tapeworm
Pancreatic insufficiency
Surgical resection of ileum
Crohn disease

Vitamin B_{12} deficiency can present with gastric mucosal atrophy, neuropsychiatric abnormalities (paranoia, delirium, confusion, irritability, dementia), and yellow-blue color blindness. GI manifestations include anorexia, intermittent constipation and diarrhea, and poorly localized abdominal pain. An early symptom may be glossitis or weight loss. In the early stages, neurologic symptoms include peripheral loss of position and vibratory sensation in the extremities, weakness, and loss of reflexes. Later stages include spasticity, Babinski responses, and ataxia. Early diagnosis is important because neurologic defects, if left untreated, are irreversible.

Diagnostic Criteria

Serum vitamin B_{12} assay is the most commonly used method for establishing B_{12} deficiency. There is variability between laboratories as to what is a low normal vitamin B_{12} level. This ranges from 150 to 200 pg/mL. Serum concentrations of homocysteine as well as serum and urinary concentrations of methylmalonic acid can aid in the detection of vitamin B_{12} deficiency. These levels are elevated in vitamin B_{12} deficiency due to a decreased metabolism rate. In patients with an intrinsic factor deficiency, the Schilling test can confirm the diagnosis.

Initiating Drug Therapy

Pernicious anemia, malabsorption syndromes, weight loss surgery, or surgical removal of the stomach causes absence of intrinsic factor. Therefore, dietary vitamin B_{12} cannot be absorbed. In this case, therapy consists of parenteral administration of vitamin B_{12}. In the case of inadequate intake, dietary allowance and supplementation can be recommended.

Goals of Drug Therapy

Clinical improvement is evidenced by increased alertness, appetite, and cooperation. Reticulocytosis occurs within 2 to 3 days and peaks within 5 to 8 days. The hematocrit begins to rise within 2 weeks and reaches normal values within 2 months. The MCV will increase initially due to increased reticulocytes and then will gradually decrease to normal.

Vitamin B12 (Cyanocobalamin)

Pernicious anemia is typically treated with parenteral (i.e., intramuscular or deep subcutaneous) cyanocobalamin in a dose of 1,000 mcg (1,000 mcg, 1 mg) every day for 1 week followed by 1 mg every week for 4 weeks. Then, if the underlying disorder persists (e.g., pernicious anemia, surgical removal of the terminal ileum), 1 mg is administered every month for the remainder of the patient's life.

Oral vitamin B_{12} therapy is not usually recommended for pernicious anemia because of insufficient absorption due to lack of intrinsic factor.

For dietary insufficiency, the recommended daily doses of vitamin B_{12} are 0.4 mcg for patients ages 0 to 6 months; 0.5 mcg, ages 7 to 12 months; 0.9 mcg, ages 1 to 3; 1.2 mcg, ages 4 to 8; 1.8 mcg, ages 9 to 13; 2.4 mcg, ages 14 and older; 2.6 mcg in pregnant patients; and 2.8 mcg in breast-feeding women.

Folate Deficiency

Pathophysiology

Folic acid is necessary for the production of nucleic proteins, amino acids, purines, and thymine. Humans are unable to synthesize total daily folate requirements and depend on a dietary source. Major sources of folate include fresh vegetables and fruits, yeast, mushrooms, and animal organs such as liver and kidney. The minimum daily requirement is 50 to 100 mcg. Folic acid deficiency results in the development of large functionally immature erythrocytes (megaloblasts). Major causes of folic acid deficiency include inadequate intake, inadequate absorption, inadequate utilization, increased requirement (pregnancy, lactation, infancy, malignancy, increased metabolism), and increased excretion (renal dialysis; Box 51.5). Folic acid deficiency is associated with poor eating habits as seen in the elderly, alcoholics, food faddists, and those who are chronically ill. It is also seen in patients with malabsorption syndromes, Crohn disease, and celiac disease. Several drugs reported to cause folic acid deficiency include co-trimoxazole, primidone, phenytoin, and phenobarbital.

BOX 51.5 Causes of Folate Deficiency

Dietary deficiency
Decreased absorption due to
  Phenytoin
Sulfasalazine
  Trimethoprim–sulfamethoxazole
Increased requirements
  Chronic hemolytic anemia
Pregnancy
  Exfoliative skin disease

Symptoms associated with folate deficiency are similar to those in patients with vitamin B_{12} deficiency. Symptoms include weakness, fatigue, difficulty concentrating, irritability headache, shortness of breath, and palpitations. However, the major difference is the absence of neurologic manifestations.

Diagnostic Criteria

Laboratory assessment of folate status includes a serum folic acid level. Serum folic acid levels less than 4 ng/mL suggest deficiency. A low RBC folate level identifies tissue deficiency; however, the values depend on the laboratory method used. Serum homocysteine measurement provides the best evidence of tissue deficiency. Both methylmalonic acid and homocysteine must be measured because B_{12} uses the same pathway. A normal methylmalonic acid level with an elevated homocysteine level confirms the diagnosis of folate deficiency.

Initiating Drug Therapy

A serum folate level less than 4 ng/mL indicates deficiency. Folic acid 1 mg daily is started to replenish the vitamin deficiency. A serum folate level can be followed to evaluate adequate folate stores.

Goals of Drug Therapy

The evaluation of symptomatic improvement is the same as those with vitamin B_{12} deficiency.

Folate Replacement

Folic acid is present in most fruits and vegetables (citrus fruits and green leafy vegetables). The recommended dietary allowances for adult men are 0.15 to 0.2 mg and for women, 0.15 to 0.18 mg. Total body stores are approximately 5 mg and supply requirements for up to 2 to 3 months. Folate deficiency is treated by oral replacement therapy. The usual dose of folate is 1 mg daily. Higher doses up to 5 mg daily may be required for folate deficiency due to malabsorption. The duration of therapy depends on the cause of deficiency. Patients with hemolytic anemia or those with malabsorption or chronic malnutrition should receive oral folic acid indefinitely. Side effects include erythema, skin rash, nausea, abdominal distention, altered sleep patterns, irritability, mental depression, confusion, and impaired judgment.

Aplastic Anemia

Aplastic anemia is a condition of bone marrow failure that can be hereditary or arise from injury to or abnormal expression of the stem cell. Aplastic anemia is defined as pancytopenia with a hypocellular bone marrow in the absence of an abnormal infiltrate and with no increase in reticulin (Marsh et al., 2009). There are several causes of aplastic anemia (Box 51.6). One cause is direct stem cell injury from radiation, chemotherapy (alkylating agents), antimetabolites, antimitotics, toxins (benzenes), or pharmacologic agents (Box 51.7).

BOX 51.6 Causes of Aplastic Anemia

Congenital
Idiopathic/autoimmune
Systemic lupus erythematosus
Chemotherapy
Radiation therapy
Toxins
  Benzene, toluene, insecticides
Heavy metals
  Gold, arsenic, bismuth, mercury
Drugs
Pregnancy

BOX 51.7 Drugs Associated with Aplastic Anemia

Antiprotozoals (quinacrine and chloroquine, mepacrine)
NSAIDs (phenylbutazone, indomethacin, ibuprofen, sulindac, aspirin)
Anticonvulsants (hydantoins, carbamazepine, phenacemide, felbamate)
Sulfonamides
Antithyroid drugs (methimazole, methylthiouracil, propylthiouracil)
Antidiabetic drugs (tolbutamide, chlorpropamide)
Carbonic anhydrase inhibitors (acetazolamide, methazolamide)
Antihistamines (cimetidine, chlorpheniramine)
D-penicillamine
Estrogens
Sedatives and tranquilizers (chlorpromazine, prochlorperazine, piperacetazine, chlordiazepoxide, meprobamate, methyprylon)
Allopurinol

Methyldopa
Quinidine
Lithium
Guanidine
Potassium perchlorate
Thiocyanate
Carbimazole

Pathophysiology

Erythrocytes, granulocytes, and platelets, which are normally produced in the bone narrow, decrease to dangerously low levels. The bone marrow becomes hypoplastic with replacement of normal marrow hematopoietic cells by fat cells, and pancytopenia develops. This results in bleeding and increased risk of infection. Patients most commonly present with fatigue, dyspnea, weakness, and skin or mucosal hemorrhage or visual disturbance due to retinal hemorrhage. Physical examination may reveal signs of pallor, purpura, and petechiae.

Diagnostic Criteria

A CBC typically shows pancytopenia. In most cases, the hemoglobin level and neutrophil, reticulocyte, and platelet counts are depressed with a preserved lymphocyte count. The bone marrow aspirate and bone marrow biopsy appear hypocellular with scant amounts of normal hematopoietic progenitors. Magnetic resonance imaging of the vertebrae shows uniform replacement of marrow with fat.

Initiating Drug Therapy

Mild cases of aplastic anemia may be treated with supportive care. Foremost, RBC transfusions and platelets are given for bleeding, and antibiotics are given for infections (Marsh et al., 2009). Antifungals are given prophylactically for a low neutrophil count. Treatment for severe acquired aplastic anemia includes hematopoietic stem cell transplantation and immunosuppression therapy. When the cause of aplastic anemia is related to drugs or chemicals, these should be discontinued. Patients presenting with aplastic anemia should be referred to a hematologist/oncologist.

Special Population Considerations

Pediatric

The American Academy of Pediatrics recommends hemoglobin screening and risk evaluation for iron deficiency anemia in all children at 1 year of age. The Centers for Disease Control and Prevention recommends screening for low-income or newly immigrated families to begin at 9 to 12 months of age and low-birth-weight infants before 6 months of age if they are not fed iron-fortified formula. Iron deficiency anemia significantly impairs mental and psychomotor development in infants and children. Iron deficiency can be reversed with treatment; however, the reversibility of the mental and psychomotor effects is unclear. Furthermore, iron deficiency increases a child's susceptibility to lead toxicity as lead replaces iron in the absorptive pathway when iron is unavailable.

Young children are at greatest risk for iron deficiency anemia due to rapid growth, increased iron requirements, and lack of iron in the diet. Poverty, abuse, and living in a home with poor household conditions also place children at risk for iron deficiency anemia. Iron deficiency anemia is seen most commonly in children ages 6 months to 3 years. Those at highest risk are low-birth-weight infants after age 2 months, breast-fed term infants who receive no iron-fortified food or supplemental iron after age 4 months, and formula-fed term infants who are not consuming iron-fortified formula. During the first months of life, the newborn rapidly uses iron stores due to an accelerated growth rate and increased blood volume. Maternally derived iron stores are generally sufficient for the first 4 to 6 months; however, sustained growth demands an increased iron supply. By the end of the second year of life, the growth rate decreases and accompanying iron needs level off. During adolescence, growth accelerates and iron needs increase. Adolescent girls are at increased risk and need additional iron to compensate for menstrual loss. Patients with iron deficiency who are responding poorly to the usual dietary supplementation regimens should be screened for lead poisoning. Heavy metal poisoning, as with lead and bismuth, is often overlooked.

Geriatric

Anemia should not be accepted as an inevitable consequence of aging. Mild anemia, less than 10 g/dL as defined by the WHO criteria, is associated with significant negative outcomes including decreased physical performance, increased number of falls, increased frailty, decreased cognition, increased dementia, increased hospitalization, and increased mortality.

Anemia in the elderly is a risk factor of adverse outcomes including hospitalization, morbidity, and mortality. The prevalence of anemia increases after 50 years of age and exceeds 20% of those 85 years and older (Goodnough & Schrier, 2014). There is no specific recommended hemoglobin threshold, but it is prudent to maintain hemoglobin level of 9 to 10 g/dL unless otherwise indicated. The most common causes of anemia in elderly patients are chronic disease (CKD, infections, malignancies, and inflammatory disorders), iron deficiency, and nutritional and metabolic disorders. Anemia resulting from blood loss due to surgery, injury, and GI and genitourinary bleeding is more common in hospitalized patients.

Women

Pregnant women and women who are 4- to 6-week postpartum are at risk for asymptomatic iron deficiency anemia. As such, the American Academy of Family Physician, U.S. Preventative Services Task Force, and the Centers for Disease Control and Prevention recommend routine screening. Pregnant women who are iron deficient are at increased risk for a preterm delivery and delivering a low-birth-weight baby. Two to three times more iron is required in pregnancy and in childhood. In pregnant women who had a previous pregnancy with a fetus or infant with a neural tube defect, the recommended dose of folate is 5 mg daily. Also, women who may become pregnant and have seizure disorders should take folate supplementation.

Monitoring Patient Response

In almost all cases of anemia, evaluation should proceed in an orderly manner and therapy withheld until a specific diagnosis can be made. Patients with significant cardiopulmonary disease, who may be compromised by a decreased oxygen capacity, require immediate correction of anemia. This may require inpatient evaluation and consideration of transfusion therapy when they are experiencing dyspnea, angina, or marked fatigue related to anemia. Once treatment has been initiated, patient response should be evaluated on at least a monthly basis. Correction of anemia decreases morbidity and reduces hospitalization and mortality among patients with CKD. Benefits of correcting anemia include improvements in the patient's quality of life, exercise capacity, cognitive function, and sexual function.

Patient Education

Patients need to be told to what extent the anemia accounts for symptoms, what the possible causes are, and what the appropriate workup will be. Patient education and the importance of adherence to therapy are integral to successful management. Because some cases of anemia require the need for medication, the patient needs to be informed about possible side effects and when to report dangerous side effects.

Nutrition

All patients are encouraged to limit the use of alcohol, to avoid tobacco, to exercise, and to consume a diet of meat, poultry, fish, and fresh fruits and vegetables. To prevent deficiency, all patients are encouraged to eat fortified foods (fortified cereals, dairy products) or take supplements as prescribed by their physician. Patients with specific problems, such as pica, may need additional counseling.

Complementary and Alternative Medications

Herbal medicine to supply iron, iodine, and calcium include yellow dock root, Irish moss, and horsetail in equal parts made into a tea. Other herbal medicines for the treatment of iron deficiency include burdock, devil's bit, meadow sweet, mullein leaves, restharrow, salep, silver weed, stinging nettle, strawberry leaves, and toad flax. Patients should be educated that herbs are not regulated by the U.S. FDA and may interact with prescription medications. Patients must also understand that they should report any adverse reactions and stop the herbal medication immediately.

Case Study*

M.W. is a 69-year-old African American man and was referred to clinic for evaluation of increasing shortness of breath.

Past medical history
Chronic renal insufficiency
Hypertension
Congestive heart failure
Diabetes mellitus type 2, poor control
Deep vein thrombosis
Alcohol abuse
Chronic obstructive pulmonary disease with respiratory failure
Family history
Noncontributory
Physical examination
Height 69 inches, weight 205 lb
Blood pressure: 138/88
Pulse 86 beats/min, regular
Lungs clear, neck supple negative for jugular venous distention
Lower extremities +1 edema
Laboratory findings
Scr = 2.8 K^+ = 5.1
BUN = 56 Na^+ = 147
WBC = 5.0 Hb = 8.2
Hct = 24.6
Serum ferritin 189 mg/dL
Social history
Tobacco: 52 pack-years
Alcohol: distant past

Diagnosis: Anemia Of Ckd

1. List specific goals of treatment for M.W.
2. What drug therapy would you prescribed? Why?
3. What are the parameters for monitoring success of therapy?
4. Discuss specific patient education based on the prescribed therapy.
5. List one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What would be the choice for second-line therapy?
7. What over-the-counter and/or alternative medications would be appropriate for M.W.?
8. What dietary and lifestyle changes would you recommended for M.W.?
9. Describe one or two drug–drug or drug–food interactions for the selected agent.

UNIT 13
Pharmacotherapy in Health Promotion

52 Immunizations

Jean M. Scholtz

The use of immunizations is described as one of the 10 greatest public health achievements. Immunization rates in the United States are at their highest, with more than 90% of children 3 years of age receiving all required vaccines (Hill et al., 2015). As a result, cases of diphtheria, polio, rubella, mumps, measles, and *Haemophilus influenzae* type B (Hib) are at record low levels. Immunization prophylaxis is important for all age groups—infants through older adults. Unfortunately, immunization rates in adolescents and adults are not as high as those in preschool age children. Immunization rates in persons 18 to 64 years of age against influenza and pneumococcus range from 33% to 69%, with pneumonia and influenza the 8th leading cause of death in the United States (Xu et al., 2014). There are even lower immunization rates in the socioeconomically disadvantaged and various ethnicities. In addition, there are individuals who continue to be antivaccinators due to the fear of autism. Practitioners need to develop a system that facilitates review of immunization status at all health care visits so that no opportunity is missed to educate and update immunizations for those who are not adequately vaccinated and thus inadequately protected against preventable diseases.

Immunization prophylaxis offers an opportunity to prevent disease, improve clinical outcomes for those at high risk, and realize significant savings to the person in terms of cost, time, and resources. Healthy People 2020 continues to promote the movement throughout the United States to increase immunization rates and reduce preventable infectious diseases. They continue to have a significant impact on preventing communicable diseases, reducing preventable complications, and improving clinical outcomes. However, because these diseases persist in other countries, immunization prophylaxis needs to be continued. Recommendations for immunization prophylaxis come from multiple sources, and useful resources are listed in Box 52.1. The CDC is responsible for providing vaccine management, technical assistance, information, epidemiology, and assessment. In February of each year, the immunization schedule is reviewed and revised as indicated.

Characteristics of Immunizations

Many infectious diseases can be prevented by immunoprophylaxis, which is accomplished either through active or passive immunization. Active immunization involves giving a person either live or attenuated (live but killed; inactivated) vaccine to stimulate the development of immune system defenses against future natural exposure.

Active immunization involves administration of all or part of a microorganism or a modified product of that microorganism (e.g., toxoid, a purified antigen, or an antigen produced by genetic engineering) to evoke an immune response that mimics the response of the body to natural infection but that usually presents little or no risk to the recipient. Protection may be afforded for a limited time or for a lifetime. If protection is for a limited time, the vaccine must be readministered at specified intervals.

Passive immunization is used for those people who have already been exposed or who have the potential to be exposed to certain infectious agents. Passive immunization involves the administration of a preformed antibody when the recipient has a congenitally acquired defect or immunodeficiency, when exposure is likely to result in high-risk complications, or when time does not permit adequate protection by active immunization (e.g., immunizations against rabies or hepatitis B). In addition, passive immunity can be used therapeutically during active disease states to help suppress the effects of a toxin or the inflammatory response.

Vaccines

Vaccines are the pharmacologic substances used to provide or boost immunity to disease. The major constituents of vaccines include active immunizing antigens (toxoid, live virus, or killed bacteria), suspending fluid, preservatives, stabilizers, antibiotics, and adjuvants. The differences depend on the manufacturer, and the person prescribing or administering the vaccine should check the package insert for the active and inert ingredients for each product. Potential allergic reactions may result from one or more of the preservatives, stabilizers, adjuvants, or antibiotics in the vaccine, and the recipient's sensitivity to one or more of the additives should be anticipated as a hypersensitivity. Current vaccines licensed in the United States are identified in Box 52.2.

BOX 52.2 Vaccines Licensed in the United States

Adenovirus type 4 and type 7
Anthrax
BCG
Diphtheria and tetanus toxoid adsorbed
Diphtheria and tetanus toxoids and acellular pertussis vaccine adsorbed
Diphtheria and tetanus toxoids and acellular pertussis vaccine adsorbed and inactivated polio
Diphtheria and tetanus toxoids and acellular pertussis adsorbed, inactivated polio, and *H. influenzae* B conjugate
H. influenzae B conjugate
H. influenzae B conjugate and hepatitis B
Hepatitis A
Hepatitis B
Hepatitis A and hepatitis B
Human papillomavirus quadrivalent (types 6, 11, 16, 18)
Human papillomavirus 9-valent
Human papillomavirus bivalent (types 16, 18)
Influenza A (H1N1)
Influenza (H5N1)
Influenza virus (trivalent, types A and B)
Influenza vaccine (quadrivalent, types A and B, intranasal, live)
Influenza vaccine (quadrivalent, types A and B, injectable)
Japanese encephalitis
Measles and mumps (live)
Measles, mumps, and rubella (live)
Measles, mumps, rubella, and varicella (live)

Meningococcal (groups A, C, Y, and W-135) oligosaccharide diphtheria CRM197 conjugate
Meningococcal polysaccharide (serogroups A, C, Y, and W-135) diphtheria toxoid conjugate
Meningococcal polysaccharide groups A, C, Y, and W-135 combined
Meningococcal (groups C and Y) and *Haemophilus* b tetanus toxoid conjugate and W-135
Meningococcal (groups A, C, Y, and W-135) polysaccharide diphtheria toxoid conjugate
Meningococcal group B
Plague
Pneumococcal polyvalent
Pneumococcal 7-valent conjugate
Pneumococcal 13-valent conjugate
Poliovirus, inactivated
Rabies
Rotavirus (live, oral)
Rotavirus pentavalent (live)
Smallpox (live)
Tetanus and diphtheria toxoids adsorbed for adults
Tetanus toxoid adsorbed
Tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis, adsorbed
Typhoid (live, oral)
Typhoid Vi polysaccharide
Varicella virus (live)
Yellow fever
Zoster (live)

The recommended immunization schedule for persons aged 0 through 18 years in the United States is listed in Figure 52.1. The schedules have columns added at 4 to 6 years and 11 to 12 years of age to highlight school entry and adolescent age group vaccine recommendations. Footnotes are listed for each vaccine and contain the recommendations for routine vaccination, catch-up, and vaccination to individuals with high-risk conditions or special circumstances. Figure 52.2 presents the recommended immunizations for persons aged 4 months through 18 years who are behind in immunizations.

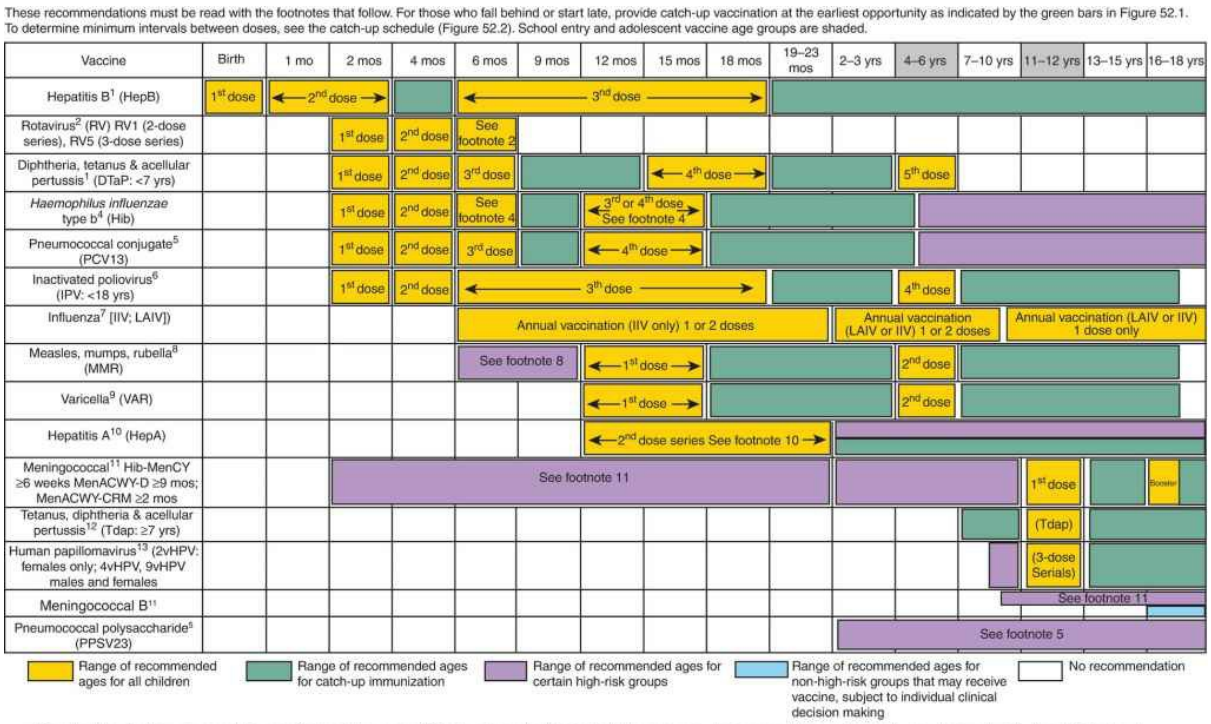

FIGURE 52.1 Recommended immunization schedule for persons aged 0 through 18 years —United States, 2016 (Centers for Disease Control and Prevention, 2014).

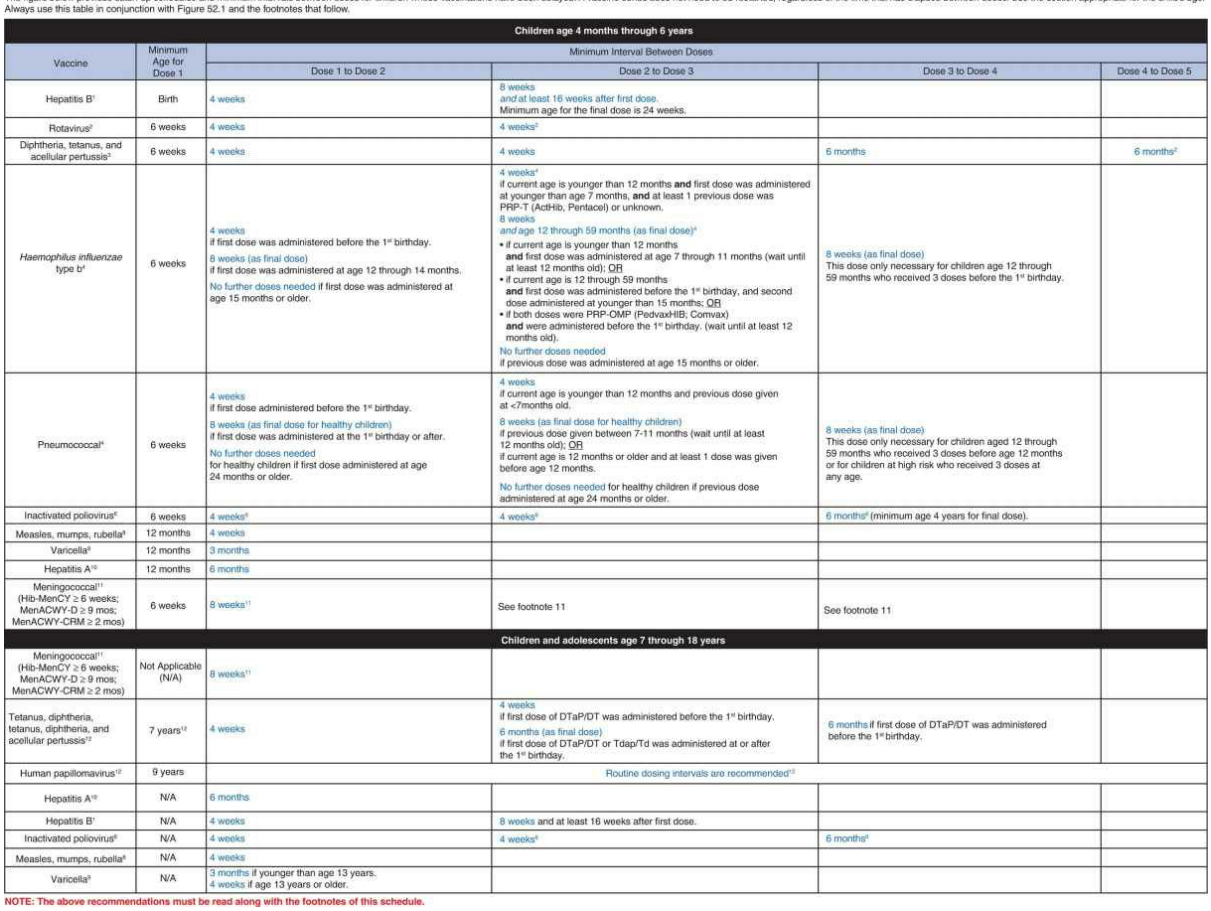
The figure below provides catch-up schedules and minimum intervals between doses for children whose vaccinations have been delayed. A vaccine series does not need to be restarted, regardless of the time that has elapsed between doses. Use the section appropriate for the child's age. Always use this table in conjunction with Figure 52.1 and the footnotes that follow.



Vaccine	Minimum Age for Dose 1	Minimum Interval Between Doses			
		Dose 1 to Dose 2	Dose 2 to Dose 3	Dose 3 to Dose 4	Dose 4 to Dose 5
Children age 4 months through 6 years					
Hepatitis B[1]	Birth	4 weeks	8 weeks *and* at least 16 weeks after first dose. Minimum age for the final dose is 24 weeks.		
Rotavirus[2]	6 weeks	4 weeks	4 weeks[2]		
Diphtheria, tetanus, and acellular pertussis[3]	6 weeks	4 weeks	4 weeks	6 months	6 months[3]
Haemophilus influenzae type b[4]	6 weeks	4 weeks if first dose was administered before the 1st birthday. 8 weeks (as final dose) if first dose was administered at age 12 through 14 months. No further doses needed if first dose was administered at age 15 months or older.	4 weeks[4] if current age is younger than 12 months **and** first dose was administered at younger than age 7 months, **and** at least 1 previous dose was PRP-T (ActHib, Pentacel) or unknown. 8 weeks *and* age 12 through 59 months (as final dose)[4] • if current age is younger than 12 months **and** first dose was administered at age 7 through 11 months (wait until at least 12 months old); OR • if current age is 12 through 59 months **and** first dose was administered before the 1st birthday, and second dose administered at younger than 15 months; OR • if both doses were PRP-OMP (PedvaxHIB; Comvax) **and** were administered before the 1st birthday. (wait until at least 12 months old). No further doses needed if previous dose was administered at age 15 months or older.	8 weeks (as final dose) This dose only necessary for children age 12 through 59 months who received 3 doses before the 1st birthday.	
Pneumococcal[5]	6 weeks	4 weeks if first dose administered before the 1st birthday. 8 weeks (as final dose for healthy children) if first dose was administered at the 1st birthday or after. No further doses needed for healthy children if first dose administered at age 24 months or older.	4 weeks if current age is younger than 12 months and previous dose given at <7months old. 8 weeks (as final dose for healthy children) if previous dose given between 7-11 months (wait until at least 12 months old); OR if current age is 12 months or older and at least 1 dose was given before age 12 months. No further doses needed for healthy children if previous dose administered at age 24 months or older.	8 weeks (as final dose) This dose only necessary for children aged 12 through 59 months who received 3 doses before age 12 months or for children at high risk who received 3 doses at any age.	
Inactivated poliovirus[6]	6 weeks	4 weeks[6]	4 weeks[6]	6 months[6] (minimum age 4 years for final dose).	
Measles, mumps, rubella[8]	12 months	4 weeks			
Varicella[9]	12 months	3 months			
Hepatitis A[10]	12 months	6 months			
Meningococcal[11] (Hib-MenCY ≥ 6 weeks; MenACWY-D ≥ 9 mos; MenACWY-CRM ≥ 2 mos)	6 weeks	8 weeks[11]	See footnote 11	See footnote 11	
Children and adolescents age 7 through 18 years					
Meningococcal[11] (Hib-MenCY ≥ 6 weeks; MenACWY-D ≥ 9 mos; MenACWY-CRM ≥ 2 mos)	Not Applicable (N/A)	8 weeks[11]			
Tetanus, diphtheria, tetanus, diphtheria, and acellular pertussis[12]	7 years[12]	4 weeks	4 weeks if first dose of DTaP/DT was administered before the 1st birthday. 6 months (as final dose) if first dose of DTaP/DT or Tdap/Td was administered at or after the 1st birthday.	6 months if first dose of DTaP/DT was administered before the 1st birthday.	
Human papillomavirus[12]	9 years	Routine dosing intervals are recommended[12]			
Hepatitis A[10]	N/A	6 months			
Hepatitis B[1]	N/A	4 weeks	8 weeks and at least 16 weeks after first dose.		
Inactivated poliovirus[6]	N/A	4 weeks	4 weeks[6]	6 months[6]	
Measles, mumps, rubella[8]	N/A	4 weeks			
Varicella[9]	N/A	3 months if younger than age 13 years. 4 weeks if age 13 years or older.			

NOTE: The above recommendations must be read along with the footnotes of this schedule.

FIGURE 52.2 Catch-up immunization schedule for persons aged 4 months through 18 years who start late or who are more than 1 month behind—United States, 2016.

Recommendations for hepatitis B; rotavirus (RV1/RV5); diphtheria, tetanus, and pertussis (DTaP); tetanus, diphtheria, and pertussis (Tdap); *H. influenzae* type B (Hib); pneumococcus; poliomyelitis; influenza; measles, mumps, and rubella (MMR); varicella; hepatitis A; human papillomavirus; and meningococcus are included from birth to age 18.

Combination vaccines are available that assist in reducing the number of injections a child must receive at any one time. In addition, recommended acceptable ranges for administration provide some flexibility regarding the number of injections administered at any one time as recommendations for catch-up vaccinations. A consideration for flexible scheduling should include parental or guardian compliance with appointments as well as office follow-up methods used for those patients who do not keep scheduled appointments for immunizations.

Special Circumstances

Preterm infants and children who are immunocompromised, infected with human immunodeficiency virus (HIV), lack a spleen, or have a personal or family history of seizures require special consideration when immunization prophylaxis is reviewed and administered.

Preterm Infants

Preterm (<37 weeks' gestation) and low-birth-weight (<2,500 g) infants are at high risk for vaccine-preventable deaths due to an immature immune system and possible decreased maternal antibody levels. Preterm infants born to mothers who are hepatitis B surface antigen (HBsAg) negative should receive their first hepatitis B immunization at 1 month of age or at hospital discharge.

Preterm infants born to mothers who test positive for HBsAg should receive hepatitis B immune globulin within 12 hours of birth and concurrent hepatitis B vaccine (in the appropriate dose per package insert) at a different site. If the maternal HBsAg status is unknown, the vaccine should be given at 1, 2, and 6 months of age. In addition, all preterm infants should receive the influenza vaccine annually in the fall beginning at age 6 months.

Immunosuppressed Children

Children who are immunosuppressed or immunodeficient are at risk for actually contracting the disease or experiencing serious adverse effects from live bacteria or live virus vaccines. Live vaccines are therefore contraindicated. In general, experience with vaccine administration to an immunosuppressed or immunodeficient child is limited. Efficacy is suboptimal because their ability to develop immunogenicity to a specific agent is altered owing to a depressed immune system. Theoretical considerations are the only guide because experiential data are lacking or adverse consequences have not been reported.

Children with a deficiency in antibody-synthesizing capacity cannot respond to vaccines. These children should receive regular doses of immune globulin, usually intravenous immune globulin, that provides passive protection against many infectious diseases. Specific immune globulins (e.g., varicella-zoster immune globulin) are available for postexposure prophylaxis for some infections. An exception appears to be the judicious use of live virus varicella vaccine in children with acute lymphocytic leukemia in remission in whom the risk of natural varicella outweighs the risk from the attenuated vaccine virus. This vaccine may be obtained from the manufacturer on a compassionate use protocol for patients' aged 12 months to 17 years who have acute lymphocytic leukemia in remission for at least 1 year.

Children with Transplants

Transplant recipients (e.g., bone marrow transplant recipients) should also be viewed in a special light. Some experts elect to reimmunize all children without serologic evaluation, and others, because of the limited amount of data, recommend that immunization protocols be developed for these children in conjunction with experts in the fields of infectious disease and immunology. Information about the use of live virus vaccines in organ transplant recipients is also limited. Only inactivated poliovirus vaccine should be given to transplant recipients and their household contacts.

Children Taking Corticosteroids

Children receiving corticosteroids also need careful consideration and thorough review of their medical history, including a review of the underlying disease, the specific dose and schedule of corticosteroids prescribed, and the current immunization status, which includes an evaluation of risk factors relative to infectious disease. In general, children who have a disease (which suppresses the immune response) and who are receiving either systemic or locally administered corticosteroids (which also suppress the immune response) should not be given live virus vaccines except in special circumstances. The guidelines for administering a live virus vaccine to patients receiving corticosteroid therapy are based on the dosage in relation to the child's weight in kilograms and the duration of corticosteroid therapy. The following treatments do not contraindicate administration:

1. Topical therapy or local injections of corticosteroids
2. Physiologic maintenance doses of corticosteroids
3. Low or moderate dosage of systemic corticosteroids (less than 2 mg/kg/d of prednisone [Deltasone] or its equivalent or less than 20 mg/d or on alternate days if the child weighs greater than 10 kg)

Special consideration should be given if high-dose corticosteroids are prescribed. Administration of high-dose corticosteroids (≥2 mg/kg/d of prednisone or its equivalent or ≥20 mg/d if the child weighs >10 kg) given daily or on alternate days for 14 days or less preempts the administration of live virus vaccines until the treatment is discontinued. Some experts recommend delaying immunization until 2 weeks after discontinuation of therapy (Centers for Disease Control and Prevention, 2011).

Patients who receive high doses of systemic corticosteroids—daily or on alternate days for 14 days or more—should not receive live virus vaccines until steroid therapy has been discontinued for at least 1 month. In addition, if clinical or laboratory evidence of systemic immunosuppression results from prolonged application, live virus vaccines should not be administered until corticosteroid therapy has been discontinued for at least 1 month.

Children with Seizures

Infants and children with a personal or family history of seizures are at increased risk for having a convulsion after receiving either pertussis (as DTaP) or measles (as MMR) vaccine. Seizures are usually brief, self-limited, and generalized and occur in conjunction with fever

(Pickering et al., 2009). However, in the case of DTaP vaccine administered during infancy, administration may coincide with or hasten the inevitable recognition of a seizure-related disorder, such as infantile spasms or epilepsy. This causes confusion about the role of the pertussis vaccine, and in this instance, pertussis immunization should be deferred until a progressive neurologic disorder is excluded or the cause of the seizure diagnosed.

Measles immunization, however, is usually given at an age when the cause and nature of the seizure activity have been established. Therefore, measles immunization should not be deferred in children with a history of one or more seizures.

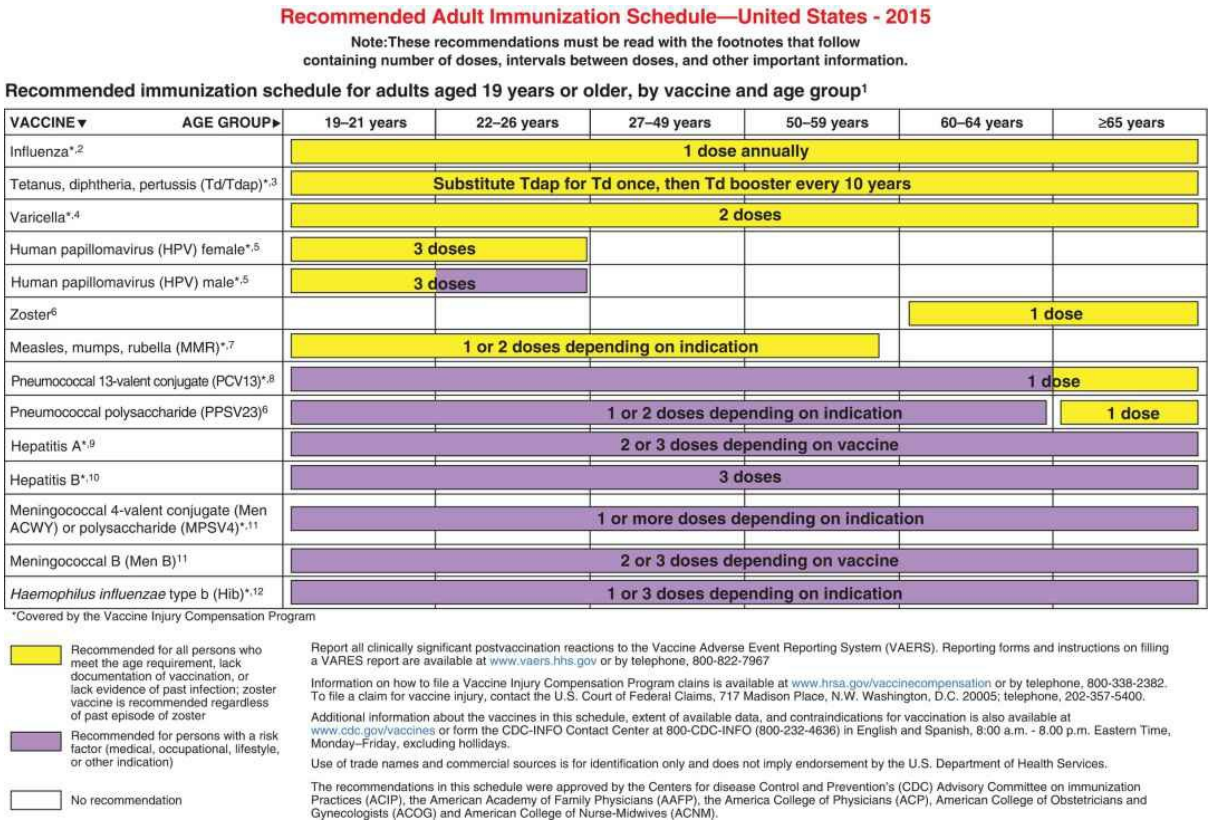
Adolescents

Adolescents continue to be adversely affected by vaccine-preventable disease, including varicella, hepatitis B, measles, meningococcus, HPV, and rubella. Recommendations for adolescents at ages 11 and 12 aim to improve the vaccine coverage and to establish routine visits to health care providers. These strategies reflect the recommendations (see Box 52.1) of the Advisory Committee on Immunization Practices (ACIP), American Academy of Pediatrics (AAP), American Academy of Family Physicians, and American Medical Association. In addition to providing an opportunity for administering needed vaccines, such as hepatitis B, varicella, second dose of MMR, tetanus and diphtheria booster, and HPV, this visit provides an opportunity to render other recommended preventive services, including health behavior guidance; screening for biomedical, behavioral, and emotional conditions; and delivery of other health services. For more information, see Figure 52.1 and Box 52.1.

Immunization Recommendations for Adults

Immunization prophylaxis is as important for adults as it is for children. However, the practice of assessing the vaccination status of adults at their routine health visits remains an issue.

As a result, many adults continue to be affected adversely by vaccine-preventable diseases such as varicella, pertussis, measles, and rubella. The guidelines are updated yearly in February, and all schedules are published in *Morbidity and Mortality Weekly Report* (http://www.cdc.gov/mmwr/index.html) and may be found at http://www.cdc.gov/vaccines/schedules/index.html. The ACIP recommendations are available at http://www.cdc.gov/vaccines/hcp/acip-recs/. Each patient's immunization records should be reviewed at each patient visit and determined if any vaccines are required. For more information, see Figure 52.3 and Box 52.1.



Recommended Adult Immunization Schedule—United States - 2015

Note:These recommendations must be read with the footnotes that follow containing number of doses, intervals between doses, and other important information.

Recommended immunization schedule for adults aged 19 years or older, by vaccine and age group[1]

VACCINE ▼ AGE GROUP ▶	19–21 years	22–26 years	27–49 years	50–59 years	60–64 years	≥65 years
Influenza*,2	1 dose annually					
Tetanus, diphtheria, pertussis (Td/Tdap)*,3	Substitute Tdap for Td once, then Td booster every 10 years					
Varicella*,4	2 doses					
Human papillomavirus (HPV) female*,5	3 doses					
Human papillomavirus (HPV) male*,5	3 doses					
Zoster6					1 dose	
Measles, mumps, rubella (MMR)*,7	1 or 2 doses depending on indication					
Pneumococcal 13-valent conjugate (PCV13)*,8	1 dose					
Pneumococcal polysaccharide (PPSV23)6	1 or 2 doses depending on indication					1 dose
Hepatitis A*,9	2 or 3 doses depending on vaccine					
Hepatitis B*,10	3 doses					
Meningococcal 4-valent conjugate (Men ACWY) or polysaccharide (MPSV4)*,11	1 or more doses depending on indication					
Meningococcal B (Men B)11	2 or 3 doses depending on vaccine					
Haemophilus influenzae type b (Hib)*,12	1 or 3 doses depending on indication					

*Covered by the Vaccine Injury Compensation Program

Recommended for all persons who meet the age requirement, lack documentation of vaccination, or lack evidence of past infection; zoster vaccine is recommended regardless of past episode of zoster

Recommended for persons with a risk factor (medical, occupational, lifestyle, or other indication)

No recommendation

Report all clinically significant postvaccination reactions to the Vaccine Adverse Event Reporting System (VAERS). Reporting forms and instructions on filling a VARES report are available at www.vaers.hhs.gov or by telephone, 800-822-7967

Information on how to file a Vaccine Injury Compensation Program claims is available at www.hrsa.gov/vaccinecompensation or by telephone, 800-338-2382. To file a claim for vaccine injury, contact the U.S. Court of Federal Claims, 717 Madison Place, N.W. Washington, D.C. 20005; telephone, 202-357-5400.

Additional information about the vaccines in this schedule, extent of available data, and contraindications for vaccination is also available at www.cdc.gov/vaccines or form the CDC-INFO Contact Center at 800-CDC-INFO (800-232-4636) in English and Spanish, 8:00 a.m. - 8.00 p.m. Eastern Time, Monday–Friday, excluding hollidays.

Use of trade names and commercial sources is for identification only and does not imply endorsement by the U.S. Department of Health Services.

The recommendations in this schedule were approved by the Centers for disease Control and Prevention's (CDC) Advisory Committee on immunization Practices (ACIP), the American Academy of Family Physicians (AAFP), the America College of Physicians (ACP), American College of Obstetricians and Gynecologists (ACOG) and American College of Nurse-Midwives (ACNM).

FIGURE 52.3 Recommended adult immunization schedule—United States, 2016.

Disease-Specific Vaccine Recommendations

Pneumococcal Vaccine 23-Valent (PPSV23)

Pneumococcal infection causes an estimated 5,000 deaths annually in the United States, accounting for more deaths than any other vaccine-preventable bacterial disease. *Streptococcus pneumoniae* colonizes the upper respiratory tract and can cause disseminated invasive infections, including bacteremia and meningitis, pneumonia and other lower respiratory tract infections, and upper respiratory tract infections, including otitis media and sinusitis. The pneumococcal vaccine protects against invasive bacteremic disease, although existing data suggest that it is less effective in protecting against other types of pneumococcal infections.

The ACIP recommends giving one dose of pneumococcal vaccine to elderly patients (65 years or older), with an additional dose given earlier to identified high-risk populations (Box 52.3). Two available vaccines include a 13-valent pneumococcal conjugate and a 23-valent purified capsular polysaccharide antigens of *S. pneumoniae*. If an elderly patient's vaccination status is unknown, he or she should receive one dose of the vaccine. There are no data to support revaccination beyond two doses.

BOX 52.3 Recommendations for the Use of Pneumococcal Vaccine

Groups for Which Vaccination Is Recommended

People aged 65 y and older

People aged 2–64 y with chronic cardiovascular disease including congestive heart failure and cardiomyopathies, chronic pulmonary disease including chronic obstructive lung disease, emphysema, and asthma, sickle cell disease, diabetes mellitus, and people who smoke

People aged 2–64 y with alcoholism, chronic liver disease including cirrhosis, cochlear implants, or cerebrospinal fluid leaks

People aged 2–64 y with functional or anatomic asplenia

People aged 2–64 y living in nursing homes or other long-term care facilities

Immunocompromised People

Immunocompromised people aged 2 y and older, including those with HIV infection, leukemia, lymphoma, Hodgkin disease, multiple myeloma, generalized malignancy, chronic renal failure, or nephrotic syndrome; those receiving immunosuppressive chemotherapy (including corticosteroids); and

those who have received an organ or bone marrow transplant

Response to Vaccine

Antibodies develop within 2 to 3 weeks in healthy young adults; immune responses are not consistent among all 23 serotypes in the vaccine. Antibody concentrations and responses to individual antigens tend to be lower in the following populations:

- People aged 65 years or older
- People with alcoholic cirrhosis, chronic obstructive pulmonary disease, type 1 diabetes mellitus, Hodgkin's disease, or asthma
- People who smoke
- People with chronic renal failure requiring dialysis, renal transplantation, or nephrotic syndrome
- People with acquired immunodeficiency syndrome or HIV infection

Special Circumstances

Antibody response is diminished or absent in people who are immunocompromised or who have leukemia, lymphoma, or multiple myeloma. The antibody levels to most pneumococcal vaccine antigens remain elevated for at least 5 years in healthy adults.

A more rapid decline (within 3 to 5 years) occurs in certain children who have undergone splenectomy after trauma and in those who have sickle cell disease. Antibody concentrations also decline after 5 to 10 years in elderly people, those who have undergone splenectomy, patients with renal disease requiring dialysis, and people who have received transplants. A lower antibody response or rapid decline in antibody levels is also noted in patients with Hodgkin's disease and multiple myeloma. At least 2 weeks should elapse between immunization and the initiation of chemotherapy or immunosuppressive therapy.

Revaccination is recommended once for patients who are aged 2 or older, who are at highest risk for serious pneumococcal infection, and who are likely to have a rapid decline in antibody levels provided that 5 years has elapsed since receiving the first dose of vaccine.

Pneumococcal Conjugate Vaccine

In February 2010, the U.S. Food and Drug Administration licensed a 13-valent pneumococcal conjugate vaccine, PCV13 (Prevnar-13). This vaccine is recommended for universal use in children aged 23 months and younger. The number of doses for the primary series varies with the age of the child at the first dose.

Children ages 24 to 59 months who are at high risk for invasive pneumococcal infection and who have not been previously immunized should also receive 23-valent vaccine to expand the serotype coverage. In June 2012, the ACIP recommended routine use of the PCV13 for adults with immunocompromising conditions. It should be administered in addition to the PPSV23 to all eligible adults.

Influenza Vaccine

Influenza and pneumonia are the eighth leading causes of death in the United States and fifth in older adults. Fatalities from influenza begin to rise in midlife and are highest in persons with chronic disease. Measures available to reduce the incidence of influenza include immunoprophylaxis with inactivated (killed virus) vaccine and chemoprophylaxis. Before the influenza season gets under way, vaccination of people at risk and those likely to transmit influenza to at-risk populations is the most effective measure. The vaccine is associated with a decrease in influenza-related respiratory illness in all age groups, decreased hospitalization and death in people at high risk, decreased incidence of otitis media in children, and decreased work and school absenteeism. Influenza vaccine is recommended in anyone aged 6 months and older.

Two types of influenza vaccine are available—inactivated virus and live attenuated vaccine (in the form of nasal spray). The live virus is recommended for those aged 2 to 49 years and is contraindicated in patients who are immunocompromised and require a protected environment, health care workers, and household members who are in close contact with the immunocompromised individual. If a live virus is given, the patient should not have contact with those who are immunocompromised for 7 days. The antigenic composition of the influenza vaccine changes each year; thus, this vaccine must be administered every year. It provides protection against influenza A and B and is available as either a trivalent inactivated influenza vaccine (IIV3) or a quadrivalent live (LAIV4) or inactivated vaccine (IIV4). The IIV3 vaccine is available in a high-dose formulation for patients 65 years and older, and there is an intradermal IIV4 formulation approved for patients 18 to 64 years. Children aged 6 months through 8 years require 2 doses of influenza vaccine (administered ≥4 weeks apart) during their first season of vaccination to optimize response. Recombinant (RIV3) and cell-cultured (ccIIV3) influenza vaccines should be utilized in patients with severe allergic and anaphylactic reactions to various influenza vaccine components (Centers for Disease Control and Prevention, 2015a, 2015b, 2015d).

Groups at Risk

People at increased risk for influenza-related complications include:

1. Those aged 50 and older
2. Children ages 6 to 23 months
3. Adults and children with pulmonary disease, including asthma
4. Adults and children who have required regular medical follow-up or hospitalization during the preceding year because of chronic metabolic diseases (including diabetes mellitus), renal dysfunction, hemoglobinopathies, or immunosuppression (including immunosuppression caused by medications or HIV infection)
5. Children and teenagers on long-term aspirin therapy who might be at risk for

development of Reye syndrome after influenza
6. Women in the second or third trimester of pregnancy during the influenza season
7. Persons who live with or care for persons at high risk, including health care workers and household contacts (including children from birth to age 23 months)

Transmission of Influenza

Just as immunizing people in groups at high risk for flu and its complications is important, so too is immunizing those who are most likely to transmit the disease. Groups that can transmit influenza to people at high risk include health care workers (in hospital and outpatient settings and in emergency response service), employees of nursing homes and chronic care facilities who have contact with patients or residents, employees of assisted living and other residences for people in high-risk groups, providers of home care to people at high risk (e.g., visiting nurses, volunteers), household contacts of high-risk individuals, and providers of essential community services. Additional populations for consideration include people with HIV infection, breast-feeding mothers, people traveling to foreign countries, students or other people in institutional settings, and the general populace who want to reduce the likelihood of contracting influenza.

The current 2- to 3-month time frame over which patients are traditionally immunized is too short to fully implement immunization recommendations and inconsistent with the duration of influenza activity. Health care providers and patients should re-evaluate their approach to influenza vaccination and recognize the need to extend the immunization time period into January and beyond. To increase influenza immunization rates, the CDC and other professional societies recommend an expanded immunization season, with vaccination offered at every opportunity between October and May.

Antibody development after vaccination can take as long as 2 weeks in healthy adults and as long as 6 weeks in children—or 2 weeks after the second dose. Most persons recommended for influenza vaccination should receive a single dose each year. The exception is children ages 6 months to 9 years who are receiving an influenza vaccine for the first time. They should receive 2 doses administered at least 1 month apart. No influenza vaccine is currently approved for children age 6 months and younger; these vulnerable infants should be protected indirectly through the vaccination of close contacts.

Chemoprophylaxis with antiviral agents, amantadine (Symmetrel), rimantadine (Flumadine), zanamivir (Relenza), and oseltamivir (Tamiflu) can also be helpful. When administered within 48 hours of the onset of illness, they can reduce the severity and shorten the duration of illness in otherwise healthy people. Oseltamivir can be used in the prevention of influenza in adults and children aged 13 and older.

Meningococcal Vaccine

Approximately 3,000 cases of meningococcal diseases occur in the United States each year, with a fatality rate of 10% despite antibiotic therapy early in the illness. During 1991 to 1998, the highest rate occurred among infants younger than age 12 months. The three serogroups of meningococcal disease that are most commonly seen in the United States are serogroups B, C, and Y. Three kinds of meningococcal vaccines are now available in the United States. Meningococcal polysaccharide (MPSV4) and meningococcal conjugate (MCV4) provide coverage against types A, C, Y, and W. MPSV4 is the only vaccine licensed for patients older than 55 years of age, and MCV4 is the preferred vaccine for patients 55 years of age or younger. The recently released serogroup B meningococcal (MenB) vaccines provide short-term protection against most strains of serogroup B meningococcal disease. The Advisory Committee on Immunization Practices recommends routine vaccination of all adolescents aged 11 to 18 years with the quadrivalent meningococcal conjugate vaccine (MCV4). A single dose should be administered at age 11 or 12 years with a booster dose at age 16 years for persons who receive the first dose before age 16 years. The MenB vaccine series should be administered to persons aged 16 to 23 years (preferred age 16 to 18 years) with routine vaccination of certain persons at increased risk for meningococcal disease with MenACWY and serogroup B meningococcal (MenB) vaccine. Meningococcal vaccine (MCV4) is recommended for high-risk patients (e.g., sickle cell disease, anatomic or functional asplenia, complement deficient) beginning at 2 months of age.

Pertussis Vaccine

Pertussis continues to be poorly controlled in the United States despite high compliance with childhood pertussis vaccination. In 2009, 16,858 pertussis cases and 12 infant deaths were reported. In October 2010, the ACIP expanded the use of tetanus toxoid and reduced diphtheria toxoid and acellular pertussis (Tdap) for adolescents and adults to improve immunity against pertussis. Adolescents aged 11 through 18 years who have completed the recommended childhood diphtheria and tetanus toxoids and pertussis/diphtheria and tetanus toxoids and acellular pertussis (DTaP) vaccination series and any adults greater than 19 years should receive a single dose of Tdap. Pregnant women should receive one dose of Tdap during each pregnancy at 27 to 36 weeks' gestation.

Human Papillomavirus Vaccine

Three human papillomavirus (HPV) vaccines, bivalent (2vHPV), quadrivalent (4vHPV), and 9-valent (9vHPV), are currently available. All three vaccines target HPV types 6 and 11, which are most commonly associated with clinical diseases and cause over 95% of genital warts. Types 16 and 18, believed to be responsible for approximately 66% of cases of cervical cancer, are contained in the quadrivalent and 9-valent vaccines. The 9-valent product provides additional protection against HPV 31, 33, 45, 52, and 58, which account for 14% for females and 4% males of HPV-associated cancers. The ACIP guidelines (Petrosky et al., 2015) recommend 9vHPV, 4vHPV, or 2vHPV for routine vaccination of females 9 through 26 years of age who have not been vaccinated previously or who have not completed the three-dose series. The 9vHPV or 4vHPV is recommended for routine vaccination of males 9 through 21 years of age, who have not been vaccinated previously or who have not completed the three-dose series, and through age 26 years in men who have sex with men and immunocompromised men (including those with HIV infection) through age 26 years if not vaccinated previously. It can be given to immunocompromised women, but the immune response may be reduced. Pregnant women should not receive the HPV vaccine, even if the series has been started before pregnancy. It can be administered to lactating women.

Ideally, the vaccine should be administered before potential exposure to HPV through sexual contact. The vaccine is a series of three doses. The second dose is administered 1 to 2 months after the first dose, and the third dose is administered 6 months after the first dose.

Rotavirus Vaccine

Rotavirus is the most common cause of severe gastroenteritis in children younger than age 5.

Before rotavirus vaccines were available in the United States, more than 200,000 children younger than age 5 received care in hospital emergency departments for rotavirus disease each year, and 55,000 to 70,000 young children were hospitalized. Two years after the introduction of the vaccine in 2006, a significant reduction in rotavirus hospitalization rates ($P < 0.001$) was observed among all age groups (87% reduction in 6 to less than 12 months old, 96% reduction in 12 to less than 24 months old, and a 92% reduction in 24 to less than 36 months old). Multiple studies have continued to show that the U.S. rotavirus season has become less pronounced and shorter since the utilization of the vaccine (Payne et al., 2011).

Rotavirus is very contagious. People who get a rotavirus infection shed large amounts of the virus in their feces. The disease spreads when infants or young children get rotavirus in their mouth. This happens through contact with the hands of other people or objects (such as toys) that have been contaminated with small amounts of rotavirus.

The first dose of the rotavirus vaccine can be given as early as age 6 weeks and needs to be given before an infant is age 15 weeks. Children should receive all doses of rotavirus vaccine before they are age 8 months.

Haemophilus influenzae Type b Vaccine

Haemophilus influenzae type b (Hib) vaccine prevents meningitis and pneumonia caused by Hib. It is given to all infants at 2, 4, and 6 months for a total of two- to three-dose primary series (depending on brand) and a booster dose at age 12 to 15 months. More than 95% of infants will develop protective antibody levels after a primary series with clinical efficacy estimated at 95% to 100%. Invasive Hib disease in a completely vaccinated infant is very uncommon. Unimmunized older children, adolescents, and adults with certain specified medical conditions (anatomic or functional splenectomy, HIV infection, sickle cell disease, immunoglobulin or complement deficiency, chemotherapy recipients, hematopoietic stem cell transplant) should receive additional doses of Hib vaccine, as they have an increased risk for invasive Hib disease.

Hepatitis A Vaccine

Hepatitis A is a serious liver disease caused by hepatitis A virus (HAV) and transmitted by hand-to-mouth contact through eating and drinking. Proper sanitation and good personal hygiene can help prevent its spread. It is typically self-limiting, but may lead to jaundice and, if severe, death (about 3 to 6 deaths per 1,000 cases) (Hamborsky et al., 2015). In 2006, the hepatitis A vaccine became available for the long-term protection of HAV infections. A two-dose series should be routinely administered to children beginning at 12 months of age. This vaccine should also be given to individuals traveling to countries with an intermediate to high prevalence of hepatitis A, men who have sex with men, drug abusers, chronic liver disease, or those treated with clotting factors.

Hepatitis B Vaccine

Hepatitis B is a serious disease caused by hepatitis B virus (HBV) that attacks the liver. The virus is very resilient and is viable outside the body for up to 7 days. It can cause lifelong infection, cirrhosis (scarring) of the liver, liver cancer, liver failure, and death. It is spread through person-to-person contact through blood, semen, or other body fluids. All children should get their first dose of hepatitis B vaccine at birth and complete the vaccine series by 6 to 18 months of age. Children and adolescents younger than 19 years of age who have not yet gotten the vaccine and adults with risk factors (e.g., men who have sex with men, IV drug users, health care and public safety personnel, persons with chronic liver disease, HIV, or undergoing renal dialysis, those residing in correctional facilities, and travelers to endemic regions) should also be vaccinated. A series of 3 or 4 shots should be given over a 6-month period. The hepatitis B vaccine provides greater than 90% protection to infants, children, and adults if they are immunized prior to being exposed to HBV.

Inactivated Poliovirus

Polio is an infectious disease caused by *Enterovirus*. A polio outbreak in the United States in 1952 resulted in over 21,000 cases of paralysis. The incidence fell rapidly following introduction of effective vaccines. The inactivated polio vaccine (IPV) is the only polio vaccine available in the United States. Children should receive a total of 4 doses of IPV beginning at 2 , 4, 6 to 18 months, and a booster dose at 4 to 6 years. The last case of wild-virus polio reported in the United States was in 1979, and global polio eradication may be achieved within the next decade.

Measles, Mumps, and Rubella Vaccine

The measles, mumps, and rubella (MMR) vaccine provides protection against three diseases and has been administered since 1967. Two doses of MMR provide complete protection. Children should be given the first dose of MMR vaccine at 12 to 15 months of age. The second dose can be given 4 weeks later, but is usually given before the start of kindergarten at 4 to 6 years of age. Measles and mumps are contagious diseases transmitted by contact with an infected person through coughing and sneezing, and both spread very easily. The measles consists of an erythematous, maculopapular, pruritic, splotchy rash, which lasts about 5 days and is preceded with a several-day prodrome of malaise, fever, coryza, and conjunctivitis. It may result in encephalitis (permanent brain damage) or death in 1 to 2 of every 1,000 cases (Marshall, 2012). The mumps consists of fever, headache, malaise, myalgias, and bilateral swelling of the parotid glands (parotitis). Testicular swelling and tenderness (orchitis) and aseptic meningitis may occur in 30% and 10% of patients, respectively. Patients with rubella (also called German measles or 3-day measles) exhibit a transient, erythematous, and sometimes pruritic rash, with about 60% of postpubertal women developing arthritis. If a woman in her first trimester of pregnancy contracts rubella, fetal damage is almost 100%. If contracted in second or third trimester, babies are born with congenital rubella syndrome (CRS) at birth. CRS will result in deafness, cataracts, cardiac defects, and CNS abnormalities.

By 2001, administration of the MMR vaccine eradicated measles from the United States, decreased the incidence of mumps by 99%, and provided lifelong protection against rubella. However, due to parents' concern of the MMR vaccine causing autism, mumps and measles cases have increased over the last several years. In 2010, there were 2,600 cases of the mumps, which decreased to 229 in 2012. In 2014, there were over 600 cases of measles reported, which has decreased to 189 cases in the United States from January to September 2015 (Hamborsky et al., 2015; Perry et al., 2015).

Varicella Vaccine

Chickenpox is a highly contagious disease caused by the varicella-zoster virus. In an unvaccinated child, it appears as an itchy, uncomfortable rash with blisters and vesicles. Before the chickenpox vaccine was widely used, nearly 11,000 people were hospitalized each year and about 50 children and 50 adults died every year from chickenpox. A live varicella vaccine was licensed for use in the United States in 1995, and since then, the number of hospitalizations and deaths due to chickenpox has decreased by more than 90% (Hamborsky et al., 2015). Two doses of the chickenpox vaccine are recommended, with the first dose given at age 12 through 15 months old and the second at age 4 through 6 years.

Zoster Vaccine

Herpes zoster, or shingles, occurs when latent varicella-zoster virus (VZV) reactivates and causes recurrent disease. Patients contracting zoster experience a painful, vesicular eruption unilaterally along a sensory nerve. The patient may experience pain and paresthesias a few days prior to the rash. Shingles is typically associated with aging and immunosuppression. A complication that may result after the lesions have resolved is postherpetic neuralgia (PHN) or pain in the area of the occurrence. About 30% of Americans will develop herpes zoster each year, and the risk of the disease increases with increasing age with more than half the cases occurring in people 60 years or older. In May 2006, the FDA approved herpes zoster vaccine for use in persons 60 years of age and older. It is a live vaccine with 64% efficacy in people aged 60 through 69 years versus about 18% efficacy in people aged 80 years and older. ACIP recommends a one-time dose of the zoster vaccine in patients at least 60 years of age (Hamborsky et al., 2015).

Adverse Events Associated With Vaccines

Risks of vaccination vary from inconvenient to severe and life-threatening. Common vaccine side effects (e.g., fever and local irritation to DTaP vaccine) are usually mild to moderate in severity and without permanent consequences. However, serious side effects and adverse reactions are possible, although the occurrence of an adverse event does not prove causation by the vaccine (i.e., the adverse event may be caused by factors other than the vaccine).

Reporting of adverse events is important because it may provide clues to unanticipated adverse reactions. It is important to interview the patient or guardian regarding any side effects after past immunizations. Any unexpected, reported, and observed event that required medical attention soon after the administration should be described in detail in the patient's medical record and reported using the Vaccine Adverse Events Reporting System (VAERS) (accessible online, https://vaers.hhs.gov/esub/index).

The VAERS is a result of the National Childhood Injury Act of 1986, which made provisions for health care providers to report occurrences of certain adverse events and to maintain permanent immunization records. Pertinent information to be reported includes a detailed description of the event (signs and symptoms reported and observed) and the time from administration of vaccine to presentation of signs and symptoms.

Pertinent patient history information should be noted regarding any existing physician-diagnosed allergies, medical conditions, and birth defects as well as any illness at the time of vaccine administration. In addition, information about the vaccine must be included. Documentation should identify the type of vaccine; the manufacturer, lot number, site, and route of administration; and any previous doses received.

Staff members from the VAERS contact the provider (reporter) to follow up about the patient's condition at 60 days and at 1 year after the initial reporting of adverse events. Figure 52.4 contains the VAERS form.

FIGURE 52.4 Vaccine adverse event reporting system form.

Contraindications to Vaccinations

The primary contraindications to vaccine administration are acute febrile illness, allergy to a vaccine component, or history of hypersensitivity/anaphylactic reaction to vaccine constituents. Table 52.1 includes a detailed listing of contraindications by vaccine. The four main types of hypersensitivity reactions include:

TABLE 52.1 Guide to Contraindications and Precautions to Commonly Used Vaccines in Adults (Centers for Disease Control and Prevention, 2014)

Vaccine	Contraindications	Precautions
Influenza, inactivated (IIV)	Severe allergic reaction (e.g., anaphylaxis) after previous dose of any influenza vaccine or to a vaccine component, including egg protein	Moderate or severe acute illness with or without fever History of Guillain-Barré syndrome within 6 wks of previous influenza vaccination
Influenza, recombinant (RIV)	Severe allergic reaction (e.g., anaphylaxis) after previous dose of RIV or to a vaccine component. RIV does not contain any egg protein Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component	Moderate or severe acute illness with or without fever History of Guillain-Barré syndrome within 6 wks of previous influenza vaccination
Influenza, live attenuated (LAIV)	Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to any component of the vaccine Pregnant women Immunosuppressed adults Adults who have taken influenza antiviral medications within the previous 48 h	Moderate or severe acute illness with or without fever History of Guillain-Barré syndrome within 6 wks of previous influenza vaccination Asthma in patients ≥ 5 y Other chronic medical conditions, e.g., other chronic lung diseases, chronic cardiovascular disease (excluding isolated hypertension), diabetes, chronic renal or hepatic disease, hematologic disease, neurologic disease, and metabolic disorders
Tetanus, diphtheria, pertussis (Tdap); tetanus, diphtheria (Td)	Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component For pertussis-containing vaccines: encephalopathy (e.g., coma, decreased level of consciousness, or prolonged seizures) not attributable to another identifiable cause occurring within 7 d of administration of a previous dose of Tdap or diphtheria and tetanus toxoids and acellular pertussis (DTaP) vaccine	Moderate or severe acute illness with or without fever History of Guillain-Barré syndrome within 6 wks after a previous dose of vaccine containing tetanus toxoid component History of Arthus-type hypersensitivity reactions after a previous dose of tetanus or diphtheria toxoid–containing vaccine; defer at least 10 y since the last tetanus toxoid–containing vaccine For pertussis-containing vaccines: progressive or unstable neurologic disorder, uncontrolled seizures, or progressive encephalopathy until condition has stabilized
Varicella	Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component Known severe immunodeficiency Pregnancy	Recent (within 3–11 mo) receipt of antibody-containing blood product (specific interval dependent on product) Moderate or severe acute illness with or without fever Receipt of specific antivirals (i.e., acyclovir, famciclovir, or valacyclovir) 24 h before vaccination; avoid these for 14 d after vaccination
Human papillomavirus (HPV)	Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component	Moderate or severe acute illness with or without fever Pregnancy
Zoster	Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component Known severe immunodeficiency Pregnancy	Receipt of specific antivirals (i.e., acyclovir, famciclovir, or valacyclovir) 24 h before vaccination; avoid these for 14 d after vaccination Moderate or severe acute illness with or without fever
Measles, mumps, rubella (MMR)	Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component Known severe immunodeficiency Pregnancy	Recent (within 3–11 mo) receipt of antibody-containing blood product (specific interval dependent on product) Moderate or severe acute illness with or without fever
Pneumococcal conjugate (PCV13)	Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component, including to any vaccine containing diphtheria toxoid	Moderate or severe acute illness with or without fever
Pneumococcal polysaccharide (PPSV23)	Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component	Moderate or severe acute illness with or without fever
Meningococcal, conjugate (MenACWY); meningococcal, polysaccharide (MPSV4); serogroup B meningococcal (MenB)	Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component	Moderate or severe acute illness with or without fever

Vaccine	Contraindications	Precautions
Hepatitis A	Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component	Moderate or severe acute illness with or without fever
Hepatitis B	Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component	Moderate or severe acute illness with or without fever
Haemophilus influenzae type b (Hib)	Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component	Moderate or severe acute illness with or without fever

1. Allergic reactions to egg-related antigens (e.g., yellow fever, influenza)

2. Mercury sensitivity in some recipients of vaccines or immune globulin
3. Antibiotic-induced allergic reactions (e.g., inactivated poliovirus vaccine—trace streptomycin, neomycin, and polymyxin B; MMR, including single or combined with varicella—trace neomycin; varicella and herpes zoster vaccines-neomycin)
4. Hypersensitivity to other vaccine components, including the infectious agent (e.g., shingles vaccine-gelatin)

Acute febrile illness suggesting a moderate to severe illness is sufficient reason to defer vaccination until the person recovers. Guidelines in this instance are based on the provider's assessment of the illness and the vaccines scheduled for administration. The rationale for withholding vaccination in moderate to severe illness, with or without fever, is that evolving signs and symptoms associated with the illness may be difficult to distinguish from the reaction to the vaccine. Minor illness (minor respiratory, gastrointestinal, or other illness) and low-grade fevers are not contraindications to immunization. The benefit of the immunization at the recommended age, regardless of the presence of mild illness, outweighs the risk of vaccine failure (Pickering et al., 2009).

One needs to use special attention to contraindications when administering live vaccines. Contraindications for all live vaccines include pregnancy and known severe immunodeficiency (e.g., from hematologic and solid tumors, receipt of chemotherapy, congenital immunodeficiency, or long-term immunosuppressive therapy, or patients with human immunodeficiency virus [HIV] infection who are severely immunocompromised) (see the preceding discussions on immunocompromised children).

Patient and Provider Education and Issues

Patient and health care provider/practitioner education, updates on immunization protocols, and established office systems with designated areas of responsibility are significant factors in improving immunization rates. Office routines and systems should incorporate pediatric immunization standards (Box 52.4) and facilitate the use of all possible opportunities to review and update the immunization status of each patient (National Vaccine Advisory Committee, 2003). Tickler systems, chart reminders, and flow sheets that identify needed immunizations clearly and visibly are useful adjuncts to patient care.

BOX 52.4 Standards for Pediatric Immunization Practices

Standard 1. Immunization services are readily available.
Standard 2. No barriers or unnecessary prerequisites to the receipt of vaccines exist.
Standard 3. Immunization services are available free or for a minimal fee.
Standard 4. Providers use all clinical encounters to screen and, when indicated, immunize children.
Standard 5. Providers educate parents and guardians about immunization in general terms.
Standard 6. Providers question parents or guardians about contraindications and, before immunizing a child, inform them in specific terms about the risks and benefits of the immunizations their child is to receive.
Standard 7. Providers follow only true contraindications.
Standard 8. Providers administer simultaneously all vaccine doses for which a child is eligible at the time of each visit.
Standard 9. Providers use accurate and complete recording procedures.
Standard 10. Providers co-schedule immunization appointments in conjunction with appointments for other child health services.
Standard 11. Providers report adverse events after immunization promptly, accurately, and completely.
Standard 12. Providers operate a tracking system.
Standard 13. Providers adhere to appropriate procedures for vaccine management.
Standard 14. Providers conduct semiannual audits to assess immunization coverage levels and to review immunization records in the patient populations they serve.
Standard 15. Providers maintain up-to-date, easily retrievable medical protocols at all locations where vaccines are administered.
Standard 16. Providers operate with patient-oriented and community-based approaches.

Standard 17. Vaccines are administered by properly trained individuals.

Standard 18. Providers receive ongoing education and training on current immunization recommendations.

From Centers for Disease Control and Prevention. (1993). Standard for pediatric immunization practices: Recommended by National Vaccine Advisory Committee (ACIP). *Morbidity and Mortality Weekly Report*, 42(RR-5), 1–13.

A team approach to staff involvement also helps to enhance vaccination rates. Support staff should be aware of immunization needs when scheduling return or preventive visits as well as visits for illness or minor health problems. Visual reminders on the patient's chart or visit encounter form can be used to alert the practitioner to review specific vaccine needs or requests. Box 52.5 presents recommendations related to the immunization schedule, and Box 52.6 offers answers to frequently asked questions about immunization.

BOX 52.5 Immunization Schedule Tips

Restarting Vaccine SeriesWith the exception of oral typhoid vaccine, it never is necessary to restart a vaccine series because the interval has been prolonged—although every effort should be made to adhere to the recommended schedule.

Vaccines Given Too SoonThese will not be accepted at school entry and revaccination will be recommended.

Lack of Written Vaccination RecordAn attempt should be made to verify vaccination status. If no record can be verified, the child should be considered unimmunized and should be revaccinated as appropriate for age.

Hepatitis BIn the case of an interrupted or incomplete series, resume the series; do not repeat or restart. Dose should be appropriate in accord with the manufacturer's instructions. The third dose should be given at least 2 mo after the second dose and at least 4 mo after the first dose but not before 6 mo of age.

PPD/MMRPPD can be done before or at the same time as the measles vaccine is administered. Give PPD 4 to 6 wk after measles vaccine, if measles is given first, because measles can reduce the reactivity of PPD. This reduction in reactivity is due to mild suppression of cell-mediated immunity, which can lead to false-negative test results.

DtaPThe fourth dose can be given if a child is ≥12 mo of age and 6 mo has elapsed since DTaP dose 3 (especially if the child is unlikely to return at 15 to 18 mo of age). The fifth dose should be given at 4 to 6 y. Children should not receive more than six doses of diphtheria or tetanus-containing toxoid before their seventh birthday. No pertussis-containing vaccines are licensed for use in people ≥7 y of age.

HIBNo HIB vaccine should be given to infants younger than 6 wk of age and is not recommended after age 5 y. Minimum age for last HIB is 12 mo, if at least 2 mo has

passed since the previous dose. DTaP/HIB combination products should not be used for primary series (2, 4, 6 mo of age).

VaricellaDosage for people 12 mo and older: Single 0.5-mL dose subcutaneously suffices for protection 12 mo to 12 y. People 13 y of age and older should receive two 0.5-mL doses at least 4 wk apart.

BOX 52.6 Questions and Answers About Immunization

Q.How long should the vaccination needle be?

A.Subcutaneous injections for children and adults: 5/8 to ¾ in., 23- to 25-gauge needle.

Intramuscular injections for infants and children: minimum needle length of 7/8 in. for anterolateral thigh and minimum of 5/8 in. for deltoid injection; for adults: 1 to 1½ in. needle (Marshall, 2012).

Q.What are the immunization recommendations for children of parents or household residents who were never vaccinated for polio?

A.If the unvaccinated or inadequately vaccinated person resides in the household, an all-IVP schedule is recommended for the child. Parents and household contacts may receive IVP too.

Q.Which HIB vaccines are the best?

A.Different manufacturers' products are considered interchangeable for the primary series and the booster. However, no HIB vaccine is recommended for infants younger than 6 wk of age. If it is given, it may make the child incapable of responding to subsequent doses.

Q.What are some special concerns related to pregnancy?

A.There are no contraindications to immunization of a household member if another household member is pregnant. However, if a woman in the household wants to become pregnant and also wants to be vaccinated, she should wait to become pregnant at least 1 mo after receiving mumps, measles, varicella and 3 mo after receiving rubella.

Q.What happens if someone has an extra vaccination?

A.Extra doses of live vaccine do not appear to have adverse consequences, and they may boost immunity. Extra doses of inactivated vaccines can induce very high antibody titers. If these people are revaccinated, large local inflammatory reactions may ensue.

Q.Is it harmful to receive vaccines simultaneously?

A.No evidence exists that simultaneous administration of vaccines reduces vaccine effectiveness or increases adverse events.

Q.What are the implications of an error, such as previous administration of a

vaccine at the wrong site, in a wrong dose, by a wrong route?

A. Unfortunately, they do not count. Only full doses in acceptable sites should be counted. Revaccinate according to age. The exception to the rule is live vaccines (MMR, varicella), which are recommended to be administered subcutaneously—intramuscular administration of these vaccines is not likely to decrease immunogenicity. *Note:* Reducing or dividing doses of any vaccine including those to preterm or low-birth-weight infants is not indicated.

Q. What is the recommended way to administer multiple injections to infants?

A. The recommended approach is to place the vaccine most likely to cause a local adverse reaction (e.g., DTaP) in one leg and the two less reactive in different sites in the other leg.

Q. How effective is the varicella vaccine?

A. Effectiveness is 70% to 90% protection against infection with 95% protection against severe disease. Protection persists at least 7 to 10 y. The risk of transmission appears low but somewhat higher if the vaccine develops a varicella-like rash after vaccination. Recommend that vaccines avoid contact with immunocompromised people when the rash is present.

Q. Why is the MMR vaccine given twice?

A. The second dose is given because 2% to 5% of people do not develop immunity after the first dose, and 95% of the people who did not respond to the first dose respond to the second.

Note: Birth before 1957 is generally considered evidence of rubella immunity; laboratory evidence of immunity is recommended. Combined MMR vaccine is the drug of choice if vaccination is needed.

Q. What is the standard dosing schedule for hepatitis B vaccine?

A. There is no standard dose. That is why it is so important to read the package insert for hepatitis B vaccine carefully. The formulations vary, and the appropriate microgram dose must be selected.

Vaccines should be stored in the office in sufficient amounts to meet the needs of the patients. Staff should have specific assignments to monitor stock levels, lot numbers, and expiration dates. Vaccines should be stored according to the manufacturer's recommendations with a backup system to address times when power outages may have affected vaccines, particularly during nonbusiness hours. Methods can range from plugging in a digital clock in the same outlet to use of alarm systems on the freezer or refrigerator. An inexpensive method of detecting a power outage uses a cup of ice with a penny or other coins placed on top of the ice. The length of a power outage may be judged by how far the coin sinks in the previously completely frozen ice. If power outages occur, the pharmaceutical manufacturer should be contacted for information about vaccine use, revised expiration dates, or unusable vaccine. Staff members should not automatically assume that vaccine should be discarded.

A central log book, maintained by date and time and including lot numbers and expiration dates of the vaccines, is recommended. Used with patient schedule information and chart documentation, the log book helps identify patients should a pharmaceutical company notify the office of a vaccine recall or a need to reimmunize patients receiving a specific lot of vaccine. Immunization screening processes are necessary for all populations to determine if an individual can receive the required vaccines. The screening questions, asked prior to vaccination, should be as follows:

Do you have diarrhea or a substantial fever, or are you vomiting today?
Do you have any drugs or food allergies?
Have you ever had a reaction to any vaccine? If yes, describe it.
Are you being treated by a doctor for a disease?
Do you have cancer or any disease that affects the immune system?
Have you received blood or antibodies (immune globulins) in the past 3 to 11 months?
Are you pregnant or planning to become pregnant in the next month or so?
Does the infant or child have any neurologic problem (e.g., seizures) that is not resolved or stabilized?

A focus on adolescent and adult populations as well as infants and children is critical. Current recommendations include routine screening at ages 11, 12, and 50. An interim process for high-risk people in combination with aforementioned recommended screenings provides the best mechanism for implementing a comprehensive immunization program.

It is extremely important to keep updated and be familiar with Web sites and organizations that provide vaccine information to be aware of changes that occur.

Case Study*

B.E. is a 58-year-old female with no food or drug allergies. She presents to your clinic on November 10 for a follow-up visit for type 2 diabetes mellitus diagnosed 2 months ago. Her history is significant for the following:

- Type 2 diabetes mellitus controlled with diet and exercise.
- Her daughter is pregnant and B.E. plans to care for the infant.
- Vaccination history: oral polio vaccine 1964, Td 2010, physician confirmed chicken pox, mumps, and measles as a child.

1. You assess that B.E. requires several vaccines. Which of the following screening questions should you ask to determine if she can be immunized today?
   a. Have you had a fever or diarrhea in the last 24 hours?
   b. Do you have cancer or are you being treated for any immune problem?
   c. Are you a smoker?
   d. A and B

E. All of the above

2. You determine that B.E. can be immunized today. Which of the following vaccines should B.E. receive today?
   a. PPSV-23, inactivated influenza, Tdap
   b. Inactivated influenza, Tdap, MMR
   c. Inactivated influenza, Tdap
   d. PPSV-23, Tdap
   e. Live influenza nasal spray, Tdap

3. B.E. asks you if she will need any vaccines in the future. How should you respond?
   a. You will need to get a yearly influenza vaccine.
   b. In 2 years, you will qualify for the zoster vaccine to provide protection against shingles.
   c. When you turn 65 years of age, you will require PPSV-23 and PCV-13.
   d. A and B
   e. All of the above

53 Smoking Cessation

Tyan F. Thomas

A traditional cigarette is one of many tobacco products. Tobacco products may be categorized as traditional cigarettes or smokeless tobacco. Nicotine is the addictive compound in tobacco products, and it is important to note that nicotine may also be delivered by tobacco-free products, such as electronic cigarettes (e-cigarettes). e-Cigarettes do not contain tobacco but deliver nicotine by vaporizing nicotine-containing liquids. Because the majority of adult tobacco and nicotine users smoke traditional cigarettes, this chapter will focus on cessation of cigarette smoking (CDC, 2014b). Table 53.1 provides a list of forms of tobacco available in the United States (CDC, 2014a).

TABLE 53.1 Tobacco Products Available in the United States

Traditional Cigarettes	
Chewable tobacco	Tobacco leaf
	Cured tobacco plug
	Tobacco leaf roll
Ground tobacco (snuff)	Dry
	Moist
	U.S. snus (moist snuff packaged in ready-to-use pouches resembling tea bags)
Dissolvable tobacco	Lozenges
	Orbs
	Sticks
	Strips

Cigarette smoking is a chronic condition. Like sufferers of other chronic conditions, many cigarette smokers cycle through periods of remission (i.e., periods of abstinence from cigarette use) and relapse (i.e., periods of active cigarette use). Similar to other chronic conditions, cigarette smoking contributes to morbidity and mortality and is the leading cause of preventable morbidity and mortality in the United States (U.S. Department of

Health and Human Services [USDHHS], 2014).

The U.S. Department of Health and Human Services (USDHHS) estimates that in the United States, cigarette smoking and secondhand exposure to cigarette smoke results in at least 480,000 premature deaths annually. Lung cancer, coronary heart disease (CHD), and chronic obstructive pulmonary disease (COPD) are the three leading causes of smoking-related deaths (USDHHS, 2014). Smoking accounts for a little over 80% of all lung cancer deaths and is attributable to deaths caused by 11 non–lung-related cancers, including oral–pharyngeal and stomach cancers (Siegel et al., 2015). Life expectancy is estimated to be 10 years shorter for smokers compared to lifelong nonsmokers (Jha et al., 2013).

In addition to the variety of cancers, smoking is a major risk factor for cardiovascular diseases, such as CHD and aortic aneurysm, cerebrovascular disease, and peripheral arterial disease. It is estimated that each year, as many as 24% of all deaths related to CHD in American adults 35 years of age and older may be attributable to cigarette smoking (USDHHS, 2014) and that smoking doubles the risk of ischemic stroke (Meschia et al., 2014). Furthermore, smoking increases the risk of acute respiratory infections. It is also a major risk factor for the development of COPD and is estimated to account for nearly 80% of COPD-related deaths (USDHHS, 2014).

In the United States, the total economic burden of smoking is estimated to be at least $289 billion annually, with costs for medical expenditures for care of smoking-related illnesses estimated to be at least $132 billion and costs related to lost earnings and loss of productivity estimated to be at least $151 billion (USDHHS, 2014).

Adverse health effects associated with smoking seem to lessen with smoking cessation. Jha and colleagues found that adult smokers who quit at younger ages gained years of life compared to adults who continued smoking: adults who quit when aged 25 to 34 years gained 10 years of life, compared to 9 years of life gained when quitting from ages 35 to 44 years, and 6 years gained when quitting from ages 45 to 55 years. In fact, adults who quit smoking between 25 and 34 years of age had survival curves similar to adults who never smoked (Jha, 2013).

The CDC estimates that in 2013, approximately 17.8% (42.1 million) of adults in the United States smoked cigarettes, which is down from 20.9% (45.1 million) in 2005 (Jamal et al., 2014). According to the CDC, more men than women in the United States smoke (20.9% of adult males compared to 15.3% of adult females) (Jamal et al., 2014). Among racial and ethnic populations in the United States, Asians have the lowest rates of cigarette use (9.6%), while American Indians/Alaska natives had the highest rates (26.1%) (Jamal et al., 2014). Smoking rates vary by age group as well, with the lowest rates among those older than age 65 years (8.8%) and higher rates among adults aged 25 to 44 years (20.1%) (Jamal et al., 2014). In 2014, an estimated 24.6% (3.7 million) of U.S. high school students reported on the National Youth Tobacco Survey using tobacco or nicotine products (including e-cigarettes, hookah, traditional cigarettes, and other tobacco products) during the preceding 30 days prior to taking the survey (Arrazola et al., 2015). Use of e-cigarettes

was most common, with hookah and traditional cigarettes rounding out the top three most commonly used nicotine-containing products by high school students (Arrazola et al., 2015). While use of traditional cigarettes and other tobacco products has decreased in high schoolers, this decrease is offset by the increased use of e-cigarettes and hookah (Arrazola et al., 2015).

Although nearly 70% of adult smokers report that they would like to quit, only 52.4% will make a quit attempt during any given year, and only 6% are likely to be successful; however, many who attempt to quit smoking do not use recommended cessation methods and most relapse within the first week of quitting (Fiore et al., 2008; Malarcher et al., 2011). Fortunately, most smokers make multiple attempts, and nearly half of users will eventually abstain (American Psychiatric Association [APA], 2013). The U.S. Department of Health and Human Services/Public Health Service guidelines (DHHS/PHS) recommend that all health care professionals, including physicians, pharmacists, nurses, and others, ask about and document their patients' smoking status (Fiore et al., 2008). The 2008 DHHS/PHS guidelines urge clinicians to treat tobacco use disorder as a chronic disease similar in many respects to other diseases such as hypertension, diabetes mellitus, and hyperlipidemia and to provide patients with appropriate advice and pharmacotherapy (Fiore et al., 2008).

Pathophysiology

Nicotine is the addictive substance in cigarette smoke. It is absorbed and distributed to most tissues of the body, where it binds with nicotinic receptors and produces its physiologic effects on the heart, brain, and other organ systems. Nicotine is a ganglionic cholinergic receptor agonist whose pharmacologic effects are highly dose dependent. These effects include central and peripheral nervous system stimulation and depression, respiratory stimulation, skeletal muscle relaxation, epinephrine release by the adrenal medulla, peripheral vasoconstriction, and increased blood pressure, heart rate, cardiac output, and oxygen consumption (Doering et al., 2014). In addition, nicotine increases dopamine levels in the central nervous system, thus stimulating the reward system and reinforcement of its use (O'Brien, 2011). Activation of nicotine receptors in the brain produces relaxation, decreases stress and anxiety, and improves concentration and reaction times (Benowitz, 2010). Cessation of smoking leads to depressed mood, irritability, difficulty concentrating, and anxiety. Smokers use nicotine to experience the rewarding effects and to avoid the unpleasant effects of nicotine withdrawal.

A common endocrine and metabolic effect of nicotine is weight loss. Smokers tend to weigh 2.4 to 4.5 kg less than nonsmokers (Audrain-McGovern & Benowitz, 2011; Molarius et al., 1997). Additional endocrine effects include increased risk of osteoporosis and earlier menopause (Benowitz, 2008). Finally, smoking alters the liver's metabolic effects by inducing hepatic (cytochrome P-450) enzymes. These effects on hepatic enzymes result in the increased metabolism of certain medications, such as theophylline and acetaminophen, and substances such as caffeine.

Diagnostic Criteria

Chronic nicotine ingestion may lead to physical and physiologic dependence and tolerance to some of its pharmacologic effects. Tobacco use disorder has been defined as a form of substance abuse that can lead to clinically important impairment or distress (American Psychiatric Association [APA], 2013). The key features required for the diagnosis of tobacco use disorder are continued use despite wanting to quit, prior attempts at quitting, persistent use despite the presence of physical illness, tolerance, and presence of withdrawal symptoms (APA, 2013). Box 53.1 highlights the APA criteria for tobacco use disorder and tobacco withdrawal. Another clinical assessment tool for tobacco/nicotine dependence is the Fagerstrom Test for Nicotine Dependence, which assesses a patient's level of nicotine dependence, in part, by determining the time to first cigarette (TTFC) of the day (Heatherton et al., 1991). Nicotine has a relatively short half-life, and nicotine-dependent tobacco users may experience significant discomfort on waking unless they quickly have their first cigarette (Mallin, 2002). The number of cigarettes smoked per day and the TTFC both have been shown to correlate with the degree of nicotine dependence. Therefore, the use of the Fagerstrom test may be used (Box 53.2) in addition to the APA criteria for diagnosis of tobacco use disorder among smokers.

BOX 53.1 APA Criteria for Tobacco Use Disorder and Tobacco Withdrawal

Tobacco Use Disorder

Tobacco use disorder is defined as a problematic pattern of use of tobacco that leads to clinically important impairment or distress, as demonstrated by the presence of two or more of the following, occurring within a 12-month period:

1. Tobacco is taken in larger amounts over a longer period of time than was intended.
2. There exists a persistent desire to cut down or control tobacco use, or unsuccessful efforts are made to cut down or control tobacco use.
3. A significant amount of time is spent in activities necessary to obtain or use tobacco.
4. Craving, or a strong desire or urge to use tobacco, exists.
5. Recurrent tobacco use results in a failure to fulfill important obligations or responsibilities at work, school, or home.
6. Tobacco use continues despite its contribution to persistent or recurrent social or interpersonal problems (e.g., tobacco use causes or contributes to arguments with others).
7. Tobacco use results in the individual giving up important social, occupational, or recreational activities.

8. Tobacco use recurs in situations that are physically hazardous (e.g., smoking in bed).
9. Persistent tobacco use despite knowledge of having chronic tobacco-related physical or psychosocial problems
10. Tolerance to tobacco exists, with tolerance being defined as either one of the following: (1) the need for a markedly increased amount of tobacco to produce the intended effect or (2) a markedly diminished effect with the continued use of the same amount of tobacco
11. Withdrawal occurs (see below for characteristics of withdrawal). Withdrawal is manifested by either one of the following: (1) the presence of characteristic tobacco-related withdrawal symptoms; (2) tobacco, or other nicotine-containing products, is taken to relieve or avoid withdrawal symptoms.

Withdrawal

Withdrawal symptoms may be initiated and characterized by the following:

1. Daily use of tobacco for at least several weeks
2. Abrupt cessation of nicotine use, or reduction in the amount of nicotine used, followed within 24 hours by four or more of the following:
   a. Irritability, frustration, or anger
   b. Anxiety
   c. Difficulty concentrating
   d. Increased appetite
   e. Restlessness
   f. Depressed mood
   g. Insomnia
3. The signs and symptoms outlined in item 2 cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
4. The signs or symptoms are not due to a different medical condition and are not better accounted for by another mental disorder, including intoxication or withdrawal from another substance.

BOX 53.2 Fagerstom Tolerance Test for Nicotine Dependence

Write the number of the answer that is most applicable on the line to the left of the question.

1.How soon after you awake do you smoke your first cigarette?
3 points: Within 5 minutes
2 points: 6 to 30 minutes
1 point: 31 to 60 minutes

0 points: After 60 minutes

2.Do you find it difficult to refrain from smoking in places where it is forbidden such as the library, theater, or doctor's office?

1 point: Yes

0 points: No

3.Which cigarette would you hate most to give up?

1 point: The first one in the morning

0 points: Any other cigarette

4.How many cigarettes a day do you smoke?

0 points: 10 or less

1 points: 11 to 20

2 point: 21 to 30

3 points: 31 or more

5.Do you smoke more frequently during the first hours after waking than during the rest of the day?

1 point: Yes

0 points: No

6.Do you smoke when you are so ill that you are in bed most of the day?

1 point: Yes

0 points: No

Scoring Instructions: Add you up your responses to all the items. Total scores should range from 0 to 10, where a score of 6 to 7 suggests a high level of physical dependence to nicotine and a score of 8 to 10 suggests a very high level of physical dependence to nicotine.

TOTAL SCORE:

Heatherton, T. F., Kozlowski, L. T., Frecker, R. C., et al. (1991). The Fagerstrom Test for Nicotine Dependence: A revision of the Fagerstrom Tolerance Questionnaire. *British Journal of Addictions*, 86, 1119–1127.

Development and Course of Tobacco Use Disorder and Nicotine Dependence

Many teenagers experiment with use of tobacco and nicotine products, and by age 18, 20% use these products at least monthly; many of these individuals will become daily users (APA, 2013). Commencement of tobacco use after the age of 21 is rare (APA, 2013). Individuals may have some of the APA-defined criteria of tobacco use disorder soon after beginning tobacco use, and many individuals will have a pattern of use that meet the APA's definition of tobacco use disorder by late adolescence (APA, 2013).

Patients who are addicted to nicotine may experience withdrawal symptoms. Onset of these symptoms usually occurs within 24 hours and may last for days, weeks, or longer (Henningfield et al., 2009). Nicotine withdrawal is associated with a well-described syndrome characterized by irritability, awakening from sleep, anxiety, impaired concentration, impaired reaction time, restlessness, drowsiness, confusion, increased appetite, and weight gain (Henningfield et al., 2009; Shiffman et al., 2004). In health care settings, a patient should be asked about his/her tobacco use and responses about use documented every visit. The DHHS/PHS expert panel recommends that tobacco use status be adopted as a new vital sign to be assessed along with blood pressure, temperature, pulse, and respiration rates (Fiore et al., 2008).

Initiating Drug and Nondrug Therapy

The DHHS/PHS guidelines recommend that all clinicians aggressively motivate and assist their smoking patients to quit (Fiore et al., 2008). The expert panel's analysis of various studies and trials has found that a wide variety of clinicians can effectively implement these strategies and such interventions as brief as 3 minutes can increase the cessation rate significantly (Fiore et al., 2008). Such interventions should be made by clinicians in patients unwilling to attempt to quit at the time of inquiry because such interventions increase motivation and the likelihood of future attempts (Fiore et al., 2008). The panel reminds clinicians that effective treatment of tobacco dependence now exists and that every patient should receive at least minimal intervention (i.e., as little as 3 minutes of time dedicated to counseling the patient about the benefits of smoking cessation) every time he or she visits a clinician. The first step in this process, identification and assessment of tobacco use status, separates patients into three treatment categories:

1. Patients who use tobacco and are willing to quit should be offered assistance to increase chances of successful cessation and arrange follow-up contact soon after quit date, preferably within the first week after quit date (Box 53.3).
2. Patients who use tobacco but are willing to quit at the time of inquiry should go through the five Rs of motivational interventions: Relevance, Risks, Reward, Roadblocks, and Repetition (Box 53.4) with the goal to increase motivation to stop smoking.
3. Patients who have quit using tobacco recently should be provided relapse prevention treatment. Clinicians should reinforce the patient's decision to quit, review the benefits of quitting, and assist the patient in resolving any residual problems arising from quitting (Fiore et al., 2008).

BOX 53.3 The "Five As" Model for Treating Tobacco Use and Dependence

Ask every patient about tobacco use and record information in patient's medical record at every visit.

Strongly *advise* every tobacco user to quit, using a personalized approach.

Assess the patient's willingness to make an attempt to quit.

Assist the patient who is willing to make an attempt to quit by offering medication and providing or referring for smoking cessation counseling.

Arrange for follow-up contact within the first week after the quit date. For patients unwilling to make a quit attempt, address willingness to quit at next visit.

BOX 53.4 Tobacco Users Unwilling to Quit: The "Five Rs"

Relevance

Encourage patient to discuss why quitting is personally relevant to him or her. Motivational information has the highest impact when it is relevant to a patient's disease status or risk, family or social situation (e.g., having children in the home), health concerns, and other patient factors (e.g., prior quitting experience, personal barriers to cessation).

Risks

The clinician should ask the patient to identify potential negative consequences of tobacco use. The clinician may suggest and highlight the negative consequence that seems most relevant to the patient. The clinician also should emphasize that smoking low-tar/low-nicotine cigarettes or use of other forms of tobacco (e.g., smokeless tobacco, cigars, and pipes) will not eliminate these risks.

Rewards

The clinician should ask the patient to identify potential benefits of stopping tobacco use. The clinicians may suggest and highlight the benefits that seem most relevant

to the patient. Examples of rewards include improved health, greater ability to taste food, improved sense of smell, saving money, less smoke-related odors in home, car, clothing, feeling better physically, and improved appearance (less wrinkling/aging of skin and whiter teeth).

Roadblocks

The clinician should ask the patient to identify barriers or impediments to quitting and provide treatment (e.g., problem-solving counseling, medication) that could address barriers. Typical barriers may include withdrawal symptoms, fear of weight gain, lack of support, depression, and being around other tobacco users.

Repetition

The motivational intervention should be repeated every time an unmotivated patient is encountered in a clinical setting. Tobacco users who have failed previous quit attempts should be encouraged by telling them that most people make repeated quit attempts before they are successful.

Source: U.S. Department of Health and Human Services, Public Health Service, Agency for Health Care Policy and Research. (2008). *Treating tobacco use and dependence: 2008 update*. Rockville, MD: Author.

Once the diagnosis of tobacco use disorder is made, the next step is to assess the patient's readiness to change (Mallin, 2002). The five-step transtheoretical stages of change (SOC) model are useful for assessing the patient's readiness to quit. The SOC model identifies smoking behavioral change as a process involving movement through a series of five motivational stages (Mallin, 2002):

- Stage 1—Precontemplation: the patient has no intention to quit.
- Stage 2—Contemplation: a smoker is interested in quitting but has no definite plans.
- Stage 3—Preparation: the smoker in this stage is planning to quit within the next month and has made a failed attempt to quit during the previous year.
- Stage 4—Action: the smoker makes a serious effort to quit by modifying his or her behavior and environment. During this stage, the patient has abstained anywhere from 1 day to 6 months. After 6 months of abstinence, the patient enters the final stage.
- Stage 5—Maintenance.

The first step in any cessation program should be to target a quit date with the patient. This date should be identified; otherwise, the patient may never actually make the attempt to stop smoking. In addition, picking a definite date provides the patient with an obtainable goal and avoids overwhelming the patient with the thought of having to change an entire lifestyle.

Nonpharmacologic approaches to smoking cessation consist of various individual and group behavioral interventions, including self-management, group counseling and support, nicotine fading, and aversion techniques (APA, 1996). Behavioral therapy is based on the theory that learning processes operate in the development, maintenance, and cessation of

smoking (APA, 1996). The core feature of behavioral therapies is to educate the patient about the benefits of smoking cessation. When used alone, these interventions have low success rates because they do not satiate cravings or prevent withdrawal symptoms. However, patients who are highly motivated or who smoke only a few cigarettes a day may benefit the most from these approaches. The DHHS/PHS recommends combining behavioral therapy and pharmacologic therapy, as the combination yields higher quit rates than behavioral or pharmacologic therapy alone (Fiore et al., 2008).

Self-Management

Self-management techniques are commonly used to make patients more aware of their smoking habits and cues. By becoming more familiar with the environment and events that precede smoking a cigarette, patients may be able to interrupt these patterns by avoiding certain situations. If a relapse occurs, the patient should determine what may have triggered the failed attempt and eliminate those factors. Some nondrug methods to enhance smoking cessation and prevent relapse include getting rid of ashtrays, drinking water and breathing deeply between sips, avoiding places with smoke-filled air, making a dental appointment to get teeth cleaned, exercising, calling on friends or family for support and encouragement, eating a balanced diet, chewing gum or a toothpick, and avoiding the routine that causes craving a cigarette, such as drinking coffee every morning with a cigarette (Mallin, 2002). An analysis of self-help programs showed these programs to be relatively ineffective compared to individual, group, or proactive telephone counseling.

Individual and Group Counseling and Support

The DHHS/PHS expert panel emphasized the strong dose–response relationship between the intensity of tobacco dependence counseling and its effectiveness, meaning that the more intensive interventions are, the more effective they are. Person-to-person contact (via individual, group, or proactive telephone counseling) delivered across four or more sessions seems especially effective in increasing abstinence rates. Two types of counseling and behavioral therapies are recommended by the expert panel to be included in smoking cessation interventions:

a. Provision of practical counseling (problem solving/skills training)
b. Provision of social support as part of treatment (intratreatment social support)

Group counseling programs help to educate the patient on the risks and benefits of smoking cessation. In addition, the patient is presented with strategies to cope with and avoid situations that may lead to relapse. These programs are intended to keep the patient motivated to quit smoking.

Nicotine Fading

Nicotine fading consists of a slow decrease in the intake of nicotine. This can be accomplished by decreasing the number of puffs taken or the number of cigarettes smoked per day or by switching to a brand of cigarettes that contains less nicotine. However, the success rate of this technique is limited because the patient can compensate by inhaling more deeply or for longer periods.

Cutdown to Quit Method with Nicotine Replacement Therapies

Some investigations have shown that the cutdown to quit method may improve sustained abstinence from tobacco (Canadian Agency for Drugs and Technology in Health [CADTH], 2014). This method requires the smoker to reduce the number of cigarettes smoked per day and to supplement cigarettes smoked with a nicotine replacement product, such as nicotine gum. Moreover, this method appears to be less effective than planned, abrupt smoking cessation, but may be an option for smokers who are unwilling to abruptly cease smoking, smokers who failed a previous quit attempt, or smokers who desire gradual cessation from smoking (CADTH, 2014). This method is not endorsed at this time by any U.S. smoking cessation treatment guideline, and no nicotine replacement product currently has the U.S. Food and Drug Administration (FDA) approval for this use.

Aversion Therapy

Finally, aversion techniques have been used to make smoking less desirable to the patient. The first method, satiation, requires the patient to smoke double or triple the usual amount in a short time. In the second method, rapid smoking, the patient must inhale rapidly every 6 to 8 seconds until the cigarette is finished or the patient is nauseated. The use of these methods is limited because of possible health problems and compliance issues. Aversive smoking procedures (e.g., rapid smoking, puffing) have been shown to be more effective than providing no counseling, but this method is not recommended by the DHHS/PHS expert panel.

Other Emerging Approaches to Counseling

Recently, individually tailored materials have been researched. Tailored materials are designed to address variables specific to the smoker, such as letters mailed to patients, or web-based materials such as interactive Web sites. Some components of tailored therapy have been shown to be effective. Computerized interventions via the use of e-health and Internet interventions have the potential to reach a larger portion of the smoking population and are inexpensive to deliver. These computer programs collect information from the smoker and use this information to provide tailored feedback and/or recommendations. However, the most effective features of computerized interventions have yet to be identified, and some Web sites may be confusing and may not tailor information to an individual patient's needs. Stepped care interventions employ the use of low-intensity intervention with progression to more intensive interventions in treatment failures. While each of these interventions is promising, none has been adequately studied to be recommended as standard interventions at this time (Fiore et al., 2008).

A health care professional who merely advises his or her patient to quit smoking is providing at least minimal assistance in the efforts.

Goals of Drug Therapy

All patients attempting to quit should be encouraged to use effective pharmacotherapies for smoking cessation. Long-term smoking cessation pharmacotherapy should be considered as a strategy to reduce the likelihood of relapse (Fiore et al., 2008). As with other chronic diseases, smoking cessation requires repeated intervention and multiple quit attempts (Fiore et al., 2008). The most effective treatment of tobacco dependence requires the use of multiple modalities (Fiore et al., 2008). According to the DHHS/PHS guidelines, clinicians should encourage all patients initiating a quit attempt to use one or a combination of efficacious medications, although medication use requires special consideration in some patient groups (i.e., those with medical contraindications, those who use smokeless tobacco products, pregnant/breast-feeding women, and adolescent smokers; Fiore et al., 2008). Long-term abstinence is the ultimate goal of treatment of tobacco use disorders. Initial goals include moving smokers from precontemplating to contemplating quitting or taking action to quit and actually attempting to quit.

Drug therapy known as *nicotine replacement therapy* (NRT), the most commonly used pharmacotherapy for smoking cessation, aims to control nicotine levels in the bloodstream so that withdrawal does not occur while the patient is adjusting to life without cigarette smoking. The goal of therapy is to maintain the cessation of smoking for a period that allows the patient to develop preventive strategies to avoid relapse.

The primary mechanism of action by which NRT enhances smoking cessation is to obtain plasma levels of nicotine that can relieve or prevent withdrawal symptoms (Benowitz, 2008). The pharmacokinetic effects underlie the concept of nicotine replacement as an aid to smoking cessation, providing that steady-state levels of nicotine can prevent a smoker from experiencing intense withdrawal while not providing the reinforcing peaks achieved from smoking (Le Houezec, 2003). Figure 53.1 shows the pharmacokinetic profiles of currently available NRT products. Smokers can, therefore, achieve abstinence by dealing with the various behavioral aspects of smoking. Once abstinence is achieved, the smoker can taper of the nicotine by gradual reduction (Le Houezec, 2003).

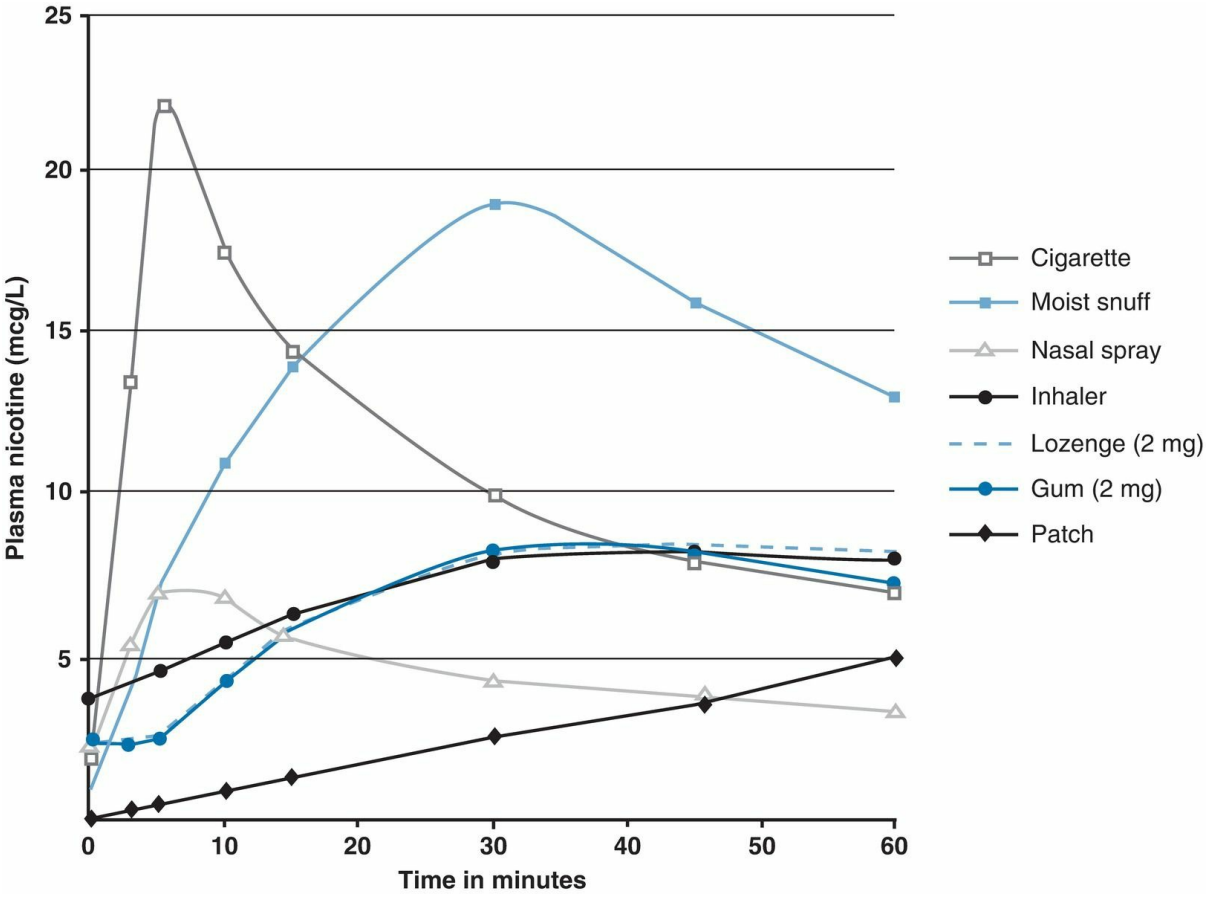

FIGURE 53.1 Pharmacokinetic profiles of nicotine replacement products. (Reprinted with permission from *Rx for Change: Clinician-Assisted Tobacco Cessation* program. Copyright © 1999–2016 The Regents of the University of California. All rights reserved.)

One benefit of NRT includes not exposing the smoker to the carcinogens and other toxins in cigarette smoke. NRT is approved by the FDA as an aid to smoking cessation for the relief of nicotine withdrawal symptoms when used as part of a comprehensive behavioral program. The guideline panel identifies seven first-line medications (bupropion SR, nicotine gum, nicotine inhaler, nicotine nasal spray, nicotine patch, nicotine lozenge, and varenicline) (Table 53.2). Two second-line medications (clonidine and nortriptyline) are also identified for smoking cessation but are not approved by the FDA. The DHHS/PHS expert panel found in research studies that the abstinence rate with NRT was 1.5 to 2.3 times that of a placebo at 6 months after therapy. It is ideal that the patient stops smoking completely before initiating treatment, regardless of which formulation is used, as this may increase the patient's risk of nicotine-associated adverse effect and relapse. However, the FDA has found that overlapping use of NRT with an occasional cigarette poses no significant health risks; this may be communicated to the patient that "slip" with use of a cigarette while using NRT is acceptable, but complete abstinence from smoking is preferred (FDA, 2015). The DHHS/PHS expert panel does not endorse the use of any one NRT over another because of similar effectiveness demonstrated with all products. Patient

preference will help guide the clinician's treatment decisions.

TABLE 53.2 Overview of Selected Agents Used in Smoking Cessation

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Nicotine Products			
Nicotine patch (Habitrol and various generic products) ≥10 cigarettes/d: 21 mg for 4 wk, then 14 mg for 2 wk, then 7 mg for 2 wk <10 cigarettes/d: 14 mg for 6 wk, then 7 mg for 2 wk	Cutaneous irritation, GI disturbances, dizziness, headaches	None noted	Patch worn for 16–24 h/d
Nicotine patch (Nicoderm CQ) ≥10 cigarettes/d: 21 mg for 6 wk, then 14 mg for 2 wk, then 7 mg for 2 wk <10 cigarettes/d: 14 mg for 6 wk, then 7 mg for 2 wk	Same as above	Same as above	Same as above
Nicotine polacrilex gum (Nicorette) Start: 2 mg q1–2h for 6 wk 2 mg q2–4h for 2 wk 2 mg q4–8h for 2 wk Range: 1–24 pieces per day	Sore throat, hiccups, undesirable taste	Dentures, temporomandibular joint disease, dizziness	Gum should be chewed until patient feels a tingling sensation, then "parked" between cheek and gum. Repeat chewing every 15–30 min. When given as monotherapy, patient should chew at least 9 pieces each day during the first 6 wks
Nicotine nasal spray (Nicotrol NS) Start: 1–2 sprays in each nasal hourly (one spray = 0.5 mg) Range: 1–40 sprays per day	Nasal irritation, sore throat, dizziness, headache	Hypersensitivity to preservatives Rhinitis, sinusitis	No more than 5 sprays per hour When given as monotherapy, patient should use at least 8 doses each day
Nicotine inhaler (Nicotrol inhaler) Start: 6 cartridges per day; self-titrated to avoid withdrawal Range: 6–16 cartridges per day	Throat irritation, dizziness, headache, cough	Hypersensitivity to menthol	A minimum of 6 cartridges must be used for 3–6 wk. Do not use for >6 mo
Nicotine lozenge (Commit) First cigarette within 30 min of waking: 4 mg First cigarette >30 min after waking: 2 mg One lozenge every 1–2 h for first 6 wk, then one every 2–4 h for 2 wk, and one lozenge every 4–8 h for 2 wk	Hiccups, dyspepsia, dry mouth, and irritation/soreness of the mouth	Those who continue to smoke, chew tobacco, or use other nicotine products	Lozenge should be placed in mouth and allowed to dissolve for about 20–30 min. Do not swallow or chew the lozenge. Occasionally, move the lozenge from one side of the mouth to other until completely dissolved
Nonnicotine Products			
Bupropion (Zyban) Start: 150 mg PO once daily for 3 d, then increase to 150 mg PO bid for 7–12 wk Range: 150–300 mg/d	Headache, dry mouth, insomnia	History of seizures, eating disorders	Patient must set a target quit date the second week of therapy May be a good agent for initial therapy in smokers with concomitant depression
Varenicline (Chantix) Start: 0.5 mg PO once daily for 3 d, then increase to 0.5 mg PO bid for 4 d, then increase to 1 mg PO bid for 12–24 wk	Neuropsychiatric disturbances such as mood changes, anxiety, suicidal ideation	History of anaphylaxis or skin reactions	Do not start in patients with preexisting psychiatric illness Patient should set quit date for eighth day of therapy

Nicotine Replacement Patches

Nicotine Transdermal Patches

Currently, there are two nicotine transdermal systems on the market, and both products are available without a prescription (Table 53.2): Nicoderm CQ and Habitrol are available as brand name products and as various generic nicotine transdermal patch products.

Nicoderm CQ varies slightly from other available products in its weaning regimen. The recommended dosing regimen for Nicoderm CQ patches for patients who smoke more than 10 cigarettes daily is 21 mg for 6 weeks, 14 mg for 2 weeks, and 7 mg for 2 weeks. The recommended dosing regimens for Habitrol, for other generic patch products, and for patients who smoke more than 10 cigarettes daily are 21 mg for 4 weeks, 14 mg for 2 weeks, and 7 mg for 2 weeks. For all available products, it is recommended that patients who smoke 10 cigarettes or less per day start at a 14-mg patch for 6 weeks and then decrease to a 7-mg patch for 2 weeks.

All available transdermal products may be worn for 16 to 24 hours and should be applied at the same time each day. Patients who experience nightmares or other sleep disturbances when wearing the patch for 24 hours may be counseled to wear it for 16 hours and to remove the patch prior to falling asleep. Persistence of sleep disturbances despite removing patch before sleeping may signal the presence of nicotine withdrawal. A new patch should then be applied on waking, and only one patch should be applied at a time.

The most common side effects of the transdermal patches include a mild skin reaction with pruritus, burning, and erythema. The skin reactions are usually mild and self-limiting, resolving within 24 hours of removing the patch. Rotating application sites, changing brands, and applying nonprescription strength hydrocortisone cream may reduce the incidence and severity of these events. Transdermal patches should not be used on patients with systemic eczema, atopic dermatitis, or psoriasis because these patients are more likely to develop skin reactions.

The initial patch should be applied immediately on awakening on the patient's targeted quit date. The application site should be clean and dry before applying the patch. The patient should press the patch onto a hairless portion of the upper outer arms or upper chest and hold it for approximately 10 seconds. To decrease irritation that may occur with the patches, the patient should rotate application sites with each new patch. It is common to experience mild tingling, itching, or burning sensations for the first minute after application. If these symptoms persist for more than 4 days, however, the prescriber should be notified and an alternative method should be used.

If the patch gets wet or if it falls off, a new patch should be applied to a different site and then removed at the original time the first patch would have been removed. Proper disposal of the patch is important. After the patch is removed, it should be placed in the wrapper from the newly applied patch and discarded responsibly—out of the reach of

children and pets.

It is important to advise patients not to use the patch if they use other nicotine-containing products or continue to smoke or chew tobacco unless informed by their physician. However, the patient may be reassured that health risks appear to be minimal if a tobacco product is used while wearing the patch (FDA, 2015). Instruct patients not to smoke even if they are not wearing the patch because the nicotine in the skin will be entering the bloodstream for several hours after the patch is removed.

Nicotine Gum

Nicotine polacrilex gum (Nicorette) was the first NRT to be approved and is available without a prescription. The patient should chew the gum slowly until he or she senses a peppery, citrus, or minty taste or tingling. Then, the gum should be "parked" between the cheek and the gingiva to increase absorption. This cycle should be repeated with the same piece of gum approximately every minute for 15 to 30 minutes. The gum is more effective if used on a fixed schedule as opposed to an "as-needed" basis (APA, 1996). This may be explained in part by the fact that one piece of gum stays in the bloodstream for 2 to 3 hours. Therefore, a fixed schedule will help to ensure consistent nicotine levels in the blood, and the patient should be advised to chew one piece of gum every 1 to 2 hours (Hukkanen et al., 2005). Chewing at least nine pieces a day during the first 6 weeks of attempting to quit has been shown to increase the patient's chance of success. Most patients should use a 2-mg dose, but a 4-mg dose is also available and may be used as the initial dose in the following:

- Patients with a history of severe withdrawal symptoms
- Patients who smoke their first cigarette within 30 minutes of awakening
- Patients for whom the 2-mg gum failed
- Patients who request it

The initial duration of therapy is 6 weeks regardless of what strength is used. After the first 6 weeks, the patient should be slowly weaned off the gum to avoid withdrawal symptoms. The manufacturer of Nicorette gum recommends that the patient chew a piece of gum every 1 to 2 hours during the first 6 weeks of therapy, then decrease to one piece of gum every 2 to 4 hours during weeks 7 and 8, and then one piece of gum every 4 to 8 hours during weeks 8 to 12. The maximum dose is 24 pieces per day (see Table 53.2).

The patient should be advised not to smoke while using the gum; however, the patient may be reassured that a "slip" of smoking a cigarette while using nicotine gum is unlikely to cause harm (FDA, 2015). In addition, food and fluid should not be taken for at least 15 minutes before and after chewing the gum because certain foods (e.g., coffee, tea, carbonated beverages) cause the saliva to become more acidic, consequently decreasing the absorption of the gum. Patients should dispose of the gum and wrapper properly to avoid ingestion by small children and pets.

Common adverse effects of nicotine gum use include jaw muscle aches and fatigue, oral sores, hiccups, belching, throat irritation, and nausea. Some of these events (i.e., hiccups, throat irritation, nausea) result from rapid chewing, leading to excessive nicotine release and absorption. Patient education on the proper use of the gum decreases the incidence of these events.

Nicotine Nasal Spray

The nicotine nasal spray is a prescription product and is marketed under the brand name Nicotrol NS. Compared to other NRT products, nicotine nasal spray has the fastest rate of absorption and thus is the most similar to the onset of the effect that occurs with cigarette smoking (Hukkanen et al., 2005). This formulation may have a role for patients who fail to quit smoking by using the gum or patch or who are highly dependent smokers who require nicotine replacement at a quicker rate than the gum and patch can provide.

Each spray contains 0.5 mg of nicotine, and the minimum dose is 1 mg–delivered as one 0.5-mg spray in each nostril. The recommended initial dosage of the nasal spray is 1 mg (i.e., one spray in each nostril) or 2 mg (two sprays in each nostril) per hour. The dosage may be increased as needed to prevent withdrawal symptoms. The maximum dose is 5 doses (i.e., 5 mg) per hour or 40 sprays per day. A minimum of 8 doses should be used each day to increase the chance of success. After the initial 6 to 8 weeks of treatment, the dosage should be slowly tapered over the next 4 to 6 weeks. No one titration schedule has proven superior; some health care providers may recommend that the patient taper by inhaling half of the dose while maintaining the same dosing frequency used during the initial 8 weeks of therapy or extending the dosing interval (i.e., skipping doses) while maintaining the same dose. Using the nasal spray for longer than 6 months is not recommended because there is no greater efficacy, and the safety of use beyond 6 months has not been well studied.

Before administering the first dose, the patient must prime the pump. This is accomplished by pumping the medication into a tissue six to eight times until a fine spray appears. If the spray is not used for 24 hours or more, the pump must be primed again. Once the pump is ready for use, the patient must follow the manufacturer's directions. For a summary, see Box 53.5. The difference between the nicotine nasal spray and other nasal sprays is that the patient must remember not to sniff or inhale while administering Nicotrol NS. If the spray comes in contact with the mouth, eyes, or skin, the patient should rinse the area immediately with cold water to prevent toxicity. The patient must be aware that it takes approximately 1 week to adjust to the side effects.

BOX 53.5 How to Use a Nicotrol Inhaler

STEP 1:Blow your nose to make sure it is clear.
STEP 2:Tilt your head back slightly and insert bottle tip into nostril as far as it is

comfortable.
STEP 3:Breathe in through your mouth and hold your breath.
STEP 4:Press on the bottom of the bottle with your thumb to release one spray. Breathe out through your mouth. Do not sniff or inhale through your nose and do not swallow while spraying. If your nose runs after releasing the spray, gently sniff to keep the spray in your nose. Wait 2–3 min before blowing your nose.
STEP 5:If you are to use one spray in each nostril, repeat steps 2–4 for the other nostril.
STEP 6:Wipe bottle tip and replace the cap.

Common side effects of the nicotine nasal spray include nose and throat irritation, rhinitis, sneezing, coughing, and watery eyes. Other side effects were transient changes in sense of taste or smell, nasal congestion, and transient epistaxis. These events can occur in more than 75% of patients.

Nicotine Inhaler

In 1998, the nicotine inhaler became available as a prescription drug for smoking cessation. The inhaler is thought to improve smoking cessation through two mechanisms: when it is used, it mimics the hand-to-mouth ritual that occurs when smoking a cigarette and it produces a sensation of inhaled smoke on the back of the throat. However, because of the limited evidence, the inhaler is often reserved for patients who have failed initial treatment with other products (see Table 53.2).

The inhaler consists of a mouthpiece and a cartridge. These two separate pieces are pressed together to break the seal on the cartridge. Once the seal is broken, the nicotine-filled air is inhaled into the mouth as a cigarette would be inhaled. The best results have been found when the patient takes shallow, frequent puffs over 20 minutes.

The recommended dose is 6 to 16 cartridges per day. A minimum of six cartridges must be used during the first 3 to 6 weeks of therapy, and therapy should be continued for at least 3 months. After 3 months, the dose should be tapered over the next 6 to 12 weeks. No standard tapering schedule exists; patient and health care provider may devise a patient-specific tapering schedule. Use of the Nicotrol inhaler should not exceed 6 months. Like the nasal spray, the inhaler must be used regularly for 1 week before the patient adjusts to the side effects. Finally, because the cartridges contain high concentrations of nicotine, they should be stored and disposed of in a place that cannot be accessed by children and pets.

The nicotine inhaler is associated with dyspepsia, throat or mouth irritation, oral burning, rhinitis, and cough after inhalation. Patients should adjust to side effects after the first week of continued inhaler use.

Nicotine Lozenge

The newest formulation of NRT is the nicotine lozenge (formerly Commit, now Nicorette), which was approved by the FDA in October 2002 and is available without a prescription. The nicotine lozenge is available in 2-mg and 4-mg strengths. One study found that treatment with the nicotine lozenge results in significantly greater 28-day abstinence at 6 weeks for the 2-mg (46.0% vs. 29.7%; $p < 0.001$) and the 4-mg lozenges compared with a placebo (48.7% vs. 20.8%; $p < 0.001$; Shiffman et al., 2002). Similar treatments were maintained for a full year. Use of more lozenges also resulted in reducing cravings and withdrawal (Shiffman et al., 2002).

The nicotine lozenge helps control cravings by delivering craving-fighting medicine quickly. The lozenge uses a unique method for smokers to determine their degree of physical dependence on nicotine. This indicator is called TTFC. With TTFC, those who smoke their first cigarette within 30 minutes of waking are directed to use the 4-mg strength, whereas those who smoke their first cigarette after 30 minutes of waking are directed to use the 2-mg strength (Shiffman et al., 2002). It is hypothesized that the TTFC is a better method than number of cigarettes smoked per day as a way of identifying patients who are highly nicotine dependent. This is because some patients may not smoke often each day but are physiologically dependent on nicotine since they develop withdrawal symptoms during prolonged periods without smoking (i.e., upon awakening after no cigarette use while sleeping; Shiffman et al., 2002). Utilizing TTFC may allow clinicians to identify more patients with physiologic nicotine dependence and recommend higher, more effective doses of NRT. It is recommended that during the first 6 weeks, an individual should take one lozenge every 1 to 2 hours, for at least 9 days. This dosage is then reduced to one lozenge every 2 to 4 hours in weeks 7 to 9 and every 4 to 8 hours in weeks 10 to 12. The recommended length of treatment of therapy for the nicotine lozenge is 12 weeks. Because it delivers 25% more nicotine per dose, the lozenge may be an alternative for patients who report the presence of withdrawal symptoms with the gum (Shiffman et al., 2002).

The patient should be advised not to eat or drink for 15 minutes before using the nicotine lozenge. The lozenge should be placed in the mouth and sucked on for 20 to 30 minutes to allow the lozenge to slowly dissolve. The lozenge should not be swallowed or chewed. The patient will feel a warm or tingly sensation. Occasionally, the lozenge should be moved from one side of the mouth to the other until it is completely dissolved. Only one lozenge should be used at a time, and patients should not use more than 5 lozenges in 6 hours or more than 20 per day.

The most common side effects of the nicotine lozenge are hiccups, dyspepsia, dry mouth, nausea, and irritation/soreness in the mouth and throat (Shiffman et al., 2002). These effects mainly occurred in patients who chewed or swallowed the lozenge. Patient education on how to properly administer the lozenge can help decrease these incidences. Finally, because the lozenge looks similar to hard candy, it should be stored and disposed properly to avoid access to children.

Nonnicotine Therapies

Bupropion

Bupropion is the first nonnicotine product approved for smoking cessation. The drug has been commonly used as an antidepressant under the brand name Wellbutrin SR. It is available by prescription as an aid to smoking cessation under the brand name Zyban. The exact mechanism of action is unknown; however, it is believed to be related to dopaminergic or noradrenergic properties. In a randomized double-blind, placebo-controlled trial (Dale et al., 2001), 27% of patients who received the active drug were abstinent at 6 months compared with 16% of patients taking a placebo ($p < 0.001$).

The initial dose of bupropion SR is 150 mg/d for 3 days to decrease the incidence of insomnia. After 3 days, the dose can be increased to 150 mg twice a day for 7 to 12 weeks. Dosages higher than 300 mg/d are not recommended because of the increased risk of seizures. Unlike NRT, bupropion SR therapy should be initiated while the patient is still smoking because the drug takes approximately 1 week to reach steady-state plasma concentrations. The patient should set a target quit date during week 2 of therapy. If the patient has not made significant improvements by week 7 of treatment, the attempt is unlikely to be successful and the medication should be discontinued. Additionally, a patient who successfully quits after 7 to 12 weeks of treatment should be considered for continuation of bupropion SR therapy. Tapering the dose is not required when stopping the medication.

The most common side effects of bupropion SR are dry mouth and insomnia. Insomnia may be reduced by avoiding bedtime administration, but the patient must be counseled to allow 8 hours between the 2 daily doses. Other adverse events that can occur include nervousness or difficulty concentrating, rash, and constipation. Seizures have also occurred but are very rare (Dale et al., 2001).

It is important that patients taking bupropion SR participate in behavioral therapy programs that include counseling both during and after therapy. Patients need to be informed not to use Wellbutrin, Wellbutrin SR, or Wellbutrin XL while taking Zyban because these medications all contain bupropion. In addition, monoamine oxidase inhibitors should not be used during or within 14 days of bupropion SR treatment. The interaction between these agents increases bupropion toxicity (i.e., seizures, psychotic changes). Zyban SR should not be chewed or crushed because it will damage the sustained release formulation, which may increase the risk of overdose and adverse events.

Varenicline

Varenicline is the newest approved agent on the market to aid in smoking cessation. It is available in the United States with a prescription under the brand name Chantix. It aids in smoking cessation by binding to a subunit of the nicotinic acetylcholine receptor. When attached to this subunit, varenicline blocks nicotine's binding to the same subunit and

blocks nicotine's effects in the brain (i.e., reward, stimulant, depressant affects). Varenicline is also a partial agonist of the nicotine acetylcholine receptor, so it alleviates withdrawal symptoms produced with smoking cessation. In short, varenicline provides patients attempting to quit some of the rewarding effects felt with smoking while blocking the reinforcement effects of continued nicotine use. In one randomized controlled trial, varenicline given for 12 weeks improved successful quit rates during weeks 9 to 12 when compared to a placebo (43.9% vs. 17.6%, $p < 0.001$) and when compared to bupropion (43.9% vs. 29.8%; $p < 0.001$; Jorenby et al., 2006). However, as is the case with many smoking cessation interventions, quit rates during weeks 9 to 52 were lower in all treatment groups but still highest in the varenicline treatment group: 23% varenicline versus 10.3% placebo ($p < 0.001$) and 23% varenicline versus 14.6% bupropion ($p < 0.004$).

To reduce the risk of nausea, varenicline should be titrated over a 1-week period to its effective dose of 1 mg twice daily. The starting dose is 0.5 mg once daily for days 1 to 3, which is then increased to 0.5 mg twice daily for days 4 to 7, and finally increased to the target dose of 1 mg twice daily on day 8. Patients who develop intolerable nausea when taking 1 mg twice daily may have the dose reduced to 1 mg once daily, but a dose titration to 1 mg twice daily should be attempted at a later time. For people with severe renal impairment (creatinine clearance less than 30 mL/min), the starting dose is 0.5 mg once daily, which may be titrated to a target dose of 0.5 mg twice daily. Varenicline should be started 1 week before the patient's set quit date. As with other smoking cessation treatments, varenicline should be given along with behavioral counseling.

The most commonly reported adverse events are nausea, constipation, and abnormal dreams. Other side effects are headaches, difficulty concentrating, somnolence, and visual disturbances. There have been several reports of accidents and near-miss accidents while driving or operating heavy machinery in people taking varenicline, which may have been a result of somnolence and visual disturbances. Patients should be counseled not to drive or operate heavy machinery until they know how varenicline will affect them.

Varenicline use has been reported to cause neuropsychiatric symptoms (e.g., mood changes, psychosis, hallucinations, suicidal ideation, suicide attempts, and completed suicides). Because of this effect, varenicline should not be prescribed to patients with preexisting psychiatric conditions, and patients who experience any changes in mood or behavior or develop suicidal ideation should immediately stop varenicline and contact their health care provider immediately. Recommendations regarding varenicline use in patients with stable depression or previously treated depression may change as more data become available. Anthenelli and colleagues found that varenicline did not exacerbate depression in patients on stable depression treatment (stable treatment = no dose changes to antidepressant for at least 2 months) or patients whose depression was effectively treated within the 2-year period preceding study enrollment (Anthenelli et al., 2013). For now, the recommendation remains that varenicline use should be avoided in patients with a history of psychiatric disorders.

Clonidine and Nortriptyline

Two other nonnicotine products are also available to aid in smoking cessation but are not approved by the FDA for smoking cessation. These two products are clonidine and nortriptyline, which are both available only with a prescription. Clonidine therapy has been examined for use in treatment of nicotine addiction because of its availability to reduce withdrawal symptoms in people addicted to narcotics or alcohol. Clonidine treatment increased the chance of a successful quit attempt when compared to a placebo (odds ratio 2.1, CI: 1.2 to 3.7; Fiore et al., 2008). Clonidine therapy is usually started 3 to 7 days before the quit date. Oral clonidine can be given 0.10 mg orally twice daily initially, and the dosage can then be adjusted as tolerated to 0.1 to 0.75 mg/d administered in divided doses (Fiore et al., 2008). Alternatively, the clonidine transdermal patch can be used at a dosage of 0.1 to 0.2 mg/d. Duration of therapy is for 3 to 10 weeks, during the time acute nicotine withdrawal symptoms would be present. The dose should be tapered over several days in all patients to reduce withdrawal effects from clonidine, but tapering is especially important in patients with hypertension to avoid rebound hypertension and patients with diabetes who may experience relative hypoglycemia (Gourlay et al., 2008). Those with rebound hypertension should not use clonidine. Common side effects include dry mouth, drowsiness, dizziness, and sedation.

Nortriptyline is another second-line nonnicotine agent that has been effective and well tolerated for the treatment of addiction to smoking (Da Costa et al., 2002). Nortriptyline dosage may be started at 25 mg/d and titrated to a target dose range of 75 to 100 mg/d and duration for 12 to 24 weeks (Fiore et al., 2008). It may double the chances of smoking cessation compared to a placebo (odds ratio 1.8, CI: 1.2 to 1.7; Fiore et al., 2008). Nortriptyline is contraindicated in those with risk of arrhythmias. Common side effects include sedation and dry mouth (Da Costa et al., 2002).

The DHHS/PHS guidelines recommend the use of these two products as second-line therapy because they are not FDA approved for the treatment of nicotine dependence and withdrawal and because of concerns with the side effect profiles of these agents.

Uses of Electronic Cigarettes to Aid in Smoking Cessation

A recent systematic review was conducted to analyze published data on the use of e-cigarettes to aid in smoking cessation efforts. The authors concluded that e-cigarette use, when compared to placebo, may improve chances for maintaining smoking cessation at 6 months. However, the recommendation was deemed weak because of the relatively small numbers of patients included in the analysis. There were no observed differences in success rates when e-cigarette use was compared to nicotine transdermal therapy, but this finding may have been the result of small numbers of participants included in the trials (McRobbie et al., 2014).

Because e-cigarettes are not regulated by the FDA, ingredients in various products may be unknown. According to a National Institute of Drug Abuse publication, some e-

cigarettes that underwent testing were found to contain formaldehyde, a known carcinogen, and to contain heavy metal nanoparticles from the vaporizing apparatus (National Institute of Drug Abuse, 2014). Use of e-cigarettes should not be recommended to aid in smoking cessation efforts because of unconfirmed effectiveness and potential safety concerns. FDA-regulated NRT may be considered for the patient who finds appealing the hand-to-mouth ritual associated with the use of e-cigarettes.

Combination Drug Therapy

Although most of the drugs discussed above have only been approved as single pharmacologic agents, combined treatment may be appropriate for smokers who are unable to quit with monotherapy. Three combinations of nicotine replacement have shown to be safe and effective in smoking cessation and are recommended by the DHHS/PHS expert panel: long-term (greater than 14 weeks) nicotine patch + other NRT (gum or spray), nicotine patch + nicotine inhaler, and nicotine patch + bupropion SR (Fiore et al., 2008).

An analysis of three studies showed that compared to treatment with nicotine patch monotherapy, combination therapy with long-term nicotine patch and nicotine gum or nicotine spray doubled smoking cessation rates at 6 months (odds ratio 1.9, CI: 1.3 to 2.7; Fiore et al., 2008). Kornitzer and colleagues studied smoking cessation rates in people given nicotine patch + nicotine gum versus nicotine patch + a placebo (Kornitzer et al., 1995). The group receiving the patch + gum was more likely to have continuously abstained from smoking at 3 and 6 months compared to the group receiving the patch alone (34.2% vs. 22.7% at 3 months, $p = 0.027$; 27.5% vs. 15.3% at 6 months, $p = 0.010$). Incidence of side effects was similar in combination and monotherapy groups. A review of four studies found that combination therapy with nicotine patch and nicotine gum reduced withdrawal symptoms in heavy smokers (Okuyemi et al., 2000). Blondal and colleagues' study results showed the combination of nicotine patch + nicotine spray increased continued smoking cessation at 3 and 6 months when compared to the nicotine patch alone (37% vs. 25%, $p = 0.045$ at 3 months; 31% vs. 16% at 6 months, $p = 0.005$; Blondal et al., 1999).

An analysis of two studies showed that compared to placebo, combination therapy with nicotine patch and nicotine inhaler doubled the chances for smoking cessation at 6 months (odds ratios 2.2, CI: 1.3 to 3.6; cessation rate 25.8%; Fiore et al., 2008). However, this combination does not seem to provide additional benefits over nicotine patch monotherapy. Tonnesen and Mikkelsen found continued abstinence rates were actually lower at 3 and 6 months in the nicotine patch + nicotine inhaler group compared to nicotine patch alone. However, the authors did not report p-values, so we are unable to determine if these differences were statistically significant (14.8% vs. 19.2% at 3 months, 8.7% vs. 14.4% at 6 months; Tonnesen & Mikkelsen, 2000). Adverse events were similar in combination and monotherapy treatment arms. Combination of NRT treatments should be considered for smokers with significant cravings or withdrawal symptoms despite adequate doses of single agents and should be continued for 3 to 6 months (Okuyemi et al., 2000).

Unlike the other combinations previously described, use of combination therapy with the nicotine patch and bupropion is FDA approved. An analysis of three studies showed that compared to nicotine patch alone, the combination therapy with nicotine patch and bupropion increased the chances for continued smoking cessation at 6 months by 30% (odds ratio 1.3, CI: 1.0 to 2.8; Fiore et al., 2008). Jorenby and colleagues found that abstinence rates at 6 and 12 months were higher in the bupropion + nicotine patch group compared to patch monotherapy (38.8% vs. 21.3%, $p < 0.001$ at 6 months; 35.5% vs. 16.4%, $p < 0.001$ at 12 months; Jorenby et al., 1999). Abstinence rates in the combination group were higher compared to bupropion monotherapy, but these differences were not statistically significant. If this combination is initiated, patients should be started on bupropion 150 mg/d for 3 days, then 150 mg twice daily for 1 to 2 weeks prior to quit date. Transdermal nicotine patch therapy should be added starting on the quit date and treatment continued for 3 to 6 months (Okuyemi et al., 2000).

Koegelenberg and colleagues recently published study results showing the combination of varenicline and nicotine transdermal patch to have higher abstinence rates at 12 weeks, compared to varenicline monotherapy (Koegelenberg et al., 2014). This placebo-controlled study included 446 participants and was conducted in South Africa. The continuous abstinence rates at 12 weeks were 55.4% versus 40.9% (OR 1.85; 95% CI: 1.19 to 2.89; $p = 0.007$) in the combination and varenicline monotherapy groups, respectively. Continuous cessation rates were also higher in the combination group at 6 months: 49% versus 32.6% (OR 1.98; 95% CI: 1.25 to 3.14; $p = 0.004$). There were more reports of nausea, sleep disturbances, depression, and skin reactions in the combination group; however, skin reactions were the only adverse effect that was statistically higher than the monotherapy group (14.9% vs. 7.8%; $p = 0.03$). While these results are promising, more studies are needed, and more information about the adverse effect profile with this combination are needed before this combination should be routinely prescribed.

There are also ongoing investigations of bupropion and varenicline combination therapy for smoking cessation. Ebbert and colleagues observed statistically significant differences in long-term smoking cessation (defined as no smoking from 2 weeks after quit date) at 12 and 26 weeks for patients taking the combination of the two medications compared to those participants taking varenicline monotherapy (Ebbert et al., 2014). More patients in the combination group had maintained smoking cessation at 52 weeks, but the difference was not statistically significant. The potential benefit of higher quit rates was offset by increased reports of anxiety and depressive symptoms with combination therapy. At this time, combination therapy with bupropion and varenicline should not be recommended.

Selecting the Most Appropriate Agent

Which therapeutic agent is most effective depends on the patient and the patient's smoking history, among other factors. For a review of the recommended order of treatment and the clinical guidelines for prescribing pharmacotherapy according to the DHHS/PHS guidelines for smoking cessation, see Tables 53.3 and 53.4 and Figure 53.2.

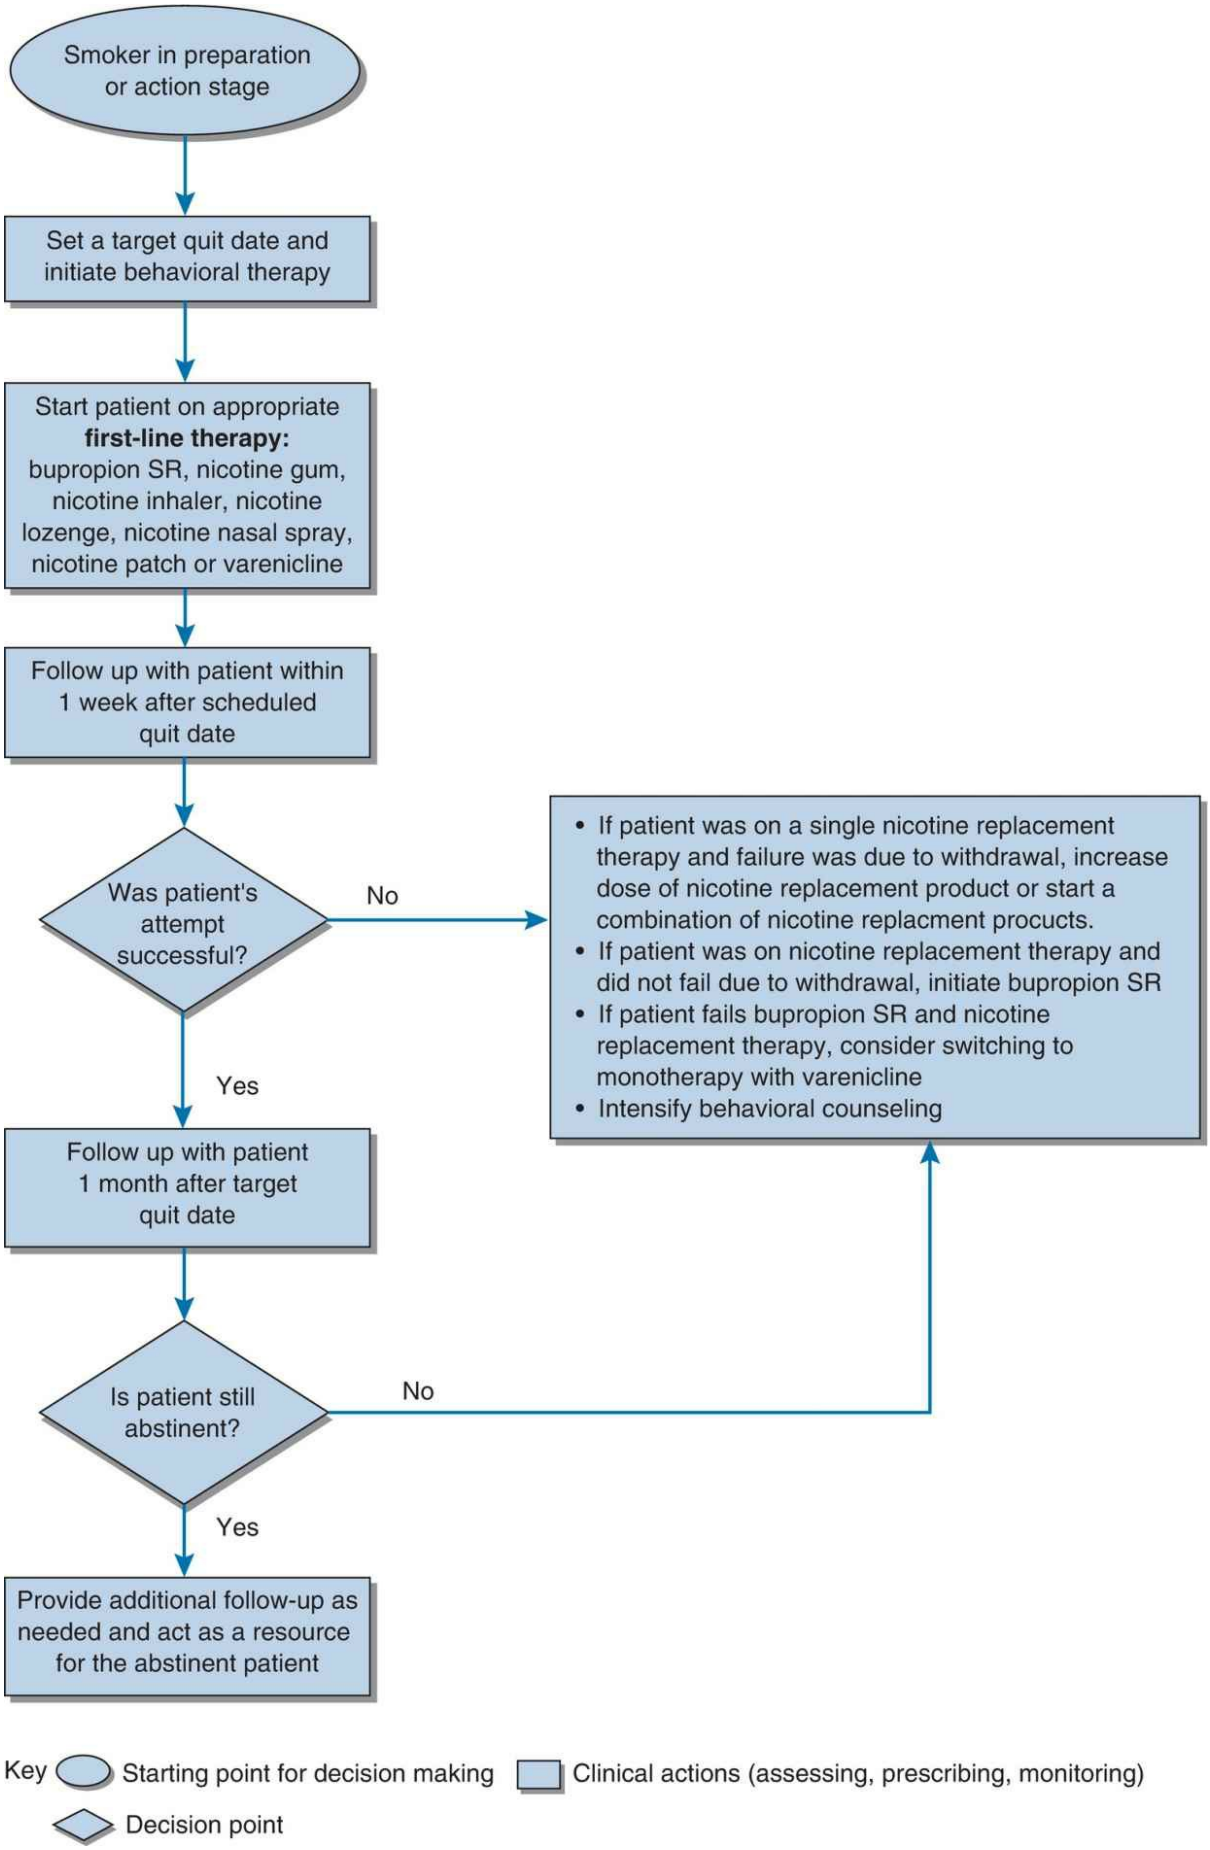
TABLE 53.3 Recommended Order of Treatment for Smoking Cessation

Order	Agents	Comments
First line	All nicotine replacement therapies, bupropion, varenicline	There is evidence showing all of these therapies increase abstinence when compared to a placebo. The patch leads to fewer compliance problems, less patient education time, and greater ease of use. Also, the patch provides continuous nicotine replacement without multiple daily dosing, unlike other forms of nicotine replacement (i.e., gum, lozenge, inhaler, nasal spray). It is recommended that the patch be used routinely in clinical practice unless contraindicated or if the patient has failed the patch
Second line	Combination therapy	Combination therapy using the patch plus the gum or the patch plus the nasal spray should be considered if patients fail or suffer withdrawal symptoms with the use of the patch alone. In this case, the patch provides continuous nicotine replacement, and the gum or spray provides relief of "breakthrough" withdrawal symptoms. The patch plus bupropion may also be considered when a single nicotine replacement agent fails. However, data are limited with regard to the efficacy of adding nicotine replacement therapy to bupropion after the patient has failed bupropion monotherapy
Third line	Clonidine, nortriptyline	Because of the side effect profile of these agents, they should be reserved for patients who fail first- and second-line therapies

TABLE 53.4 Clinical Guidelines for Prescribing Pharmacotherapy for Smoking Cessation

Who should receive pharmacotherapy for smoking cessation?	All smokers trying to quit, except in the presence of special circumstances. Special consideration should be given before using pharmacotherapy with selected populations: those with medical contraindications, those smoking fewer than 10 cigarettes/d, pregnant/breast-feeding women, those who use smokeless tobacco, and adolescent smokers
What first-line pharmacotherapies are recommended?	All seven of the FDA-approved pharmacotherapies for smoking cessation are recommended, including bupropion SR, nicotine gum, nicotine inhaler, nicotine lozenge, nicotine nasal spray, nicotine patch, and varenicline. The clinician should consider the first-line medication regimens that have been shown to be more effective than the nicotine patch alone—varenicline 2 mg/d or the combination of nicotine patch and as-needed use of nicotine gum or nicotine nasal spray
What factors should a clinician consider when choosing among the seven first-line pharmacotherapies?	Because of the lack of sufficient data to rank order these seven medications, choice of a specific first-line pharmacotherapy must be guided by factors such as clinician familiarity with the medications, contraindications for selected patients, patient preference, previous patient experience with a specific pharmacotherapy (positive or negative), and patient characteristics (e.g., history of depression, concerns about weight gain)
Are pharmacotherapeutic treatments appropriate for lighter smokers (e.g., 10–15 cigarettes/d)?	If pharmacotherapy is used with lighter smokers, clinicians should consider reducing the dose of first-line NRT pharmacotherapies. No adjustments are necessary when using bupropion SR
What second-line pharmacotherapies are recommended?	Clonidine and nortriptyline
When should second-line agents be used for treating tobacco dependence?	Consider prescribing second-line agents for patients unable to use first-line medications because of contraindications or for patients for whom first-line medications are not helpful. Monitor patients for the known side effects of second-line agents
Which pharmacotherapies should be considered with patients particularly concerned about weight gain?	Bupropion SR and nicotine replacement therapies, in particular nicotine gum and nicotine lozenge, have been shown to delay, but not prevent, weight gain
Are there pharmacotherapies that should be especially considered in patients with a history of depression?	Bupropion SR and nortriptyline appear to be effective with this population. NRT also provides some help, but varenicline should be used with caution in this population
Should nicotine replacement therapies be avoided in patients with a history of cardiovascular disease?	No. The nicotine patch in particular is safe and has been shown not to cause adverse cardiovascular effects
May tobacco dependence pharmacotherapies be used long term (e.g., 6 mo or more)?	Yes. This approach may be helpful with smokers who report persistent withdrawal symptoms during the course of pharmacotherapy, who have relapsed in the past after stopping therapy, or who desire long-term therapy. A minority of individuals who successfully quit smoking use ad libitum NRT (gum, nasal spray, inhaler) long term. The use of these medications long term does not present a known health risk. Additionally, the FDA has approved the use of bupropion SR, varenicline, and some NRTs for 6-month use
May pharmacotherapies ever be combined?	Yes. There is evidence that combining the nicotine patch with either nicotine gum or nicotine nasal spray, nicotine patch with nicotine inhaler, and nicotine patch with bupropion increases long-term abstinence rates over a placebo. The use of nicotine patch with either nicotine gum or nicotine nasal spray increases long-term abstinence over the use of a single nicotine replacement product

U.S. Department of Health and Human Services, Public Health Service, Agency for Health Care Policy and Research. (2008). *Treating tobacco use and dependence: 2008 update*. Rockville, MD: Author.



Smoker in preparation or action stage
Set a target quit date and initiate behavioral therapy
Start patient on appropriate **first-line therapy:** bupropion SR, nicotine gum, nicotine inhaler, nicotine lozenge, nicotine nasal spray, nicotine patch or varenicline
Follow up with patient within 1 week after scheduled quit date
Was patient's attempt successful?
No
• If patient was on a single nicotine replacement therapy and failure was due to withdrawal, increase dose of nicotine replacement product or start a combination of nicotine replacment procucts.
• If patient was on nicotine replacement therapy and did not fail due to withdrawal, initiate bupropion SR
• If patient fails bupropion SR and nicotine replacement therapy, consider switching to monotherapy with varenicline
• Intensify behavioral counseling
Yes
Follow up with patient 1 month after target quit date
Is patient still abstinent?
No
Yes
Provide additional follow-up as needed and act as a resource for the abstinent patient
Key
Starting point for decision making
Clinical actions (assessing, prescribing, monitoring)
Decision point

FIGURE 53.2 Treatment algorithm for smoking cessation.

Special Population Considerations

Pregnant Women

Female patients should be monitored for pregnancy because NRT can harm the fetus, and little is known about effects on the fetus with use of bupropion and varenicline Furthermore, no medication intervention has been shown to increase long-term smoking cessation rates in pregnant women (Fiore et al., 2008). The American College of Obstetrics and Gynecology recommends intensive behavioral therapy over medication therapy (ACOG, 2010). If the clinician is considering use of medication therapy for a pregnant smoker, the ACOG recommends that the clinician provides in-depth education about side effect profiles of medications and frequently monitor the patient for adverse effects (ACOG). The nicotine gum and lozenge are classified as pregnancy category C (risk cannot be excluded: animal studies have shown an adverse effect on the fetus, but there are no adequate, well-controlled studies in pregnant women), and the patches, nasal spray, and inhaler are classified as category D (positive evidence of risk: studies in humans or postmarketing have demonstrated a risk to the fetus). Bupropion and varenicline also are classified as category C.

Breast-Feeding Women

No NRT product has been evaluated in breast-feeding women, so it is unknown if these products are excreted in milk. Use of NRT should be considered only if the benefit to the mother outweighs possible harm to the breast-fed infant.

Varenicline has not been evaluated in nursing women, so it is unknown if the product is excreted in breast milk; however, it has been shown to be excreted in milk of lactating animals. For these reasons, the manufacturer recommends to avoid varenicline use in breast-feeding women, unless the benefit to the mother outweighs possible harm to the breast-fed infant. The effects of bupropion on the breast-fed infant are unknown. This agent should be used only if necessary and benefit outweighs risk.

Nicotine replacement therapy should be used with caution in those patients with cardiovascular disease because it can cause tachydysrhythmia and worsen angina. However, the risks are small compared with the cardiovascular effects of smoking. Nicotine concentrations are higher and delivered more rapidly from cigarettes compared with NRT products.

Monitoring Patient Response

Smoking status must be monitored in all patients. As mentioned, patients starting NRT must stop smoking completely before initiating treatment to avoid nicotine toxicity. Common signs of nicotine toxicity include nausea, vomiting, diarrhea, hypersalivation, abdominal pain, perspiration, dizziness, headache, hearing and visual disturbances, confusion, and weakness. On the other hand, patients beginning treatment with Zyban SR or varenicline must set a quit date after the medication has been taken for at least 1 week (1 week for varenicline and 1 to 2 weeks for bupropion SR).

A follow-up telephone call from the practitioner should occur within 1 week after the patient's scheduled quit date. If the patient is aware of the future call, compliance may be improved. In addition, the follow-up call may help detect ineffective use or adverse events early in the course of treatment. Additional follow-up contacts should occur as needed. If the patient has been successful at the time of the call, the clinician should offer congratulations and additional support. However, if the patient has relapsed, it is important to reassure the patient that it is not indicative of ultimate failure. Many smokers attempt to quit several times before achieving their goal. The reasons for failure should be identified and eliminated for the next attempt, and the patient should be encouraged to try again. Intensification of behavioral counseling may also be warranted. Therapy may be prolonged beyond 3 months if the patient develops cravings or feels he or she may relapse upon discontinuation of therapy. At least one study found that duration of therapy for 6 months or longer was associated with higher quit rates (Stead et al., 2012).

Duration of therapy must be monitored to evaluate if tolerance or physical dependence occurs to NRT. Dependence is most common with the nicotine nasal spray because of its rapid delivery of nicotine. Proper dosage titration and weaning schedule should be monitored as well to prevent withdrawal symptoms from occurring.

Patient Education

The occurrence of adverse events with any medication has a definite correlation with patient compliance. Therefore, it is important that both the practitioner and patient be aware of the common side effects that may occur when using smoking cessation products. In addition, the patient needs to be informed that tolerance to the adverse effects associated with NRT usually occurs.

Weight gain is a common outcome of smoking cessation, and many patients are hesitant to quit for this reason. Many former smokers gain 4 to 5 kg, but as many as 13% gain 11 kg or more (Pisinger & Jorgensen, 2007). The mechanism for this is thought to be a slowing of metabolism. As mentioned earlier, the average smoker weighs 2.4 to 3.0 kg less than the average nonsmoker (Audrain-McGovern & Benowitz, 2011; Molarius et al., 1997). Therefore, with the cessation of smoking, the average former smoker should weigh approximately the same as the average nonsmoker. Patients must be informed that weight gain is possible but not significant. In addition, the health risk of increased weight is small compared with continued smoking. The increase in weight can be addressed after the patient has achieved complete abstinence. If weight gain is a major deterrent to treatment, nicotine replacement therapies, particularly nicotine gum and nicotine lozenge, and bupropion may be used since these agents may delay the weight gain.

Furthermore, patient counseling on the proper use of nicotine products including dose and administration can improve efficacy and safety of the medications. Although the important role of pharmacotherapy is addressed, it should be recognized that a sustained reduction in smoking prevalence will require social desirability of limiting access to cigarettes and increasing availability and use of effective cessation interventions (Stead et al., 2012). Finally, as the effort to promote smoking cessation interventions is sustained, increase in quit rates will be expected as well as an ultimate decrease in smoking-related morbidity and mortality among both children and adults.

Case Study*

A.P., a 55-year-old white man, has been smoking 1 pack of cigarettes per day for the last 38 years. He has a very stressful job as executive of a large marketing company. A.P. and his coworkers frequently go to “happy hour” at the local bar after a long day at work. When he is at home, A.P. has a sedentary lifestyle that consists of lounging by the pool or watching television. He tried to quit smoking “cold turkey” 2 years ago and remained abstinent for approximately 6 months, but has never tried any pharmacologic smoking cessation aids. During his previous attempt to quit, he became very anxious, irritable, and depressed and had trouble sleeping and concentrating at work. He has a medical history of hypertension for the last 10 years and a bout of successfully treated depression 5 years

ago after the death of his mother. His family has been encouraging him to stop smoking for years. He is currently at the doctor's office for his blood pressure checkup and inquires about smoking cessation options; he doesn't have a definitive timeline for a quit date.

Smoking habits: He smokes 1 pack per day and describes craving his first cigarette of the day about 10 to 15 minutes after awakening. He has observed that smoking with his morning coffee, smoking when drinking at the bar with his friends, and smoking after meals to be triggers that led to his relapse with his prior smoking cessation efforts. He would like to try something to help with acute cravings.

1. What symptoms experienced by this patient during his previous attempt to quit smoking are consistent with physical dependence to nicotine?

2. What motivational level (stage of change) is this patient in?

3. When A.P. reaches the action stage, what pharmacologic options are available for him?

4. Which smoking cessation aid would you recommend starting in this patient? Why?

5. How would your recommendation for smoking cessation aids change if patient reported smoking his first cigarette more than 30 minutes upon awakening?

6. What adverse events could you see with the product that you chose in the previous question?

7. What are some nondrug methods that may enhance smoking cessation in this patient?

54 Weight Loss

Amy M. Egras

Obesity has reached epidemic proportions, affecting more than 600 million adults worldwide. According to the most recent survey from the National Health and Nutrition Examination Survey (NHANES) for 2009 to 2010, 33.1% of U.S. adults are overweight (body mass index [BMI] from 25 to 29.9 kg/m^2) and 35.7% are obese, with a BMI exceeding 30 kg/m^2.

Since the 1960s, the prevalence of obesity among adults in the United States has more than doubled (13% to 36%) and has more than tripled in children and adolescents (5% to 17%). Looking more closely at the youth, for children and adolescents aged 2 to 19, 31.8% are considered to be overweight or obese, with 16.9% considered to be obese.

Causes

The rise in obesity is attributed to physiological and psychological causes as well as social and environmental factors. Overall, obesity is determined by overall body energy stores and the energy balance. When the calories consumed exceed the calories burned, the result is an increase in body fat storage and ultimately obesity. Researchers link obesity to the development of chronic debilitating disease states such as cardiovascular disease, type 2 diabetes mellitus, cancer, sleep apnea, and cognitive dysfunction. Because of these links, the World Health Organization (WHO) and health officials have declared obesity a global epidemic. Additionally, obesity is resulting in a large economic burden. Medical spending for someone who is obese is 42% higher than someone who is normal weight. Overall, the medical burden of obesity is costing the United States as much as $147 billion per year (in 2008 dollars).

Genetic Factors

While genetics is not the primary cause of obesity, it is clear that genetics may predispose people to be obese. In fact, it has been observed that obesity tends to run in families. However, family members share not only the genes but the diet and lifestyle habits that may contribute to obesity. The combination of an imbalance of energy, secondary to psychological/social/environmental factors, plus genetics has created an "obesogenic" environment that results in obesity.

Environmental Factors

Although genetics may play a role in the development of obesity, the environmental influence on both energy intake and energy expenditure is apparent. In regard to energy intake, Americans now live in a world where there is an excess amount of readily available food that is processed (e.g., high in fat and refined sugars) and low in cost. In addition to this, an increase in portion sizes has also contributed to the increase in obesity. Americans are eating more calories than they were 30 to 40 years ago.

On top of the increased consumption of calories is the decrease in energy expenditure. Advancements in technology have moved the American population away from work that demands physical labor to a sedentary lifestyle. This is seen in both the work force and during leisure time.

Psychological Factors

Psychological factors may also influence eating habits. Eating behaviors associated with obesity may include heightened food responsiveness and enjoyment of eating, eating in the absence of hunger, eating disinhibition, and impulsive eating. Other psychosocial issues include heuristic eating, hedonistic eating, and stressful eating.

In heuristic eating, people choose foods based on familiar cues as opposed to making a conscious food choice. This often results in making poor food choices. This is opposed to hedonistic eating where the drive to eat exceeds the feeling of satiety; in other words, the pleasure associated with eating outweighs other factors. And finally, eating during stressful times can contribute to obesity as well. Also, during these situations, people not only consume more calories but often eat high fat or sweets.

Other Causes

Some illnesses can cause obesity. These include hypothyroidism, Cushing syndrome, depression, and some neurologic problems. Certain drugs, such as steroids and some antidepressants, may cause excessive weight gain.

Pathophysiology

Obesity is more than just a disorder of body weight regulation. If this were the case, it would be easy for people to lose weight. However, losing weight is difficult. This is due to some biological adaptive responses to weight loss. Some of these changes are due to dysfunctional hormonal systems.

Signals from the gut, adipose tissue, liver, and pancreas to the hypothalamus and brain stem control appetite. In particular, peptide YY (PYY) and cholecystokinin (CCK) in the gastrointestinal (GI) tract, and gastric inhibitory polypeptide (GIP) and glucagon-like peptide-1 (GLP-1), which are secreted in response to glucose, signal satiety. In addition to these hormones, ghrelin is an appetite stimulant. And, finally, leptin is an appetite suppressant. Leptin works by inhibiting neuropeptide Y/Agouti-related peptide neurons and activating proopiomelanocortin (POMC)/cocaine- and amphetamine-related transcripts in the arcuate nucleus. This cascade of events leads to decreased food intake and increased energy expenditure. A disruption of this hormonal system, along with reward and emotional factors, is believed to play a role in the pathophysiology of obesity.

Diagnostic Criteria

The main variable in obesity is excess body fat. The best way to measure body fat measurement is densitometry, which determines the density of a body submersed in water. However, the cost and technical requirements limit its usefulness in the clinical setting. The more commonly used measurement of obesity in the clinical setting is the BMI.

Body Mass Index

The BMI is the measurement of choice for clinicians and researchers studying obesity. Besides its simplicity, which eases use in clinical practice, associations have been demonstrated between BMI and adiposity, disease risk, and mortality. In general, when BMI exceeds 25 kg/m^2, morbidity and mortality rise proportionally.

The BMI takes into account both a person's height and weight (BMI = kg/m^2). In Table 54.1, the mathematics and metric conversions have already been done. To use the table, find the appropriate height in the left-hand column and then move across the row to the given weight. The number at the top of the column is the BMI for that height and weight. Table 54.2 gives the current guidelines for classification of obesity based on BMI. Similar to the weight-for-height tables, a limitation of BMI is that it does not distinguish excess fat from muscle. Therefore, some muscular people may be mistakenly classified as obese using BMI alone. In addition, it does not take body fat distribution into account, which is an independent predictor of health risk.

TABLE 54.1 Body Mass Index Conversion Chart*

Body Mass Index (kg/m²)														
19	20	21	22	23	24	25	26	27	28	29	30	35	40

*Each entry gives the body weight in pounds for a person of a given height and body mass index. Pounds have been rounded off. To use the table, find the appropriate height in the left-hand column. Move across the row to a given

weight. The number at the top of the column is the body mass index for the height and weight.

From *Understanding adult obesity*. National Institute of Diabetes and Digestive and Kidney Diseases, U.S. Department of Health and Human Services, http://win.niddk.nih.gov/publications/understanding.htm

TABLE 54.2 Classification of Obesity by Body Mass Index (BMI)

	BMI (kg/m^2)
Underweight	<18.5
Normal	18.5–24.9
Overweight	25.0–29.9
Obesity, class	
I	30.0–34.9
II	35.0–39.9
III (extreme)	≥40

Waist Circumference

Waist circumference is a marker of abdominal fat and indicative of increased cardiometabolic risk. Waist circumference is found by measuring the circumference around the waist at the level of the iliac crest (just above the hip bone). A waist circumference exceeding 40 inches (102 cm) in men and 35 inches (88 cm) in women signifies increased health risk in those who have a BMI of 25 to 34.9 kg/m^2. It is not necessary to measure waist circumference in patients with a BMI ≥ 35 kg/m^2 since it is likely to be elevated and adds no additional information regarding cardiometabolic risk.

Initiating Drug Therapy

Weight loss for those who are overweight and obese can provide many benefits such as prevention of disease and improvements in emotions and function. In fact, even modest weight loss, 5% to 10%, has been shown to significantly improve many health conditions. According to the 2013 American Heart Association (AHA)/American College of Cardiology (ACC)/the Obesity Society (TOS) Guidelines for the Management of Overweight and Obesity in Adults, those with a BMI of ≥30 kg/m^2 or BMI of 25 to 29.9 kg/m^2 with additional cardiovascular disease (CVD) risk factors (e.g., diabetes, prediabetes, hypertension, dyslipidemia, elevated waist circumference) should try to lose weight.

Weight loss requires creating an energy deficit by reducing calorie intake, increased physical activity, and behavioral therapy. All patients recommended to lose weight should be offered a comprehensive lifestyle intervention that involves trained professionals (e.g., registered dietician). A comprehensive lifestyle intervention results in greater weight loss initially and, over the long term, helps minimize weight regain. The lifestyle intervention should include the following:

- Reduced calorie diet: decrease calorie intake by ≥500 kcal/d; this is typically prescribed as 1,200 to 1,500 kcal/d for women or 1,500 to 1,800 kcal/d for men.
- Increased physical activity: increased aerobic physical activity for ≥ 150 min/wk (approximately ≥30 min/d, most days of the week).
- Behavior therapy: behavior change program that may include self-monitoring of food intake, physical activity, and weight.

Adjunctive therapy with pharmacotherapy is recommended for patients with a BMI > 30 kg/m^2 or BMI ≥ 27 kg/m^2 with comorbidity (e.g., type 2 diabetes, hypertension, dyslipidemia, CVD, nonalcoholic fatty liver disease, osteoarthritis, major depression, sleep apnea) who are unable to successfully lose weight or sustain weight loss (Table 54.3). Furthermore, for those patients with a BMI ≥ 40 kg/m^2 or BMI ≥ 35 kg/m^2 with a comorbidity, who have not been able to successfully lose weight with behavioral therapy (with or without pharmacotherapy) may be candidates for bariatric surgery.

TABLE 54.3 Overview of Agents Prescribed for Weight Loss

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Appetite Suppressants			
diethylpropion (Tenuate) Start: 25 mg TID (immediate release) or 75 mg daily (controlled release)	Increased heart rate, increased blood pressure, insomnia, tremor, and headache	Advanced atherosclerosis, uncontrolled hypertension, pulmonary hypertension, hyperthyroidism, and glaucoma Approved for those aged >16 years old	Schedule IV drug
phendimetrazine (Bontril) Tablet: 17.5–35 mg 2 or 3 times daily, 1 h before meals (maximum 70 mg TID) Capsule: 105 mg every morning before breakfast	Same as above	Same as above Approved for those aged >17 years old	Schedule III drug
phentermine (Adipex-P, Suprenza) Capsule/tablet: 15–37.5 mg daily in 1–2 divided doses ODT: 15–37.5 mg every morning	Same as above	Same as above Approved for those aged >16 years old	Schedule IV drug
Lipase Inhibitor			
orlistat (Xenical, Alli) Rx: 120 mg tid with meals OTC: 60 mg tid with meals	Oily spotting, flatus with discharge, fecal urgency, and fatty/oily stool	Chronic malabsorption syndrome or cholestasis Safety in people <12 y not established	May decrease absorption of fat-soluble vitamins (A, D, E, K)
Serotonin 5-HT$_{2c}$ Receptor Agonist			
lorcaserin (Belviq) 10 mg BID	Headache, nausea, dry mouth, dizziness, fatigue, constipation, and mood changes	SSRIs, SNRIs, MAOIs, triptans, and bupropion	Schedule IV drug
Glucagon-Like Peptide-1 Receptor Agonist			
liraglutide (Saxenda) Start: 0.6 mg subcutaneously once daily; titrate up weekly to target dose of 3 mg subcutaneously daily	Nausea, vomiting, diarrhea, constipation, and pancreatitis	Medullary thyroid cancer and multiple endocrine neoplasia type 2	
Combination			
Phentermine ER/topiramate Start: phentermine ER 3.75 mg/topiramate 23 mg once daily (maximum phentermine ER 15 mg/topiramate 92 mg once daily)	Increased heart rate, insomnia, dry mouth, constipation, paresthesia, dizziness, and dysgeusia	MAOIs, hyperthyroidism, and glaucoma	Schedule IV drug
Naltrexone/bupropion Start: naltrexone 8 mg/bupropion 90 mg once daily (maximum naltrexone 32 mg/bupropion 360 mg once daily)	Increased heart rate, increased blood pressure, nausea, constipation, headache, vomiting, and dizziness	MAOIs, uncontrolled hypertension, seizure disorders, bulimia or anorexia nervosa, and drug or alcohol withdrawal	Boxed warning: suicidal ideation and serious neuropsychiatric events

Goals of Drug Therapy

Goals of therapy are to reduce body weight and maintain a lower body weight for the long term. A weight loss program that consists of diet, physical activity, and behavior therapy interventions typically results in a 5% to 10% weight loss in the first 6 months. However, it is important to note that sustained weight loss of even 3% to 5% can lead to beneficial effects such as reductions in triglycerides, blood glucose, hemoglobin A1C, and the risk of developing type 2 diabetes. Greater weight loss results in even greater benefits such as decreases in blood pressure, improvements in plasma lipid profiles, and the decreased need for medications to treat chronic conditions such as hypertension, dyslipidemia, and diabetes.

In order to achieve weight loss, patients should be recommended to initiate a comprehensive lifestyle intervention that includes dietary, physical activity, and behavioral therapy. However, weight loss is difficult for most patients. The addition of weight loss medications may actually help with adherence to behavior change by helping to create the negative energy balance needed for weight loss. In turn, this increased weight loss may potentially have positive cardiometabolic benefits as mentioned previously. However, weight loss medications should be used in combination to lifestyle changes; they do not "work on their own." It should also be noted that they also do not change the underlying physiology of weight regulation. Therefore, gradual weight gain typically occurs when the medications are stopped. Keeping this in mind, it is important to note that, previously, most weight loss medications were only approved for short-term use. Over the past several years, there have been several medications approved for chronic weight management.

Stimulants

These agents are not widely used in the treatment of obesity primarily because of their high risk of abuse and high risk of cardiovascular side effects. As Schedule II (C-II) agents, there are often restrictions on the amount and duration of therapy, and some states even prohibit these drugs from being prescribed for weight loss. These medications are not recommended. The only medication in this class is methamphetamine (Desoxyn).

Appetite Suppressants

The nonamphetamine derivatives are considered appetite suppressants. Other terms for these nonamphetamine agents include *anorexiants*. These agents (see Table 54.3) include diethylpropion (Tenuate) extended release (ER) or immediate release, phendimetrazine (Bontril PDM), and phentermine (Adipex-P, Suprenza oral-disintegrating tablet [ODT]). They are considered adjuncts to a comprehensive weight management program. The effects of these agents are often short lived because tolerance may develop to the anorexigenic effect after a few weeks. They are only approved for short-term use.

Mechanism of Action

The mechanism of action of appetite suppressants works to decrease appetite by stimulating the hypothalamus to release catecholamines, specifically norepinephrine. The drugs are considered short-acting agents and are often dosed three times daily but are also formulated in extended-release products for once-daily dosing. The dosing varies by individual response, but it is recommended to start at the lowest dose and increase based on weight loss and tolerance of adverse events.

Contraindications

All of these agents have a potential for abuse, and as such are classified as Schedule III (C-III) or IV (C-IV) drugs. Caution should be used when prescribing these agents in patients with a history of substance abuse.

Because they lead to increased levels of norepinephrine, these agents can result in elevations of blood pressure and heart rate. Therefore, they are contraindicated in patients with advanced atherosclerosis, uncontrolled hypertension, pulmonary hypertension, hyperthyroidism, and glaucoma. In addition, patients taking monoamine oxidase (MAO) inhibitors should not take these medications due to the potential increase in blood pressure that could lead to hypertensive crisis.

Adverse Events

Adverse events include central nervous system (CNS) stimulation such as insomnia, tremor, and headache. Overstimulation may result in an impairment of ability to perform activities requiring mental alertness (e.g., driving or operating heavy machinery). Occasionally, urinary frequency, blurred vision, and changes in libido may occur.

Other adverse effects include dry mouth and nausea as well as cardiovascular effects such as increases in blood pressure and tachycardia. For this reason, blood pressure and heart rate should be monitored on a biweekly or monthly basis and even more frequently in patients with preexisting hypertension.

Lipase Inhibitor: Orlistat

Orlistat (Xenical, Alli) differs from previously available weight loss medications in that it works nonsystemically, acting locally in the GI tract. Orlistat is a GI lipase inhibitor that facilitates weight loss by lowering the absorption of dietary fat, on average by 30%. In research, orlistat users saw small but significant drops in their total cholesterol, LDL, blood pressure, and blood sugar and insulin levels.

Dosage

Orlistat is available as a prescription or OTC medication. Prescription orlistat (Xenical) should be administered at a dose of 120 mg three times a day, while OTC orlistat (Alli) should be administered at a dose of 60 mg three times a day. The doses should be taken during or up to 1 hour after a meal containing fat. The meal should contain less than 30% fat, and orlistat should not be taken with a meal containing no fat. The maximum daily dose is 360 mg/d. A primary concern with the use of orlistat is the potential for decreased absorption of the fat-soluble vitamins A, D, E, and K. Multivitamins should be taken by all patients taking orlistat, and these should be separated from the orlistat by 2 or more hours to ensure vitamin absorption.

Contraindications/Precautions

Orlistat is contraindicated in patients with chronic malabsorption syndrome or cholestasis. In addition, orlistat is not indicated in patients younger than age 12.

Adverse Events

Because orlistat is not absorbed, the primary side effects of orlistat include diarrhea, fatty stools, and flatulence. Patients should be advised of this because the fatty stools may appear as an oily leakage, particularly after flatus, and may cause embarrassment. Nausea and abdominal pain may also occur. GI effects associated with orlistat worsen with the more fat the dieter eats. However, data suggest that concomitant administration of natural fiber (psyllium mucilloid) may significantly reduce the self-reported frequency and severity of GI side effects associated with orlistat. Caution should be used in patients taking oral warfarin (Coumadin) because orlistat may inhibit the absorption of vitamin K, resulting in an increased international normalized ratio (INR). In addition, orlistat may decrease the serum concentration of the following medications: amiodarone, cyclosporine, levothyroxine, and anticonvulsants. For amiodarone and anticonvulsants, these should be administered 2 hours before or 2 hours after the orlistat dose; cyclosporine should be dosed 3 hours after orlistat; and levothyroxine and orlistat should be dosed at least 4 hours apart.

Rarely, orlistat can result in hepatotoxicity. Patients should be advised to stop using orlistat and contact their health care provider if they experience any signs or symptoms of liver injury, such as fatigue, fever, jaundice, brown urine, nausea, vomiting, and abdominal

pain.

Serotonin 5-HT2c Receptor Agonist: Lorcaserin

Lorcaserin (Belviq) is a serotonin 5-HT_{2c} receptor agonist approved for weight loss in conjunction with comprehensive lifestyle changes.

Mechanism of Action

Lorcaserin works by acting on the serotonin 5-HT_{2c} receptors. This stimulation activates pro-opiomelanocortin (POMC) neurons in the arcuate nucleus. This results in the feeling of satiety and decreased food intake.

Dosage

Although low, lorcaserin does have a potential for abuse, and as such is classified as a Schedule IV (C-IV) drug. Lorcaserin should be administered 10 mg by mouth twice daily.

Contraindications/Precautions

Lorcaserin should be used in caution with patients taking the following medications: selective serotonin reuptake inhibitors (SSRIs), serotonin norepinephrine reuptake inhibitors (SNRIs), MAOI, serotonin 5-$HT_{1B,1D}$ receptor agonists (triptans), and bupropion due to the risk of serotonin syndrome. If patient has signs and symptoms of serotonin syndrome, such as tremor, myoclonus, and agitation, discontinue treatment immediately.

Adverse Events

The most common side effects of lorcaserin include headache, nausea, dry mouth, dizziness, fatigue, and constipation. In addition, due to some of the CNS side effects, patients should use caution when performing things that may require alertness such as driving and patients should monitor signs of mood changes that may indicate depression.

While hematological side effects such as leukopenia or anemia are rare, it is recommended to monitor complete blood cell counts (CBC) during use. Hyperprolactinemia has been reported and prolactin levels should be monitored if patient experiences any signs or symptoms such as galactorrhea or gynecomastia. Finally, men have experienced priapism. If a patient experiences an erection for greater than 4 hours, he should discontinue use of lorcaserin and seek medical attention.

Glucagon-Like Peptide-1 Receptor Agonist: Liraglutide

Liraglutide (Saxenda) is a GLP-1 receptor agonist, which is a medication also used for type 2 diabetes (Victoza) and was approved by the U.S. FDA in 2014 for weight loss in conjunction with comprehensive lifestyle changes. As with other pharmacologic agents approved for weight loss, a risk evaluation and mitigation strategy (REMS) was issued due to the serious potential side effects of thyroid medullary cancer and acute pancreatitis.

Mechanism of Action

Liraglutide is a GLP-1 receptor agonist, which influences diabetes by stimulating glucose-dependent insulin secretion, decreases glucagon secretion, and slows gastric emptying. As it relates to weight loss, liraglutide also activates the POMC neurons, which results in the feeling of satiety and decreased food intake.

Dosage

Liraglutide should be titrated up over the course of 5 weeks to help minimize GI side effects. Liraglutide is dosed as 0.6 mg subcutaneously once daily for a week; then, the dose is increased by 0.6 mg subcutaneously daily at weekly intervals until the target dose of 3 mg subcutaneously daily is achieved. If the 3-mg dose cannot be achieved, then the medication should be discontinued as it has not shown efficacy at lower doses.

Contraindications/Precautions

Liraglutide has boxed warning for the potential of medullary thyroid cancer (MTC) and multiple endocrine neoplasia type 2. Both of these conditions were observed in animal studies. However, patients with a history of either of these conditions should not use liraglutide.

Adverse Events

The most common side effects experienced with liraglutide are nausea, vomiting, diarrhea, and/or constipation. The dose is titrated up at weekly intervals to help minimize these side effects. In addition to these side effects, patients have reported headache and increased heart rate. Liraglutide has been associated with pancreatitis and patients should be monitored for this.

Combination Medications

Phentermine Extended Release/Topiramate

Phentermine ER/topiramate (Qsymia) is a medication that is a combination of low-dose phentermine ER, an anorexiant medication (see above), and topiramate, an anticonvulsant medication. This medication was approved by the U.S. Food and Drug Administration (FDA) (2012) for weight loss in conjunction with comprehensive lifestyle changes. In 2014, additional REMS for Qsymia was issued to inform prescribers and female patients about teratogenic effects of the drug during pregnancy. While the drug is still available, providers must go through special training to prescribe the drug.

Mechanism of Action

As mentioned previously, the mechanism of action of phentermine works to decrease appetite by stimulating the hypothalamus to release catecholamines, specifically norepinephrine. While the mechanism of action in regard to weight loss for topiramate is not fully understood, it is believed to be due to the enhancement of gamma-aminobutyric acid (GABA) and the inhibition of kainite/alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) glutamate, which results in appetite suppression.

Dosage

Although low, phentermine ER/topiramate does have a potential for abuse, and as such is classified as a Schedule IV (C-IV) drug. Phentermine ER/topiramate should be titrated up over several weeks. The starting dose is phentermine ER 3.75 mg/topiramate 23 mg once daily for 2 weeks. If the patient is tolerating this dose, then it can be increased to phentermine ER 7.5 mg/topiramate 46 mg once daily for 12 weeks and then evaluate weight loss. If after 12 weeks, 3% of baseline body weight has not been lost, then the medication can be increased to phentermine ER 11.25 mg/topiramate 69 mg once daily for 2 weeks and then to phentermine ER 15 mg/topiramate 92 mg once daily.

Contraindications/Precautions

Phentermine ER/topiramate is contraindicated in patients with hyperthyroidism and glaucoma. In addition, patients taking MAO inhibitors should not take these medications due to the potential increase in blood pressure that could lead to hypertensive crisis. Women who are taking Qsymia and become pregnant must immediately stop the drug.

Adverse Events

The most common side effects experienced with phentermine ER/topiramate are increased heart rate, insomnia, dry mouth, constipation, paresthesia, dizziness, and dysgeusia. Due to the carbonic anhydrase inhibition of this medication, electrolytes should be monitored for

hypokalemia and metabolic acidosis, and patients should be cautioned to monitor closely during strenuous exercise or extreme heat for signs of hyperthermia. In addition, be aware of any changes in behavior that may indicate any cognitive dysfunction or psychiatric disturbances. Due to the topiramate component, this medication should be withdrawn gradually as there is an increased risk of seizures with abrupt discontinuation.

Naltrexone/Bupropion

Naltrexone/bupropion (Contrave) is a medication that is a combination of naltrexone, an opioid antagonist, and bupropion, a dopamine/norepinephrine reuptake inhibitor. This medication was approved by the U.S. Food and Drug Administration in 2014 for weight loss in conjunction with comprehensive lifestyle changes.

Mechanism of Action

The exact mechanism of action of the naltrexone/bupropion combination is not fully understood. However, it is believed that together, they stimulate the POMC neurons that lead to appetite suppression.

Dosage

Naltrexone/bupropion should be titrated up over several weeks. The starting dose is naltrexone 8 mg/bupropion 90 mg to take one tablet by mouth in the morning for 1 week. Starting week 2, increase dose to 1 tablet by mouth in the morning and 1 tablet by mouth with dinner. At week 3, increase dose to 2 tablets by mouth in the morning and 1 tablet by mouth with dinner. At week 4, increase dose to 2 tablets by mouth in the morning and 2 tablets by mouth with dinner. The final target dose should be naltrexone 16 mg/bupropion 180 mg by mouth twice a day. If a patient is taking a medication that is a CYP2B6 inhibitor such as ticlopidine or clopidogrel, then the maximum dose should be naltrexone 8 mg/bupropion 90 mg by mouth twice daily.

Contraindications/Precautions

Naltrexone/bupropion is contraindicated in patients with uncontrolled hypertension, seizure disorders, bulimia or anorexia nervosa, and drug or alcohol withdrawal. In opioid-dependent patients, naltrexone/bupropion may precipitate acute withdrawal; patients should be opioid free for 7 to 10 days before starting naltrexone/bupropion. In addition, patients taking MAO inhibitors should not take these medications due to the potential increase in blood pressure that could lead to hypertensive crisis; do not start naltrexone/bupropion in a patient receiving linezolid or intravenous methylene blue.

Naltrexone/bupropion has a boxed warning for the potential suicidal ideation and serious neuropsychiatric events. Patients should be monitored for severe psychiatric changes such as depression or mania, psychosis, hallucinations, hostility, anxiety, and suicidal ideation or attempt.

Adverse Events

The most common side effects experienced with naltrexone/bupropion are nausea, constipation, headache, vomiting, and dizziness. In addition, use caution in patients with

cardiovascular disease due to the potential increase in heart rate and blood pressure.

Other Medications

Some antidepressant, antiseizure, and diabetes medications have been studied for use in weight loss. The use of these medications for weight loss is considered an "off-label" use.

Anticonvulsant medications: Zonisamide (Zonegran) is an anticonvulsant medication that has resulted in weight loss. However, adverse effects of the medication seem to be limiting.

Diabetes medications: Metformin (Glucophage) has demonstrated the ability to help people with type 2 diabetes and obesity lose weight. In addition, pramlintide (Symlin), an amylin analog, has also demonstrated weight loss.

Alternative Medications

There are many over-the-counter weight loss products on the market. The only nonprescription product, which is regulated by the Food and Drug Administration (FDA), is orlistat (Alli), which was discussed previously. All other products on the market are dietary supplements. The manufacturer of the dietary supplement is responsible for making sure their product is safe; however, they are not reviewed by the FDA. Many of the weight loss supplements on the market do not have a lot of evidence to support their claim of weight loss. See Table 54.4 for a summary of some of the most common dietary supplements available on the market.

TABLE 54.4 Dietary Supplements for Weight Loss

Name	Selected Adverse Events
Bitter orange	Increased heart rate and blood pressure
Chitosan	Well tolerated: gastrointestinal side effects
Chromium	Well tolerated: gastrointestinal side effects
Conjugate linoleic acid	Dyspepsia, constipation, diarrhea
Green coffee extract	Anxiety, insomnia, agitation
Green tea extract	Insomnia, agitation, nausea, vomiting, bloating, diarrhea
Guar gum	Abdominal pain, gas, bloating
Hoodia	Headache, dizziness, nausea, vomiting
Raspberry ketone	Unknown

Drugs That Cause Weight Gain

In addition to considering whether or not an overweight or obese patient should be started on weight loss medication, it is also important to assess their current medication profile to see if they are taking any medications that may be associated with weight gain. Whenever possible, it is recommended to use an alternative medication that may not be associated with weight gain. However, if there is no acceptable therapeutic alternative, it is advised to try and use the lowest dose to achieve the desired clinical outcome. See Table 54.5 for a list of drugs that may cause weight gain and potential alternatives.

TABLE 54.5 Drugs That May Cause Weight Gain

Medical Condition	Drug Class or Name	Alternative Medications
Type 2 diabetes	Insulin Sulfonylureas Glitinides Thiazolidinediones	Metformin (Glucophage) Pramlintide (Symlin) GLP-1 receptor agonists
Hypertension	β-Adrenergic blockers	ACE inhibitors ARBs Calcium channel blockers
Depression	Paroxetine (Paxil) Amitriptyline Mirtazapine (Remeron)	Fluoxetine (Prozac) Sertraline (Zoloft) Citalopram (Celexa) Escitalopram (Lexapro) Bupropion (Wellbutrin)
Psychiatric disorders	Clozapine Olanzapine (Zyprexa) Quetiapine (Seroquel) Risperidone (Risperdal)	Ziprasidone (Geodon) Aripiprazole (Abilify)
Chronic inflammatory diseases (e.g., rheumatoid arthritis)	Corticosteroids	Nonsteroidal anti-inflammatory drugs Disease-modifying antirheumatic drugs

Selecting the Most Appropriate Agent

The selection of the most appropriate agent for treating an obese patient depends on a number of factors. In particular, the provider should use a patient-centered approach to determine which medication would be best for a patient. The provider should assess the patient's other health conditions and consider both potential contraindications and benefits of certain medications as it pertains to weight loss. For example, a patient with underlying cardiovascular disease or uncontrolled hypertension would not be a good candidate for any medication that increases heart rate or blood pressure such as phentermine, phentermine ER/topiramate, or naltrexone/bupropion. On the other hand, a patient with uncontrolled type 2 diabetes may benefit from the addition of liraglutide as it may help with blood glucose control in addition to weight loss.

Finally, as mentioned previously, all pharmacotherapeutic treatment should be coupled with comprehensive lifestyle intervention that involves calorie restriction, physical activity, and behavior modification.

Special Population Considerations

Pregnancy and Breast-Feeding

All of the weight loss medications are contraindicated in pregnancy and breast-feeding. Women who are pregnant or breast-feeding and concerned with their weight should discuss this with their provider and be monitored closely.

Pediatrics

Overweight and obesity are on the rise among the youth in the United States. For people aged 2 to 19 years old, 31.8% are considered to be overweight or obese and 16.9% are considered to be obese. Young children aged 2 to 5 years old have lower rates of obesity. However, for children and adolescents aged 6 to 19 years old, almost 1 in 3, 33.2%, is considered to be overweight or obese (18.2% are obese). Obesity in childhood affects both physical and psychosocial health. Like treatment for adults, childhood obesity should be addressed with a comprehensive lifestyle intervention that targets healthy eating, physical activity, and behavioral therapy. This is the cornerstone and pharmacotherapy is not routinely recommended. In regard to pharmacotherapy, however, only a few of the aforementioned medications are approved for use in children or adolescents. Phentermine and diethylpropion are approved for children aged greater than 16 years old and orlistat (Xenical) is approved for children greater than 12 years old. Childhood obesity is complex and should be facilitated by the child's primary care provider and parents/legal guardians.

Diabetes

Caution should also be used when any of these weight loss agents are prescribed for patients with diabetes. The decrease in caloric intake may decrease a patient's blood glucose level, requiring adjustment of insulin or oral hypoglycemic agents.

Smokers

Smoking in itself is a risk factor for cardiovascular disease. The additional burden of obesity places the obese smoker in a much higher risk category for long-term cardiovascular effects. Nicotine has some thermogenic and metabolic effects, which are known to decrease appetite and often associated with a lower BMI. In comparison, smoking cessation is associated with weight gain. Therefore, the obese patient, who then quits smoking, runs the risk of gaining weight or thwarting efforts at weight loss. Special attention should be paid to this category of patient. A much greater level of attention should be paid to the lifestyle changes these patients need to make, and a continued reinforcement of the need for abstinence from smoking versus weight loss should be emphasized.

Monitoring Patient Response

The patient should be monitored for weight loss, decreases in BMI, and changes in waist circumference. A comprehensive lifestyle intervention is key; patients that have a high-intensity intervention (≥14 sessions in 6 months) have the greatest weight loss. However, even low to moderate interventions resulted in more weight loss than usual care (defined as limited advice or educational materials on weight loss).

For patients taking weight loss medications, it is recommended that efficacy and safety are monitored monthly for the first 3 months and then at least every 3 months thereafter. If a patient loses ≥ 5% of their body weight at 3 months and the medication is deemed safe, then the medication can be continued. However, if a patient loses less than 5% of their body weight at 3 months or if there are any issues with safety or tolerability, then the medication should be discontinued.

Patient Education

Patients should be educated that obesity is more than just a cosmetic problem. Patients should be educated on the fact that obesity has been linked to several serious medical conditions, such as diabetes, heart disease, high blood pressure, and stroke. It is also associated with higher rates of certain types of cancer. A patient-centered approach for weight loss is essential. The provider and the patient should determine an appropriate weight loss strategy keeping in mind health goals using a comprehensive lifestyle intervention together as a team. In addition to the weight loss strategies, the provider–patient team must also acknowledge and address the fact that weight loss maintenance is a lifelong challenge and address the challenges as they arise.

For more information regarding obesity, practitioners and patients should contact the following organizations or visit their Web sites. The Web site addresses listed below will direct people to the obesity section of the organization's Web site:

Case Study*

A.P. is a 34-year-old woman who comes into your clinic looking for a medication to help

her lose weight. She states that she has tried several times to lose weight but seems to gain it back within months after stopping her dieting.

Your workup reveals a normal, young, well-developed woman in no acute distress. She is 66 inches tall and weighs 200 lb. Pertinent labs include A1c 5.9%. Her blood pressure is 128/88 and heart rate is 80. She has a history of monthly migraine headaches for which she takes sumatriptan 50 mg PO PRN headache and may repeat dose in 2 hours if there is no relief; she also has hypothyroidism for which she take levothyroxine 112 mcg PO daily. She does not smoke or drink alcohol. She works as a secretary in an office. She has a BMI of 32.3 kg/m^2.

Diagnosis: Obesity

1. List specific goals for treatment for A.P.
2. What drug therapy would you prescribe? Why?
3. The patient was prescribed phentermine ER/topiramate. What are the parameters for monitoring success of the therapy?
4. Discuss specific patient education based on the prescribed therapy.
5. Describe one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What would be the alternative therapy?
7. What over-the-counter and/or alternative medications would be appropriate for A.P.?
8. What lifestyle changes would you recommend to A.P.?
9. Describe one or two drug–drug or drug–food interactions for the selected agent.

UNIT 14
Women's Health

55 Contraception

Virginia P. Arcangelo

Contraception is the inhibition of pregnancy by a process, device, or method. The U.S. Food and Drug Administration (FDA) first approved oral contraception (OC), the use of hormones to prevent pregnancy, in the 1960s, and the last law prohibiting its use in the United States was overturned in 1973 (Speroff & Darney, 2000). Regardless of the type used, one of contraception's major benefits is its potential impact on the rate of unplanned pregnancies. Current estimates are that approximately half of all pregnancies in the United States are unintended. Of these, about 42% are aborted (Espey et al., 2008). Healthy People 2020 aims to reduce unintended pregnancy from 49% of pregnancies to 44% of pregnancies. Unintended pregnancies that continue, including both unwanted and mistimed pregnancies, are positively associated with late-entry prenatal care, low birth weight, child abuse or neglect, and behavioral problems in children. One way a decrease in unintended pregnancies may be achieved is through the increased awareness of contraception and the various available options. The widespread use of contraception in health care in the United States has expanded opportunities for women. Its use has allowed women to take on roles beyond (or in addition to) motherhood. Contraception has increased women's ability to decide when pregnancy and subsequent child rearing will occur.

Age and desire for future pregnancy greatly influence a woman's method of choice. Reversible forms of contraception are the regimens of choice among most women planning future pregnancies. Oral, transdermal, and vaginal hormonal contraception are a first choice because return of fertility after discontinuing use is expected. Among those 15 to 44 years old in the United States who use contraception, oral contraceptives are the most common method used (27.5%). Male condom use (16%) is the next most common at 16%. Intrauterine devices (IUDs) account for about 5% of contraception (Mosher & Jones, 2010).

At 48 months after discontinuing reversible forms of contraception, 82% of patients ages 30 to 34 have given birth. Among women ages 25 to 29, the pregnancy rate is 92% at the same time after discontinuation (Speroff & Darney, 2000).

Physiology

A woman's ability to reproduce begins after she has completed the developmental stage of puberty. The average age of the onset of puberty is 11.2 years, whereas the length of time for the completion of this process is 4 years. Menarche, the last step in the pubertal process, is when menses commences. The average age for menarche is 12.7 years.

The cause or trigger for the onset of puberty is not completely understood. It is thought that a decreased sensitivity of the hypothalamus and pituitary glands to already circulating sex hormones results in an increased production of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Increased LH and FSH further stimulate the gonadal response of increased secretion of estrogen, progesterone, and testosterone. LH subsequently surges, inciting the release of ova. In the absence of fertilization, menses ensues.

A woman's menstrual cycle can be described in terms of either the follicular or luteal phase. In addition, in each of these phases, endometrial, ovarian, and pituitary hormone-secreting changes occur. These two major phases and the physiologic changes occurring in each are illustrated in Figure 55.1.

FIGURE 55.1 Comparison of the phases of the reproductive cycle. A. Plasma hormone concentrations in the normal female reproductive cycle. B. Ovarian events and uterine changes during the menstrual cycle. FSH, follicle-stimulating hormone FSH; LH, luteinizing hormone. (Reprinted from Bullock, B. A., & Henze, R. L. (2000). *Focus on pathophysiology* (p. 1100). Philadelphia, PA: Lippincott Williams & Wilkins, with permission.)

The endometrial changes can be subdivided. Menstruation, occurring on days 1 to 4 of the menstrual cycle, is the shedding of the endometrial lining. The next three phases are the proliferative phase (day 4 or 5 through ovulation), the secretory phase (immediately after ovulation), and the implantation phase (approximately days 21 to 27). During these phases, the endometrial lining is prepared for implantation of a fertilized ovum. In the event that an ovum does not implant, the next phase, endometrial breakdown, begins once again.

Relative to the ovarian changes that occur during the menstrual cycle, three major subdivisions can be identified: the follicular, ovulatory, and luteal phases. During the follicular phase, a dominant follicle is produced that will be released and await possible fertilization. The regulatory hormone largely responsible for this portion of the ovarian phase of the menstrual cycle is FSH. FSH stimulates the conversion of androgens to estrogen in the granulosa cells of the ovaries. Stimulation by FSH contributes to the development of a dominant follicle that produces further estrogen. The overall increase in estrogen production stimulates development of the glandular epithelium of the uterine lining, increases cervical mucus production and reduces the viscosity of this mucus, and increases vaginal pH.

Opposing the normal negative feedback mode of the menstrual cycle, in which high concentrations of estrogen inhibit the release of FSH and LH, the eventual peak in estrogen in this late follicular phase stimulates a surge in LH. The LH surge is subsequently responsible for the final maturation, release, and rupture of the dominant follicle. Follicular rupture and ovulation occur approximately 24 to 36 hours after the beginning of the LH surge and encompass the ovulatory phase of the menstrual cycle.

After the ovulatory phase, the luteal phase of the menstrual cycle enables the implantation of a fertilized ovum and maintenance of the uterine lining. The corpus luteum that remains after the follicle ruptures, releasing the ovum, secretes progesterone and 17-β-estradiol. The secretion of these hormones increases the secretory activity of the endometrial glands. Cervical mucus also increases in viscosity. In the event that pregnancy occurs, the life of the corpus luteum is extended to continue production of these hormones. In the absence of pregnancy, the corpus luteum dies, estrogen and progesterone levels decline, and menstruation occurs.

Initiating Drug Therapy

Given the normal menstrual cycle, pregnancy can be inhibited by preventing fertilization, manipulating hormones of the menstrual cycle such that ovulation never occurs, or interfering with implantation. Contraceptive options may be nonpharmacologic or pharmacologic. Figure 55.2 identifies these options and the failure rates of each.

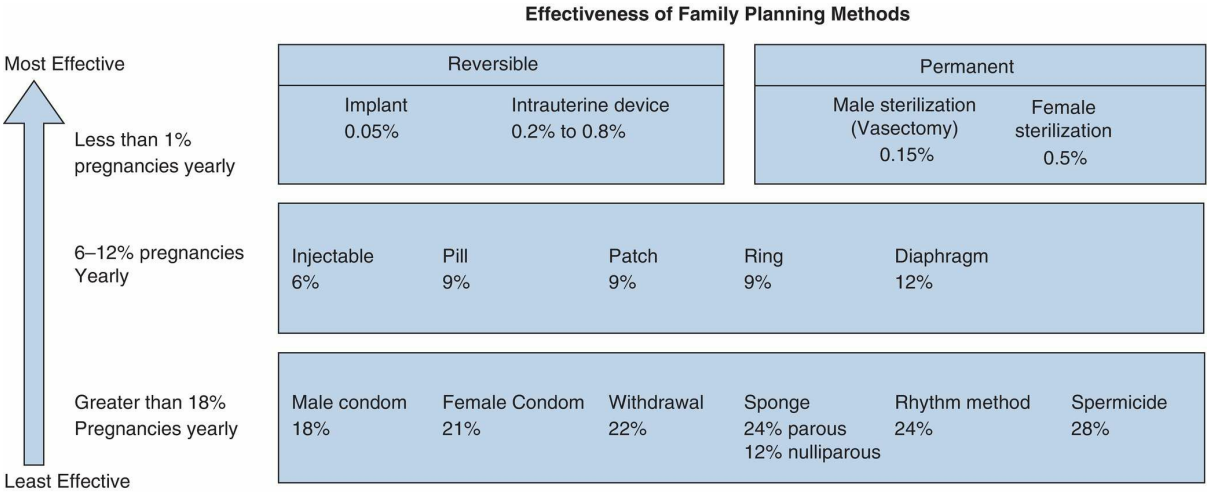

FIGURE 55.2 Effectiveness of contraceptive methods (From U.S. selected practice recommendations for contraceptive use. (2013). Adapted from the World Health Organization selected practice recommendations for contraceptive use 2nd ed. (2013). *Mortality and Morbidity Weekly Report, 62*(RR05), 1–46).

Nonpharmacologic options include periodic abstinence, barrier devices, and IUDs and intrauterine systems (IUSs). Periodic abstinence, which means avoiding sexual intercourse during the period of maximum fertility, includes several assumptions. First, the viability of sperm in the female reproductive tract is 2 to 7 days. Second, the life span of the ovum is 1 to 3 days. It is assumed, therefore, that the period of maximum fertility occurs in the 5 days before ovulation and ends on the day of ovulation. Prediction of ovulation is important in recognizing the dates to avoid sexual intercourse. Several methods may be incorporated into the periodic abstinence method to identify better the time of ovulation. Examples include the use of ovulation predictor kits, monitoring of basal body temperature, and testing of cervical mucus. The increase in progesterone concentration just before the LH surge is accompanied by a 0.4°F to 0.8°F increase in basal body temperature. The woman measures her body temperature orally with a basal thermometer just before arising from bed daily. She also may observe cervical mucus as a guide to predicting ovulation. Midcycle cervical mucus, just before ovulation, is clear, thin, and stringy. Peak mucus production occurs on the day of ovulation. After this, the mucus becomes sticky and wet. Intercourse, with a low presumed risk of pregnancy, is permitted beginning on the fourth day of this sticky, wet

mucus.

Other nonpharmacologic options for the prevention of pregnancy include the use of barrier devices such as condoms, diaphragms, and cervical caps. These options vary not only in their efficacy rates but in their abilities to prevent sexually transmitted infections (STIs). The male latex condom helps to prevent the spread of human papillomavirus and many other STIs. It is the only contraceptive option clinically proven to prevent the spread of the human immunodeficiency virus (HIV). The female condom has been shown to act as a barrier to most STIs. However, limitations include its cost, decrease in spontaneity, and improper placement.

The diaphragm and cervical cap are both devices that require fitting by a health care provider. The woman can insert a diaphragm up to 6 hours before intercourse and must leave it in place for at least 6 hours (but no more than 24 hours) after intercourse. The diaphragm has been shown to reduce the risk of cervical gonorrhea, pelvic inflammatory disease (PID), and tubal infertility secondary to STIs. It is not, however, effective against HIV infection, and urinary tract infections are twice as common in diaphragm users compared with nonusers. Comparably, the cervical cap may be left in place for a total of 48 hours. It must remain in place, however, for at least 8 hours after sexual intercourse. Like the diaphragm, it has not been shown to afford any protection against HIV infection.

The third major type of nonpharmacologic contraception is the IUD/IUS. Although its mechanism of action is not clearly understood, it is thought to prevent pregnancy through production of a "spermicidal intrauterine environment," interfering with sperm transport into and within the uterus. The intrauterine environment is rendered unreceptive to sperm or the implantation of a fertilized ovum should fertilization occur. In progesterone-implanted IUSs, the continued release of progesterone contributes to the contraceptive action of this device through production of viscous cervical mucus, which further impedes the sperm's ability to reach the ovum.

Both the American College of Obstetricians and Gynecologists and the North American Menopause Society recommend that women continue contraceptive use until menopause or ages 50 to 55. The median age of menopause is approximately 51 years in North America but can range from ages 40 to 60.

Goals of Drug Therapy

In addition to, or in place of, the nonpharmacologic contraceptive options available, pharmacologic options do exist. The primary mechanism by which these agents prevent pregnancy is through manipulation of the normal menstrual cycle, effects on cervical mucus, or both. Estrogen plus progesterone or progesterone alone is used to interfere with the process of ovulation, conception, or both. Optimal contraception features, as defined by the World Health Organization, include

- Safety
- Effectiveness
- Convenience
- Regular bleeding episodes
- Rapid reversibility

Combined (Estrogen and Progestin) Oral, Transdermal, and Vaginal Contraceptives

These prescription methods use a "combination" of two hormones—estrogen and progesterone. All combination methods work primarily by preventing ovulation. They are highly effective when taken every day, with perfect use failure rates of less than 1%. However, the typical failure rate of combination birth control pills is 3% to 8% and much higher in some populations. They also have several noncontraceptive benefits, including reducing the risk of endometriosis, ovulatory pain, ovarian cysts, benign breast disease, premenstrual syndrome, premenstrual dysphoric disorder, and ovarian and endometrial cancer. They also might improve acne, hirsutism, and other manifestations of polycystic ovary syndrome. The improvement occurs secondary to an increase in the level of sex-hormone–binding globulin, which reduces circulating free testosterone and ameliorates many androgenic effects. These methods are reversible and can be used by women of all ages.

The combination contraceptive agents contain estrogen, usually in the form of ethinyl estradiol. Doses of estrogen range from 20 to 35 mg; 98% of all prescribed OCs contain less than 35 mg of estrogen, and even OCs with as little as 20 mg of estrogen are considered effective. Pills with low estrogen content are considered safer than higher-dose OCs for certain patients, including perimenopausal women, those with a family history of heart disease, and smokers younger than age 35 (although women who take OCs and smoke remain at an increased risk of myocardial infarction [MI] and stroke due to OC-associated changes in coagulation factors). Progesterone is in the form of desogestrel, ethynodiol diacetate, levonorgestrel (LNG), norethindrone, norethindrone acetate, norgestimate, or norgestrel. A synthetic progesterone (drospirenone [DRSP]) is also available. It has antiandrogenic and antimineralocorticoid properties. It is associated with less water retention than other progesterones, less negative emotional affect, and less appetite increase after 6 months of use.

The mechanism of action of combination contraceptive agents is the suppression of the pituitary gonadotropins FSH and LH by the continued high concentrations of circulating estrogen and progesterone. The suppression of LH, primarily by the progesterone component, inhibits the LH surge responsible for ovulation. Progesterone also exerts its influence through its effects on increasing cervical mucus viscosity, thus impairing sperm transport. FSH suppression, largely through estrogen's influence, prevents the selection and emergence of a dominant follicle. Therefore, the combination of estrogen and progesterone inhibits selection of a dominant follicle and ovulation.

In addition to their influence on the reproductive cycle, the hormones used in OC pills (OCPs) exert other actions. All forms of progesterone exhibit some estrogenic, androgenic, or anabolic activity. For example, highly androgenic forms of progesterone affect lipid and carbohydrate metabolism and promote the appearance of acne, weight gain, and hirsutism.

As such, practitioners should consider the various progesterone formulations relative to their androgenic effects when choosing an OCP regimen. The least androgenic forms include the newer, third-generation progesterones desogestrel and norgestimate. In addition to their relative lack of androgenic side effects, they are also more potent than the other progesterones norethindrone, norethindrone acetate, ethynodiol diacetate, and norgestrel. Knowledge of the differences in the progesterone formulations becomes important when managing (or prospectively avoiding) certain side effects of OCPs.

A common myth is that OCPs reduce the effectiveness of antibiotics or vice versa. In fact, the only antibiotic that may reduce pill effectiveness is rifampin, an antibiotic reserved for specific circumstances and not commonly used. Similarly, many believe that anticonvulsants reduce the efficacy of OCs, an unlikely association. Although anticonvulsants may reduce the level of serum hormones, they have not been observed to be associated with increased incidence of ovulation or accidental pregnancy.

Many options exist when choosing an OC regimen for a patient. In general, combination OCPs are divided into monophasic, biphasic, and triphasic combinations. Tables 55.1 and 55.2 list the available formulations. Monophasic combinations provide a set amount of estrogen and progesterone daily for 21 days. Placebo or nothing is given on days 22 to 28, the days during which a woman menstruates. The monophasic combinations may be useful in managing adverse effects such as breakthrough vaginal bleeding. Also, women who are sensitive to fluctuations in hormone levels that occur with the biphasic and triphasic OCPs may respond more positively to the monophasic formulations. Side effects, including breast tenderness, nausea, headaches, and bloating, are usually limited to the first 1 to 2 months of use but may discourage continuation. A backup method of birth control, such as condoms, should be used for the first week after pills are started. Few clinical differences have been noted among the myriad different pill formulations (monophasic, biphasic, triphasic, different generation progestins, and other formulations), so it is reasonable to prescribe a generic monophasic pill containing 30 to 35 mcg of estrogen for most patients.

TABLE 55.1 Monophasic Contraception

Brand Name	Hormonal Components
Alesse, Aviane, Lessina	20 µg EE, 0.1 mg levonorgestrel
Brevicon	35 µg EE, 0.5 mg norethindrone
Apri, Desogen, Ortho-Cept	30 µg EE, 0.15 mg desogestrel
Kelnor 1/35	35 µg EE, 1 mg ethynodiol diacetate
Levlen, Nordette, Portia	30 µg EE, 0.15 mg levonorgestrel
Loestrin 1/20	20 µg EE, 1.0 mg norethindrone acetate
Loestrin 1.5/30	30 µg EE, 1.5 mg norethindrone acetate
Lo/Ovral, Cryselle	30 µg EE, 0.3 mg norgestrel
Norethin 1/35E	35 µg EE, 1 mg norethindrone
Norinyl 1 + 35	35 µg EE, 0.5 mg norethindrone
Nortrel 0.5/35	30 µg EE, 3 mg drospirenone
Ocella, Yasmin	35 µg EE, 0.25 mg norgestimate
Ortho-Cyclen	35 µg EE, 1 mg norethindrone
Ortho-Novum 1/35, Nortrel	50 µg EE, 1 mg norethindrone
Ortho-Novum 1/50, Norinyl 1+50	35 µg EE, 0.4 mg norethindrone
Ovcon 35	50 µg EE, 1 mg norethindrone
Ovcon 50	50 µg EE, 0.5 mg norgestrel
Ovral	30 µg EE, 0.15 mg levonorgestrel
Seasonale	20 µg EE, 3 mg drospirenone
Yaz	35 µg EE, 1 mg norethindrone
Extended Cycle	
Jolessa, Seasonale	30 µg EE, 0.15 mg levonorgestrel
Lybrel	20 µg EE, 0.09 mg levonorgestrel

EE, ethinyl estradiol.

TABLE 55.2 Biphasic and Triphasic Oral Contraceptive Pills

Brand Name	Hormonal Components
Biphasic Oral Contraceptive Pills	
Kariva, Mircette	20/10 μg EE, 15 mg desogestrel
Ortho-Novum 10/11	35/35 μg EE, 0.5/1 mg norethindrone
Triphasic Oral Contraceptive Pills	
Cyclessa, Velivet	25/25/25 30 μg EE, 0.1/0.125/0.15 mg desogestrel
Estrostep	20/30/35 μg EE, 1 mg norethindrone acetate
Ortho-Novum 7/7/7, Nortrel 7/7/7	35/35/35 μg EE, 0.5/0.75/1 mg norethindrone
Ortho Tri-Cyclen, Tri-Previfem, Tri-Sprintec	35/35/35 μg EE, 0.18/0.215/0.25 mg norgestimate
Tri-Levlen, Triphasil, Enpresse	30/40/30 μg EE, 0.05/0.075/0.125 mg levonorgestrel
Tri-Norinyl, Aranelle	35/35/35 μg EE, 0.5/1/0.5 mg norethindrone
Triphasil	30/40/30 μg EE, 0.05/0.075/0.125 mg levonorgestrel
Extended Cycle	
Seasonique	30/10/30 μg EE, 0.15 mg levonorgestrel

EE, ethinyl estradiol.

There is a variation to the traditional monophasic OCP. This formulation provides a constant amount of estrogen and progesterone daily on days 1 to 21. The woman takes placebo tablets on days 22 to 23. On days 24 to 28, a lower dose of estrogen alone is given. The rationale for providing estrogen on days 24 to 28 is to help manage problems in women who may have exhibited symptoms of estrogen deficiency during the traditional week-long placebo period. This includes, for example, women who experience rebound headaches in the absence of estrogen during days 22 to 28.

The biphasic and triphasic OCP combinations were developed to mimic more closely the normal fluctuations in hormones experienced during the menstrual cycle. Changes in

the estrogen or progesterone components occur every 7 to 10 days in these products. The phasic OCPs have not been shown to have any proven advantages in efficacy over the monophasic products. The major difference between the biphasic and triphasic regimens and the monophasic regimens is the net amount of progesterone delivered per cycle. The biphasic and triphasic regimens contain, in general, less progesterone. (See Tables 55.1 and 55.2.) Therefore, for women experiencing progesterone-related side effects, changing to a regimen containing lower doses of a product with less androgenic effects may be most beneficial.

Extended-cycle OCPs are now available. During the standard 7-day hormone-free interval that occurs with the use of low-dose estrogen formulations, the function of the hypothalamic–pituitary–ovarian axis recovers rapidly, and this increases the risk of ovarian follicle development, ovulation with unintended pregnancy, and increased spotting due to endogenous estradiol production. Fluctuating hormone levels allow endometrial buildup and can exacerbate premenstrual symptoms and menstrual headaches by creating hormone excess and withdrawal states. Extended-cycle OCPs with a shorter or eliminated hormone-free interval reduce the risk of these unwanted effects by preventing endogenous estradiol production while still providing highly effective and safe contraception.

When initiating therapy for patients, a contraceptive regimen is started relative to the woman's menstrual cycle. One can initiate either a day 1 start or a Sunday start regimen. Women who follow a day 1 start regimen begin the contraceptive agent on the first day of their period, regardless of the day of the week. Likewise, women who follow Sunday start regimens begin the OCP pack on the Sunday directly after the onset of menses. This means that the woman will not menstruate on a weekend, which is desirable to many patients. OCP packs are produced with the Sunday start regimen in mind. In the event that a patient is a day 1 start, the pharmacist places a special label on the pack noting the beginning day of the pack and the end. The situation in which the day 1 versus Sunday start becomes an issue is relative to missed doses, which is discussed later in the chapter.

In reality, combined hormonal contraceptives can be initiated at any time if it is reasonably certain that the woman is not pregnant. If combined hormonal contraceptives are started within the first 5 days since menstrual bleeding started, no additional contraceptive protection is needed. If they are started more than 5 days since menstrual bleeding started, the woman needs to abstain from sexual intercourse or use additional contraceptive protection for the next 7 days.

Another form of contraception is the transdermal patch containing 75 mcg of ethinyl estradiol and 6 mg of norelgestromin. The hormones are absorbed through the skin. The patch can be applied to the abdomen, buttocks, upper outer arm, or upper torso on clean, dry, healthy skin free of lotions. The patient can bathe, shower, or swim while wearing the patch. A new patch is applied each week, worn for 7 days, and removed and replaced with a new patch. During the fourth week, no patch is worn. The first patch should be applied on the first day of menses and a new one on the same day the next week. Detachment has been shown in only 5% of cases, but if it becomes loose or falls off, it must be replaced with a

new patch. If the patch is off for more than 24 hours, a new cycle is started and backup methods of birth control used for the next 7 days.

The most frequent complaint from users of the patch is reactions at the application site. Women who weigh more than 198 lb may experience a higher failure rate and should use a different form of contraception.

Combination contraceptive vaginal rings are also available. The NuvaRing is a flexible transparent device inserted into the vagina by the patient. It releases 15 mcg of ethinyl estradiol and 120 mcg of etonogestrel daily. It is removed after 3 weeks for 1 week and a new ring is inserted. Lower hormonal doses are required with the vaginal ring because there is no hepatic or gastrointestinal (GI) interference. It can remain in place during bathing, swimming, and intercourse.

It has been shown that there is a mean of 5.88 cycles for conception following discontinuation of combined OC (Stenchever et al., 2001).

Progestin-Only Hormonal Contraceptives

Progesterone alone to prevent pregnancy may be used in the dosage formulations of oral tablets, intramuscular injections, or subdermal implants. Regardless of the formulation, they are the hormonal contraceptive options of choice in women who cannot take or cannot tolerate estrogen-containing formulations. They are a better choice for women with problems, such as high blood pressure or smoking over age 35, which may be negatively impacted by estrogen-containing pills. The progestin-only pill is often recommended for breast-feeding women. In ease of administration, compliance, and efficacy, however, the formulations vary greatly.

The progesterone-only contraceptive pill, commonly referred to as the *minipill*, contains a very low dose of progesterone. Table 55.3 lists the available formulations and active components of each. The minipills do not consistently suppress the pituitary gonadotropins LH and FSH. Their primary effect is exerted through changing the endometrial and cervical mucus environments. The time from dosing to changes in the cervical mucus is 2 to 4 hours. The impermeability of the mucus declines 22 hours after the dose. Therefore, to help ensure maximum efficacy, it is imperative that the woman take the pill at exactly the same time daily. Recommendations are that if the dose is more than 3 hours late, the woman should use a backup form of contraception. When beginning the minipill, the woman should start on the first day of menses and use backup contraception for the first 7 days. The woman takes the minipill daily without a placebo week, as is exercised with the combination OCPs.

TABLE 55.3 Progesterone-Only Oral Contraceptive Pills

Brand Name	Hormonal Component
Micronor, Camila, Errin, Nor-QD Ovrette	0.35 mg norethindrone 0.075 mg norgestrel

The FDA approved the use of intramuscularly injected medroxyprogesterone acetate (depo MPA) in 1992. The dose of depo MPA used suppresses ovulation in addition to affecting cervical mucus. Depo MPA is dosed every 13 weeks and is a good choice for women for whom daily compliance with a combination or progesterone-only OCP is an issue. When beginning depo MPA, recommendations are that it be given within the first 5 days of the onset of menses. It can be given to women postpartum and to those who are breast-feeding. Subsequent doses must be given no later than 13 weeks from the prior dose to ensure efficacy. If a woman presents later than 13 weeks for her next injection, the provider needs to determine that the patient is not pregnant before administering the drug.

Depo-Provera is safe for women with a history of cardiovascular disease, stroke, thromboembolism, or peripheral vascular disease. It is ideal for women with hemoglobinopathies, such as sickle cell disease, because these women will likely notice a decrease in painful hemolytic crises.

In addition to the positive compliance effects of this dosage formulation, women wishing future pregnancy also frequently prefer depo MPA. On discontinuation of depo MPA, 70% of women conceive within the first year and 90% within 24 months. Limitations to the use of depo MPA include the occurrence of menstrual changes in most women and episodes of unpredictable bleeding lasting more than 7 days. The latter problem occurs more commonly in the first few months of therapy. Depo-Provera reduces serum estradiol levels, and this can adversely affect bone health. Bone loss was reversible with discontinuation of Depo-Provera. The practitioner should recommend that Depo-Provera users exercise regularly and increase their intake of calcium and vitamin D.

The Intrauterine System

Another form of contraception is IUSs. These are flexible plastic devices inserted into the uterus and cause a sterile inflammatory reaction within the uterus that interferes with sperm transport into and within the uterine cavity. This is one of the most effective methods of reversible contraception. There are two types available in the United States currently. One is the Copper T380 IUD ParaGard. It is effective for at least 10 years. It can be inserted anytime it is certain the woman is not pregnant. It can be inserted within 5 days of the first act of unprotected sexual intercourse as an emergency contraceptive.

Another IUS is a LNG-releasing device. There are two available in the United States. One releases 20 μg/d of LNG (Mirena) and is approved for 5 years of use. The other releases 14 μg/d of LNG and is approved for 3 years of use.

Because the IUS contains no estrogen component, it is appropriate for women in whom estrogen is contraindicated. The IUS may also be an effective treatment for women with dysmenorrhea, menorrhagia, and anemia and may serve as an effective transition from contraception to hormone replacement therapy. Little maintenance is required. The patient must check the string after each menstrual period to ensure that it is still in place. For women who choose to become pregnant, the device can be removed by the clinician at any time; no waiting period is required before conception, and IUS use is not associated with a decline in fertility. This system has been shown to lessen dysmenorrhea and bleeding.

The only contraindications to the use of this method are suspected pregnancy, uterine abnormalities that cause significant distortion of the uterus, PID, or unexplained vaginal bleeding prior to insertion. Immediate postpregnancy insertion is appropriate.

Progestin-Only Implants

Nexplanon is a contraceptive device that is implanted subdermally in the upper arm and remains active for 3 years. It consists of a single rod that contains etonogestrel, which is the same progestin used in the NuvaRing. Implanon has been available for more than 10 years but has been widely marketed in the United States only since 2007.

Like other progestin-only contraceptives, Implanon works by blocking the LH surge, thereby preventing ovulation. It also thickens the cervical mucus and thins the endometrial lining. Unlike other progestin-only methods, Implanon causes estradiol to gradually increase to normal endogenous levels after an initial decrease. Progestin-only implants are extremely effective in preventing pregnancy and have an efficacy rate similar to that associated with sterilization or use of an IUD. Women experience a quick return to normal cycles after implant removal, and there have been no reports of infertility after removal. Implantation and removal of Implanon require training, but they can be performed as simple office procedures.

Progestin-only implants may cause irregular bleeding. It is contraindicated in women being treated with CYP3A-inducing or CYP3A-inhibiting medications. Inducers of CYP3A might decrease the efficacy of progestin-only implants and lead to unintended pregnancy, and inhibitors of CYP3A might increase serum etonogestrel levels and cause toxicity. It is also contraindicated in women with active liver disease or active venous thromboembolism. Progestin-only methods of contraception have long been considered safe to use in women with an increased risk of venous thromboembolism (e.g., women who smoke or have hypertension, diabetes mellitus, migraine headaches, or a history of venous thromboembolism).

Emergency Contraception

Two forms of emergency contraception (or "morning-after contraception") are available: LNG (Plan B) and ulipristal acetate (UPA) (Ella). LNG has a total of 1.5 mg LNG taken in two doses (0.75 mg taken 12 hours apart or one dose [1.5 mg LNG]). Pregnancy can be prevented if taken up to 120 hours after intercourse, but it is most effective if taken immediately. The effectiveness decreases as more time passes. It has a 94% efficacy, with efficacy decreasing between 72 and 120 hours. Effectiveness is decreased in the obese. This is available without a prescription.

UPA is a progesterone receptor antagonist. It is to be taken within 5 days (120 hours) of unprotected intercourse. It inhibits follicle rupture and is effective even near ovulation. It has a greater efficacy than LNG. It is only available by prescription.

IUDs are another form of emergency contraception. The copper IUD is the most effective and can remain in place for continued contraception. See the section on IUS for more information.

Regardless of the regimen chosen, a woman should menstruate within 21 days. If she does not, the clinician should instruct her to follow up with her provider to determine whether pregnancy has occurred. In addition, the practitioner should take this opportunity to discuss other forms of contraception so that emergency contraception does not become the woman's routine method of pregnancy prevention.

According to the American College of Obstetricians and Gynecologists and the World Health Organization, there are no absolute medical contraindications to the use of emergency contraception with the exception of pregnancy.

Drug Interactions

Any agent that increases GI motility or causes diarrhea may reduce the plasma concentration of ethinyl estradiol by decreasing its absorption. Agents, such as ascorbic acid, that inhibit sulfation of ethinyl estradiol in the GI tract may increase the bioavailability of ethinyl estradiol and lead to an increase in estrogenic adverse effects.

Ethinyl estradiol is metabolized by the cytochrome P-450 (CYP) 3A4 enzyme pathway. Drugs known to induce CYP3A4 (phenytoin, primidone, barbiturates, carbamazepine, ethosuximide, topiramate, methsuximide, rifampin, and griseofulvin) can lead to decreased plasma ethinyl estradiol levels and may cause failure of emergency contraception. Reports suggest that the enterohepatic circulation of ethinyl estradiol is decreased in women taking antibiotics, which may lead to a decrease in systemic concentrations of ethinyl estradiol. Ethinyl estradiol may interfere with the metabolism of other compounds. It can inhibit microsomal enzymes, which may slow the metabolism of other drugs (i.e., analgesic anti-inflammatory drugs such as antipyrine, antidepressant agents, theophylline, and ethanol), increasing their plasma and tissue concentrations and increasing the risk of adverse effects. There is a potential interaction between warfarin and LNG given as an emergency contraceptive. The proposed mechanism is the displacement of warfarin by LNG from the FIS binding site of human alpha$_1$-acid glycoprotein, the main transport protein for drugs in the plasma. This potential interaction should be considered so that the patient's international normalized ratio levels can be monitored because the Yuzpe regimen for emergency contraception generally would not be recommended in women with a history of deep vein thrombosis who are receiving anticoagulant therapy.

Selecting the Most Appropriate Agent

When deciding which pill to select, the patient's body mass should be considered. Obese women require higher doses of estrogen and progesterone. A physical exam including blood pressure, lipid panel, and liver and renal function is important. A pregnancy test should be performed.

Most women can tolerate up to 735 μg of ethinyl estradiol for a 28-day cycle. But a 3-month trial should be done to determine tolerability. Most side effects subside after three months.

With the wide variety of forms of hormonal contraception, many questions exist about which agent should be used first and for whom. Table 55.4 addresses some of these issues and is provided as a guide to the prescription of hormonal contraception.

TABLE 55.4 Treatment Order for Available Hormonal Contraceptive Agents

Clinical Scenario	Therapeutic Options
Women wish to use hormonal contraception—adolescents; perimenopausal women; and postpartum, nonlactating women with no other medical risks	Any OCP < 50 mcg EE either continuous or cyclic
History of: • Smoking and over age 35 • Uncontrolled hypertension • Undiagnosed abnormal vaginal bleeding • Diabetes with vascular complications or more than 20 years' duration • Deep vein thrombosis or pulmonary embolism or history of ischemic heart disease • Headaches with focal neurological symptoms • History of breast cancer • Active viral hepatitis or cirrhosis	Consider progestin-only OCPs, Depo-Provera, Implanon, or IUD
History of cholestasis with OCP use or pregnancy	
Endometriosis	Monophasic continuous therapy
Postpartum, lactating	Progesterone-only minipill
Noncompliance	Depot medroxyprogesterone acetate *or* levonorgestrel subdermal implants
Breakthrough bleeding—first half of cycle	Change to combination pill with higher estrogen content in first half of cycle.
Breakthrough bleeding—second half of cycle	Change to combination pill with higher progestin content in second half of cycle

Data from Zieman, M., Hatcher, R., Cwiak, C., et al. (2010). *A pocket guide to managing contraception*. Tiger, GA: Bridging the Gap Foundation.

Monitoring Patient Response

Therapeutic drug monitoring of hormonal contraception includes, primarily, monitoring for adverse effects and preventing complications from their use. Before using any of the hormonal regimens, all sexually active patients should receive a gynecologic examination with Papanicolaou smear to observe cervical cytology. They also should have a thorough physical examination before beginning use, including information such as blood pressure and weight. A lipid panel, including baseline total cholesterol, high-density lipoprotein cholesterol, and triglyceride levels, may be especially important in women with other risk factors for heart disease. Identification of blood glucose control before and after initiating hormonal contraception is important in women with diabetes mellitus.

In addition to the initial workup and physical examination, it is also important to maintain a high index of suspicion for adverse effects associated with the use of either the estrogen or progesterone components, or both, in women receiving hormonal contraception. It is estimated that 25% to 50% of women discontinue hormonal contraception within the first 12 months of use because of physical side effects. Therefore, it is important to look for these side effects and know how to manage them. Box 55.1 identifies side effects related to excess estrogen and progesterone.

BOX 55.1 Causes of Side Effects of Hormone Contraception

Too Much Estrogen	Too Little Estrogen
Heavy bleeding	Bleeding (spotting) early in cycle
Cystic breasts	Too light bleeding
Breast enlargement	Bleeding throughout the cycle
Breast tenderness	Amenorrhea
Dysmenorrhea	
Bloating	
Premenstrual edema	
Gastrointestinal symptoms	
Premenstrual headache	
Premenstrual irritability	
Cervical exstrophy	

Too Much Progestin	Too Little Progestin
Increased appetite	Bleeding fewer days
Candidiasis	Bleeding (spotting) late in cycle
Depression	Heavy bleeding
Fatigue	Delayed withdrawal bleeding
Cervicitis	Bloating
	Dysmenorrhea
	Premenstrual edema
	Gastrointestinal symptoms
	Premenstrual headache
	Premenstrual irritability

Side effects due to insufficient estrogen and progesterone, such as breakthrough bleeding, also may occur. In the first half of the menstrual cycle, breakthrough bleeding is likely due to insufficient estrogen; in the second half of the cycle, it is likely due to insufficient progesterone. Therefore, practitioners can simplify management by adding supplemental estrogen or progesterone when appropriate or changing to a new regimen with higher estrogen or progesterone as necessary.

If there is breakthrough bleeding early in the cycle, a change to a pill with more estrogen but the same level of progestin is appropriate. Breakthrough bleeding late in the cycle requires a pill with more progestin. Heavy bleeding with periods and bloating indicates the need for a pill with lower estrogen to progestin level since estrogen builds up

the endometrium causing heavier bleeding. Breakthrough bleeding throughout the cycle indicated the need for more estrogen but the same amount of progestin. Elevated blood pressure and depression indicates the need for a lower progestin dose.

Patient Education

Poor outcomes secondary to the use of hormonal contraception may include treatment failures, potentially life-threatening side effects, or side effects beyond those commonly expected. Treatment failures frequently are related to compliance with the regimen. In the case of combination OCs, guidelines exist that explain what to do in the event of a missed pill (or pills) to help ensure continued contraceptive efficacy. Table 55.5 illustrates these guidelines. Another cause of treatment failure includes drug interactions that may affect the efficacy of the hormonal contraceptive. Agents proven to reduce circulating estrogen concentrations, therefore affecting efficacy, include rifampin (Rifadin), phenytoin (Dilantin), and carbamazepine (Tegretol). Recommendations to reduce the risk of treatment failure relative to these agents include the use of higher daily doses of estrogen (50 mg ethinyl estradiol) or use of progesterone-only options.

TABLE 55.5 Guidelines for Missed Pills

Number of Missed Pills	Recommended Action
One pill	Take missed pill as soon as possible and resume schedule; backup method of contraception is not necessary
Two 30- to 35-mg pills	Take missed pill as soon as possible and resume schedule; backup method of contraception is not necessary
Two 20-mg pills	Follow directions for more than two pills
More than two pills	Take pill and continue taking a pill daily Use condom or abstinence for 7 days If missed in week 3, finish active pills in current pack and start a new pack the next day (skip current inactive pills) If missed pills in first week and had sex, use emergency contraception (EC), then resume taking pills the next day after EC

Patients can best avoid life-threatening side effects of the hormonal contraceptives, especially combination OCs, if they follow the contraindications to their use. Box 55.2 identifies absolute contraindications to the use of combination OCs. In addition, the acronym *ACHES* is useful in teaching patients about the potential severe side effects that may occur with the use of OCPs. Clinicians should instruct patients to call their primary care provider if any of the following occur:

- Severe Abdominal pain (indicative of gallbladder disease)
- Chest pain (potentially related to pulmonary embolism or MI)
- Headache (relative to stroke, hypertension, or migraine)
- Eye problems (relative to stroke or hypertension)
- Severe leg pain (indicative of deep vein thrombosis)

BOX 55.2 Absolute Contraindications to the Use of Combination Oral Contraceptive Pills

- Thrombophlebitis, thromboembolic disorders, cerebral vascular disease, coronary occlusion*
- Markedly impaired liver function
- Breast cancer (known or suspected)
- Abnormal vaginal bleeding in the absence of a diagnosed cause
- Pregnancy
- Smokers older than age 35

*Includes a past history or other situations that may put the patient at risk for developing these conditions.

It is crucial to relay this information to the patient. Early recognition and treatment of these adverse events save lives.

Many women are unaware of the health risks and side effects of the various forms of hormonal contraception. Likewise, 25% of women are unaware that the use of combination contraceptive agents imparts benefits in addition to the prevention of pregnancy. Some of these benefits include a 50% to 60% reduction in ovarian cancer risk with 5 years of use. This benefit persists for up to 10 or more years after discontinuation. In addition, 50% to 60% reductions in PID risk and 30% to 50% reductions in the occurrence of menstrual disorders have been observed with combination agents.

Another benefit of OCPs is their use in other indications. For example, 60% to 94% of women with endometriosis who are treated with daily monophasic contraceptive agents for 6 to 9 months experience symptomatic improvement. After treatment, a 5% to 10% annual recurrence rate of the disease is noted. Benefits of contraceptive agents are listed in Box 55.3.

BOX 55.3 Noncontraceptive Benefits of Combined Oral Contraceptives

- Decreased iron deficiency anemia
- Decreased dysmenorrhea
- Decreased dysfunctional uterine bleeding
- Decreased incidence of ovarian cysts
- Improvement in acne
- Decreased incidence of pelvic inflammatory disease
- Decreased risk of osteoporosis
- Decreased incidence of endometrial cancer
- Decreased risk of benign breast disease

Several Web sites contain patient information on contraception: www.contraception.net, http://www.nlm.nih.gov/medlineplus/birthcontrol.html, and www.plannedparenthood.org.

Case Study*

J.L., a 27-year-old account executive, presents to the family medicine office for her annual checkup with her primary care provider. She has no significant past medical history except heavy menses. Her medications include calcium carbonate 500 mg orally twice a day and a multivitamin daily. She exercises regularly. Her family history is significant for cardiovascular disease (her father had an MI at age 54 and died of a further MI at age 63). She notes that she has been dating her current partner for approximately 5 months. She is interested in a reliable form of contraception. After discussing the various contraceptive options, she is here for contraceptive counseling.

1. Before prescribing an OCP regimen, what tests or examinations would you like to perform?

2. Identify three different contraceptive regimens that could be chosen for J.L. Note their differences and why you chose them.

3. Identify the potential side effects that need to be relayed to J.L. Note especially those side effects for which J.L. should seek immediate medical care.* Answers can be found online.

56 Menopause

Elena M. Umland ■ Virginia P. Arcangelo

Introduction

Menopause is the permanent cessation of menstruation resulting from loss of ovarian function. It is an endocrinopathy resulting from failure of the ovary to produce estrogen. Menopause is not an acute condition but rather a gradual transition from perimenopause to menopause and finally postmenopause. The menopausal transition is defined as that period of time from the first changes in the menstrual cycle to the final menstrual period (FMP). The menopausal transition typically begins about 2 years prior to the FMP; however, this time frame varies from woman to woman (Harlow et al., 2012).

Healthy women typically spend one third of their lives in a menopausal state. According to the North American Menopause Society (NAMS), the postwar baby boom of the 1940s and 1950s has led to an absolute increase in the over-50 population (NAMS, 2010). Every day, over 6,000 women enter menopause. American women today can expect to live beyond age 80. The mean age of menopause in the United States is 51 years, with a range of 40 to 58 years. Approximately 4% of women experience their FMP before age 40. Overall, women can expect to spend approximately 30 postmenopause. By the year 2020, it is estimated that there will be greater than 50 million women in the United States who are postmenopause. Factors that contribute to menopause occurring at an earlier than average age include a history of irregular menses before the perimenopause, African American heritage, cigarette smoking, and weight reduction diets.

The increased incidence of chronic disease in postmenopausal women appears to be influenced by decreased levels of estrogen or progesterone. Following menopause, women can expect to experience an increased probability of developing coronary heart disease (CHD), stroke, hip fracture, breast cancer, colorectal cancer, and endometrial cancer. Further, postmenopausal women have a greater increased risk of Alzheimer disease over men. While efforts in preventing these disease states as well as diagnosing them in a timely manner and effectively managing them are often the focus of health care providers, it is the management of the symptoms associated with menopause directly, namely, vasomotor symptoms (VMS) and urogenital symptoms, that is the focus of this chapter.

Physiology

Menopause involves an age-related loss of ovarian function and a resulting decrease in estrogen secretion by the ovarian follicular unit. The ovary produces 17-β-estradiol, the major circulating estrogen. At birth, approximately 1 to 2 million ovarian follicles are present. By age 45, the number drops to approximately 10,000.

During the menopausal transition, the woman herself notices changes in her menstrual pattern. This may include a change in the time span from the first day of one menstrual period to the first day of the next (variable by greater than 7 days from what was previously considered normal for the patient); the amount of menstrual flow and the number of days of bleeding may vary from month to month, increasing or decreasing. It is expected that later in the menopausal transition, cycles become skipped with phases of amenorrhea lasting ≥60 days (Harlow et al., 2012).

Amenorrhea in menopause results from the remaining follicles becoming resistant to the effect of follicle-stimulating hormone (FSH). The ovaries begin with a large number of follicles that atrophy during the reproductive years at a steady rate until there are too few to produce significant amounts of estradiol. During the perimenopause (the time frame inclusive of the menopause transition and 1 year following the FMP), estradiol and progesterone production declines. The reduction in hormone levels reduces the negative feedback loop of the hypothalamic–pituitary system, which leads to a rise in FSH levels.

Estrogen has an impact on many body tissues and systems: bone, teeth, brain, eyes, vasomotor, heart, colon, and urogenital. Ovarian failure causes changes in many organ systems, but the changes are subtle and usually not distressing to women. The most noticeable change is amenorrhea. This is the change in reproductive function that all women experience. Women are considered postmenopause following their FMP.

Morbidity in postmenopausal women is largely the result of alterations in hormone production, notably the decline in estradiol production. During the menopause transition and early postmenopause, women seek treatment for the related occurrences of VMS insomnia, mood changes, and urogenital symptoms. The most commonly noted symptoms are the VMS. Risk factors associated with the occurrence and severity of VMS include obesity, cigarette smoking, depression, anxiety, lack of exercise, low socioeconomic status, and race, specifically African American women (Thurston & Joffe, 2011). The occurrence of VMS is felt to be due to a disruption of the thermoregulatory circuitry that functions under the influence of consistent concentrations of the neurotransmitters serotonin and norepinephrine. Changes in estradiol levels have been associated with fluctuations in serotonin and norepinephrine, thus the link between declining estradiol concentrations and the presence of VMS (Deecher & Dorries, 2007; Rossaminth & Ruebberdt, 2009). According to the American College of Obstetricians and Gynecologists (ACOG), approximately 87% of women experience these on a daily basis, occurring in the form of

hot flashes or flushes, perspiration, chills, and clamminess (ACOG, 2014). These are transient sensations typically lasting from 1 to 5 minutes. Of women experiencing VMS, approximately 33% experience more than 10 hot flashes per day. They are the most annoying consequences of menopause for many women, often affecting mood and disrupting sleep.

There are also changes in the genitourinary system as a result of menopause. And it is estimated that the symptoms resulting from these changes affect up to 40% of midlife women (ACOG, 2014). The vagina, vulva, urethra, and bladder have a large number of estrogen receptors. As estrogen concentrations decline, the potential for urogenital symptoms increases. The vulva loses collagen, adipose tissue, and the ability to retain water. There is a shortening and narrowing of the vagina; the walls become thin and pale and elasticity decreases. Vaginal secretions decrease, thereby decreasing vaginal lubrication. The urethra may become irritated as well. New terminology for vulvovaginal atrophy was implemented in 2014 with this now being referred to as the genitourinary syndrome of menopause (GUSM) Portman & Gass, 2014). Unlike VMS, which do tend to improve and subside over time, menopause-related genitourinary symptoms such as vaginal dryness, itching and burning, and subsequent dyspareunia tend to be chronic and progressive and unlikely to resolve over time.

Initiating Drug Therapy

Goals of Drug Therapy

In managing symptoms related to menopause, notably VMS and menopause-related genitourinary symptoms, the goal is reduction in symptom severity and frequency and a subsequent improvement in quality of life (QoL). There are many treatment options available including regimens containing estrogen with or without the addition of a progestin as well as a variety of nonhormonal options such as the selective serotonin reuptake inhibitors (SSRIs) and gabapentin, to name just two. Newer products such as estrogen agonist/antagonist agents and tissue selective estrogen complexes (TSECs) have also been recently added to the list of options. Regardless of the treatment regimen, the goals remain the same, minimizing menopause symptoms of estrogen deficiency. Contrary to the suggested findings of early observational studies, and subsequent to prospective, randomized trials, it is no longer acceptable to use estrogen with or without the addition of a progestin to prevent long-term chronic conditions, particularly CHD (Moyer, 2013).

Hormone Therapy

Estrogen decreases the frequency of night sweats and periods of wakefulness during the night, reduces sleep latency (time between going to bed and falling asleep), and improves sleep in postmenopausal women with sleeping difficulty. Estrogen regimens reduce frequency and intensity of hot flashes by 75% and 87%, respectively (ACOG, 2014). No other method provides such consistent and significant relief of menopausal symptoms as estrogen. Hormone therapy (HT) generally refers to treatment with estrogen and progestin used in women with an intact uterus and estrogen alone in women who have no uterus. See Table 56.1 for a summary overview of select HT and related products to treat menopausal symptoms.

TABLE 56.1 Overview of Available HT and Related Agents to Treat Menopausal Symptoms

Generic (Trade) Name and Dosage	Side Effects	Contraindications	Special Considerations
Oral Menopause Hormone Therapy			
conjugated equine estrogen (CEE) (Premarin) Usual daily dose 0.3–0.65 mg Doses available: 0.3, 0.45, and 0.625 mg	Nausea, vomiting, breakthrough bleeding, edema, weight changes, swollen/tender breasts, hypertension, depression, hair loss, changes in libido, venous thromboembolic events	Estrogen-dependent neoplasia Thrombophlebitis or thromboembolic disorder Pregnancy Undiagnosed vaginal bleeding Uncontrolled hypertension Acute liver disease	May cause GI upset, may take with food Treatment should occur at the lowest effective dose for the shortest duration as needed
estradiol (Estrace) 1 mg/d	Same as above	Same as above	Same as above
Combination Products			
CEE and medroxyprogesterone acetate (MPA) (Prempro) Doses: 0.5/1.5, 0.4/1.5, 0.625/2.5, 0.625/5 mg ethinyl estradiol and norethindrone acetate (NETA)	Same as above	Same as above	Same as above
CEE and bazedoxifene (Duavee) Doses: 0.45 mg/20 mg, 0.625 mg/20 mg	Same as observed with estrogen	Same as observed with estrogen PLUS the addition of known protein C, protein S, or antithrombin deficiency	Addition of bazedoxifene further minimizes the bone loss observed with estrogen and reduces the risk for developing endometrial hyperplasia
FemHRT 1/5 5 mcg/1 ng	Same as above	Same as above	Same as above
estradiol (NETA) 1 mg/0.5 ng	Same as above	Same as above	Same as above
(Estratest) esterified estrogen 1.25 mg and methyltestosterone 2.5 mg (Estratest H.S.) esterified estrogen 0.625 mg and methyltestosterone 1.25 mg Taken daily for 3 wk and then 1 wk off	Liver function changes, nausea, breakthrough bleeding, edema, weight gain, hypertension, depression, intolerance to contact lenses, changes in libido, virilization, jaundice, gallbladder disease	Breast or endometrial cancer, undiagnosed genital bleeding, thromboembolic disease, pregnancy, lactation	Report any adverse events immediately May take at bedtime to prevent nausea
Progestins			
MPA (Amen, Curretab, Cycrin, Provera) 2.5–10 mg either daily or cyclic	Vision changes, migraine, porphyria, depression, insomnia, jaundice, nausea, thrombophlebitis, pulmonary embolism, increased blood pressure, breakthrough bleeding, breast tenderness, rash, hirsutism, increased weight, decreased glucose tolerance	Thrombophlebitis, hepatic disease, breast cancer, undiagnosed vaginal bleeding, pregnancy, lactation Caution in epilepsy, migraine, asthma, cardiac dysfunction	Report any adverse events immediately May take at bedtime to prevent nausea
norethindrone acetate (NETA) Aygestin dose: 2.5–10 mg/d	Same as above	Same as above	Same as above
Transdermal Menopause Hormone Therapy			
estradiol (Alora, Estraderm, Vivelle) Change transdermal patch twice a week Alora—0.05, 0.075, 0.1 mg/d Vivelle—0.0375, 0.05, 0.075, 0.1 mg/d	Irritation at application site, headache, breakthrough bleeding, nausea, abdominal cramps	Undiagnosed abnormal vaginal bleeding, thromboembolic disorder, pregnancy, breast or estrogen-dependent tumor	Apply to clean, dry area on lower abdomen, hips, or buttocks (not breast or waistline) Rotate application sites Use 3 wk on and 1 wk off in patient with intact uterus; continuous in patient without uterus

Generic (Trade) Name and Dosage	Side Effects	Contraindications	Special Considerations
estradiol (Climara)—0.025, 0.0375, 0.05, 0.075, 0.1 mg Change transdermal patch once a week 0.05, 0.075, 0.1 mg/d	Same as above	Same as above	Same as above
estradiol and NETA (CombiPatch) Change transdermal patch twice a wk (0.05 mg estradiol and 0.14 mg norethindrone, 0.05 mg estradiol and 0.25 mg norethindrone)	Same as above	Same as above	Apply to clean, dry area on lower abdomen, hips, or buttocks (not breast or waistline) Combination therapy
Other Related Options			
ospemifene (Osphena) 60 mg daily	Vaginal discharge, hot flashes, muscle spasms	Undiagnosed, abnormal genital bleeding, known or suspected estrogen-dependent neoplasia, a history of or active thromboembolic disease	As it is an antagonist in breast cancer, it does not have the same risk as estrogen The only product in its class approved in the United States for dyspareunia associated with vulvovaginal atrophy
Vaginal Hormones			
estradiol 0.01% (Estrace Vaginal Cream) Initially 2–4 g/d for 1–2 wk, then 1–2 g/d for 1–2 wk; maintenance dose: 1 g 1–3 times/wk (3 wk on and 1 wk off)	Uterine bleeding, vaginal candidiasis	Breast or estrogen-dependent cancer, thrombophlebitis, undiagnosed genital bleeding, pregnancy, lactation, impaired liver function	Need to take progestin if uterus present
Estring (vaginal ring) 0.0015/d ring into the vagina; replaced every 90 d	Headache, leukorrhea, back pain, urinary tract infection, vaginitis, vaginal pain, abdominal pain, bacterial growth	Same as above	Remove while treating vaginitis Re-evaluate every 3–6 mo
Femring 0.05, 0.1/d			
Premarin vaginal cream 0.625 mg/g 0.5–2 g/d	Nausea, vomiting, breakthrough bleeding, edema, weight changes, swollen/tender breasts, hypertension, depression, hair loss, changes in libido	Same as above	Therapeutic regimen consists of 3 wk on therapy and 1 wk off

QOL data have been reported for the estrogen plus progestin arm of the Women's Health Initiative (WHI). Approximately 16,600 women completed surveys at baseline and year 1. About 1,500 women completed surveys at year 3. At year 1, there was statistically significant improvement in sleep disturbance, physical functioning, and bodily pain as compared with the placebo group. However, the differences were so small that there is a question about clinical significance. There was no significant difference at year 3. In women reporting moderate to severe VMS, those taking estrogen plus progestin had significant improvement in the severity of hot flashes and night sweats (WHI, 2002). Further, the Society for Women's Health Research unanimously recommends that significant improvement in health-related QOL and global QOL are provided via HT; the greatest benefits are observed when started in a timely fashion related to the onset of menopausal symptoms (Davies et al., 2013).

In the women's health, osteoporosis, progestin, estrogen (HOPE) trial, healthy postmenopausal women ages 40 to 65 were randomly assigned to treatment with conjugated equine estrogen (CEE) alone (0.625, 0.45, or 0.3 mg daily), CEE plus MPA (0.625/2.5, 0.45/2.5, 0.45/1.5, or 0.3/1.5 mg daily), or a placebo. Over 13 cycles, women in all active treatment groups had a significant reduction in VMS. In women taking CEE alone, benefit increased with increased dosage. In women taking CEE plus MPA, the benefit was comparable with all doses (Utian et al., 2001).

If HT is prescribed solely for vaginal symptoms, health care providers are advised to consider the use of topical vaginal products (gel or cream applied locally) secondary to reduced systemic effects as compared to oral or transdermal formulations.

The slight decrease in testosterone production that accompanies menopause can cause a significant decrease or complete loss of libido in some women. For these women, testosterone can be added to HT in doses of 1.25 to 2.5 mg methyltestosterone. The adverse events of testosterone in these doses are hirsutism, voice change, and a decrease in the high-density lipoprotein cholesterol level. Long-term use is associated with the risk of hepatocellular neoplasm, increased edema, and possible elevation of cholesterol level. The only indication for treatment is severe vasomotor disturbances and decreased libido. The most frequent treatment choice is either Estratest, which is 1.25 mg esterified estrogen and 2.5 mg methyltestosterone, or Estratest H.S., which is 0.625 mg esterified estrogen and 1.25 mg methyltestosterone. Estratest H.S.may be used safely as long as baseline lipid levels are normal. Estratest, with its 1.25 mg esterified estrogen, is a high dose of estrogen and should be used only for short periods.

HT started after age 65 does not improve memory and, in fact, has been observed to increase the risk for developing dementia (Coker et al., 2010). While preliminary data suggest that there may be cognitive benefits when HT is used in younger women, it has not been well studied. The WHI memory study of younger women is currently underway to determine whether women ages 50 to 59 who start HT a short time after onset of

menopause and who are treated for an average of 5.4 years would experience cognitive benefits (Vaughan et al., 2013).

Mechanism of Action

HT with estrogen minimizes VMS and genitourinary symptoms related to estrogen deficiency. Estrogen assists in temperature control that occurs in the anterior hypothalamus. Further, estrogen receptors are located throughout the entire female genitourinary tract. Increasing the estrogen levels that declined via menopause through estrogen replacement helps to improve the symptoms of deficiency. Progestins are added to systemic estrogen formulations (oral and transdermal) in women who have a uterus. The unopposed use of estrogen in these women can lead to endometrial hyperplasia, increasing the risk for developing endometrial cancer. However, progestins may increase the risk of breast cancer above that observed with estrogen alone (further discussed under adverse events of HT).

Dosage

Several systemic estrogen and progestin formulations (oral and transdermal) are available, and there is no strong evidence that one formulation is superior to another relative to the impact on VMS or genitourinary symptoms. Hormones delivered via a transdermal patch are associated with a lower risk of venous thromboembolism (VTE) compared to oral formulations. A reasonable starting dose of estrogen for women who are having hot flashes is 0.025 mg of transdermal estradiol, 0.5 mg of oral estradiol, or 0.3 mg of CEE. The transdermal and vaginal routes of administration of estrogen avoid first-pass hepatic metabolism and may be the reason for which reduced thromboembolic risk (VTE and stroke) is observed. In relation, there is not an increase in C-reactive protein (perhaps contributing to this lower risk of VTE) seen with the nonoral products as is observed with oral therapy. However, no randomized controlled trials to support this concept have been published to date.

When considering the use of vaginal estrogen products, especially for the management of genitourinary symptoms, it is important to note that 10% to 15% of systemic estrogen users may not achieve adequate relief of their symptoms such that additional low-dose vaginal products can be added (NAMS, 2013). For genitourinary symptoms including vulvovaginal atrophy, recurrent urinary tract infections, and overactive bladder, low-dose vaginal estrogen is very effective; 80% to 90% efficacy is noted with vaginal products as compared to 75% efficacy with systemic estrogen formulations. Vaginal formulations are available as vaginal rings (7.5 mcg estradiol released daily over 90 days), vaginal tablets, and vaginal creams. The vaginal tablets contain 10 mcg estradiol and should be dosed one tablet daily for 2 weeks and then one tablet twice weekly thereafter. The vaginal creams contain 0.1 mg active estradiol per 1-g dose. The vaginal creams are dosed 2 to 4 g of cream vaginally per day for 1 to 2 weeks followed by 1 g of cream vaginally one to three times per week. Unlike the systemic estrogen products, the vaginal formulations appear safe alone (in

the absence of a progestin) relative to endometrial hyperplasia and endometrial cancer risk; however, long-term data are lacking. Overall, the benefits of these products are dose dependent and patient specific.

In addition, and during the menopause transition in particular, low-dose oral contraceptives can be used to prevent and control symptoms until the patient reaches menopause and to ensure prevention of conception because these women are still fertile. To determine when, in fact, the patient taking oral contraceptives is postmenopausal, such that alternative treatment regimens can be considered, FSH levels can be determined on the last hormone-free day of the oral contraceptive package.

The postmenopausal estrogen progestin intervention (PEPI) trial showed that CEE with cyclic micronized progesterone had the best lipid profile of any of the combined regimens. Micronized progesterone and norethindrone acetate (NETA) have better side effect profiles than MPA and should be considered when choosing a progestin (PEPI Writing Group, 1995).

Time Frame for Response and Treatment Duration

Overall, it is recommended that HT should be used at the lowest effective dose and for the shortest duration possible. Improvement in symptoms may be realized over a short period of time, days to weeks. Symptom improvement is dose related. Owing to the long-term effects such as increased risk of breast cancer, CHD, and VTE, duration of HT should be limited to 3 to 5 years for estrogen plus progestin or an average of 7 years for estrogen alone (i.e., status post hysterectomy). Women with premature menopause who are candidates for HT can use this treatment until the median age of menopause, 51 years, with longer treatment considered if needed for symptom management (NAMS, 2012).

Contraindications

The WHI was a large, 8- to 10-year study of healthy, postmenopausal women with a randomized controlled component of 27,347 postmenopausal women, ages 50 to 79 years (WHI Writing Group, 2002). They were randomized to HT (estrogen alone, estrogen plus progestin) or placebo. The estrogen used was continuous-combined CEE 0.625 mg daily and 2.5 mg MPA daily. The estrogen plus progestin arm was stopped early (after about 5.2 years). This group also had increased risk of coronary events, stroke, pulmonary embolism, and invasive breast cancer. The thought is that because there was an increased incidence of invasive breast cancer, HT promotes the growth of existing breast cancer rather than causing cancer. There was a reduced risk of colorectal cancer and hip fractures. Many of the risks appeared in year 1 (coronary and venous thromboembolic events) and year 2 (stroke). It was determined based on the data that the risk–benefit profile of estrogen plus progestin was such that its use for primary prevention of chronic conditions was not validated and it should not be prescribed to prevent chronic conditions. The study was stopped in 2002. Poststopping, and representing 13 years of cumulative follow-up for the WHI, there

continues to be (1) lack of support for the use of HT for chronic disease prevention and (2) acknowledgment that the lowest risks of long-term negative effects occur in younger women with hysterectomy receiving CEE alone. Additional subanalyses focusing on the younger cohort of the WHI (estrogen alone or HT) have failed to find adverse cardiac outcomes among this subset. In fact, women in their 50s who took estrogen appear to have less coronary artery calcification than controls (Manson et al., 2013).

Box 56.1 identifies specific contraindications to the use of HT in postmenopausal women; in addition, oral contraceptives are contraindicated in smokers older than 35 years of age.

BOX 56.1 Contraindications to HT

Absolute Contraindications

- Known or suspected breast cancer
- Known or suspected endometrial cancer
- Untreated endometrial hyperplasia
- Uncontrolled hypertension
- Acute liver disease
- Active thromboembolic disease or history of thromboembolic disease
- Known or suspected pregnancy

Relative Contraindications

- Chronic, mild liver dysfunction
- Smoking (cigarettes, marijuana)
- Acute intermittent porphyria

Adverse Events

The routine physical examination for a postmenopausal woman should include the patient's measured height, a gynecologic examination, and clinical breast examination. Investigative studies should include a pregnancy test, mammogram, and Papanicolaou (Pap) smear. Conditions that predispose women to increased risk of endometrial cancer include a lifelong history of irregular menses, polycystic ovary disease, or a recent history of irregular menses occurring closer than 21 days apart or menses lasting longer than 10 days. These women should have an endometrial biopsy before beginning HT. Adverse events include intolerance to contact lenses from steepening of corneal curvature, headache, and gallbladder disease, an increase in serum triglycerides, nausea, vomiting, abdominal cramps,

increased blood pressure, thromboembolic disease, edema, breast cancer, breast tenderness, and breakthrough bleeding. Table 56.1 identifies side effects associated with various elements of HT.

All continuous HT regimens can cause breakthrough bleeding. About 30% of all women who are recently menopausal have some breakthrough bleeding; this decreases with women who are more than 3 years postmenopausal. Amenorrhea usually occurs within 1 year of initiating therapy.

Relative to the longer term, more serious adverse events, data from the WHI show that short-term use of combined estrogen and progestin increases the incidence of breast cancer and abnormal mammograms. Those women in the study taking HT were diagnosed at a more advanced stage of breast cancer. In the WHI, this risk was an additional eight cases of breast cancer per 10,000 women using estrogen plus progestin for 5 or more years.

The results of the WHI showed that for every 10,000 women taking MHT for 1 year, there was an increase of eight strokes, seven cases of CHD, eight more invasive breast cancers, and eight additional pulmonary embolisms (Manson et al., 2013).

Interactions

Drug interactions with CEE include increased effects of corticosteroids and decreased levels of estrogen with barbiturates, phenytoin, and rifampin. Patients taking phenytoin metabolize estrogen more quickly. An increased dose of estrogen may be needed in smokers because only half the serum level achieved in nonsmokers is reached. However, any changes in CEE dose should be based upon symptom response, not anticipated responses. Alternatively, alcohol increases the circulating levels of estrogen due to the liver's preoccupation with metabolizing the alcohol at the expense of the estrogen.

Additional/Summary Recommendations

The Endocrine Society issued conclusions on the use of HT (Santen, 2010). Select conclusions with "A level" of evidence include the following:

- "Standard-dose" estrogen used with or without a progestogen is associated with marked reduction in frequency and severity of hot flashes. For many women, lower doses of estrogen are also effective.
- For symptoms of vaginal atrophy, very low doses of vaginal estradiol are effective.
- Symptoms of overactive bladder may be reduced by estrogen given vaginally or systemically.
- Vaginal estrogen is associated with lower rates of recurrent urinary tract infections.
- For women in late postmenopause, estrogen given with or without a progestogen is as effective as bisphosphonate therapy for preventing early postmenopausal bone loss and increasing bone mass.
- Use of estrogen alone and estrogen plus a progestogen is associated with a lower

incidence of hip and vertebral fractures.

- Use of HT containing estrogen plus a progestogen is linked to a lower risk of colon cancer.
- Mammographic density is increased in women taking estrogen alone or with a progestogen.
- Risk for venothrombotic episodes is approximately doubled in women using HT, and this risk is multiplicative with baseline risk factors such as age, increased body mass index, thrombophilias, surgery, and immobilization.
- Although continuous estrogen plus a progestogen does not cause endometrial cancer, estrogen alone without a progestogen is associated with an increased incidence of endometrial cancer.
- The risk of gallbladder disease is increased in women using estrogen alone or with a progestogen.

Estrogen Agonist/Antagonist

Ospemifene (Osphena), the only agent in this class of drugs approved for postmenopausal symptom management, notably for the treatment of the genitourinary symptom of dyspareunia, is an alternative to HT for this indication. Further, it is recommended by the NAMS for moderate to severe dyspareunia.

Mechanism of Action

Ospemifene binds to both estrogen receptor alpha (ERα) and estrogen receptor beta (ERβ). It acts as an agonist in some tissues and as an antagonist in other tissues. Specifically, it acts similarly to estrogen in vaginal tissues (i.e., minimizing dyspareunia) and has very weak estrogen activity in the uterus (i.e., minimal role in contributing to endometrial hyperplasia). It is a triethylene derivative, similar to tamoxifen, and as such may also have antiestrogenic activity in breast tissue therefore lacking the increased risk of breast cancer observed with traditional HT. Similar to HT, it has been shown to reduce bone turnover as measured by biochemical markers of bone turnover.

Dosage

Ospemifene is administered orally at a dose of 60 mg daily. It is recommended that it be taken with food to maximize its absorption from the gut.

Time Frame for Response

Clinical trials evaluating ospemifene have included those of 12 weeks duration and out to 52 weeks. While a meaningful response was not noted to occur before two weeks of treatment, clinical efficacy was realized by 12 weeks and observed to continue through to 52 weeks.

Contraindications

Ospemifene use should be avoided in women with undiagnosed, abnormal vaginal bleeding, women with known or suspected estrogen-dependent neoplasia, and women with a history of or active thromboembolic disease.

Adverse Events

Overall, in studies with ospemifene, 61% of women experienced an adverse event. Among these, the most common were vaginal discharge, muscle spasms, hot flashes, and hyperhidrosis. In particular, the rate of hot flashes observed with ospemifene was more than double than that observed in the placebo groups (8% vs. 3%). To date, there are no studies exceeding 1 year in duration such that any long-term side effects are yet to be identified.

The labeling for ospemifene includes a boxed warning for increased risk of VTE events,

cardiovascular disease, and endometrial cancer with its use. And while the U.S. Food and Drug Administration currently recommends the concomitant use of a progestin in women receiving ospemifene who have an intact uterus, there is currently no study to evaluate this combination.

Interactions

Ospemifene is metabolized by the cytochrome (CYP) P-450 isoenzyme system and is a highly protein-bound agent. Its concurrent use with other drugs that are inhibited or induced by CYP 3A4, 2C9, or 2C19 or that are greater than 89% protein bound may significantly alter ospemifene's effects. The manufacturer specifically recommends avoiding the concomitant use of fluconazole and rifampin.

Tissue Selective Estrogen Complex

TSEC describes the combination of CEE and bazedoxifene, an estrogen agonist/antagonist. This product is currently marketed under the brand name Duavee and is approved for the treatment of moderate to severe VMS.

Mechanism of Action

Like ospemifene, bazedoxifene acts as an estrogen agonist in some tissues and an antagonist in others. In particular, it acts as an antagonist in uterine tissue, reducing the risk for developing endometrial hyperplasia. Its effect as an estrogen agonist is responsible for its role in minimizing bone loss. When bazedoxifene is combined with CEE, the effects include a further reduction in bone mineral density loss, a reduction in VMS, and no greater increased risk of VTE (compared to the combination of CEE and progestin).

Dosage

The recommended dose following dose-ranging studies and based upon safety and efficacy data is 20 mg bazedoxifene plus 0.45 mg OR 0.625 mg CEE by mouth daily.

Time Frame for Response

A significant 74% to 80% reduction in the severity and frequency of hot flashes (compared to placebo) was observed following 12 weeks of treatment. A secondary outcome of improvement in sleep symptoms was also observed.

Contraindications

Use of the combination of bazedoxifene plus CEE should be avoided in patients with active or past history of VTE disorder, active or past history of an arterial thromboembolic disorder, a history of or current breast cancer, hepatic impairment or disease, and protein C and S or antithrombin deficiency that would predispose a woman to clot formation.

Adverse Events

In clinical trials, the adverse events observed with the combination of bazedoxifene plus CEE were comparable to those observed in the placebo treatment groups.

Interactions

The concomitant use of bazedoxifene and ospemifene is to be avoided. Other interactions with this combination product include those noted with estrogen in the HT treatment section of this chapter.

Selective Serotonin Reuptake Inhibitors and Selective Serotonin–Norepinephrine Reuptake Inhibitors

Agents including paroxetine, sertraline, venlafaxine, desvenlafaxine, citalopram, and escitalopram have been evaluated for their efficacy in reducing VMS associated with menopause. Only paroxetine, marketed as Brisdelle, has received FDA approval for the treatment of moderate to severe VMS.

Mechanism of Action

The preoptic area of the anterior hypothalamus, responsible for temperature regulation, is under the influence of serotonin and norepinephrine. The action of these two neurotransmitters at the hypothalamus is negatively affected by fluctuating estrogen levels. Therefore, the use of the SSRIs and selective serotonin–norepinephrine reuptake inhibitors (SNRIs) re-establish the neurotransmitters in the thermoregulatory center of the hypothalamus, improving VMS.

Dosage

Recommended starting doses of the abovementioned agents for the management of VMS associated with menopause are citalopram 10 mg by mouth daily, escitalopram 10 mg by mouth daily, venlafaxine 37.5 mg by mouth daily, desvenlafaxine 100 mg by mouth daily, sertraline 50 mg by mouth daily, and paroxetine 7.5 mg by mouth daily. The doses of citalopram, escitalopram, and venlafaxine can be increased to 30, 20, and 75 mg, respectively.

Time Frame for Response

While maximal dose–response effect to HT occurs in approximately 4 weeks, improvement in symptoms may be observed within the first week of treatment. To the contrary, the effects of the SSRIs and SNRIs are typically not realized until several weeks of therapy have been completed. After 4 to 8 weeks of treatment, an overall 30% to 75% reduction in hot flashes compared to placebo has been observed.

Contraindications

The SSRIs and SNRIs are not to be used within 14 days of the use of any of the monoamine oxidase inhibitors as such use may result in the development of serotonin syndrome.

Adverse Events

The most common adverse events observed with the use of the SSRIs and SNRIs include nausea, dizziness, dry mouth, nervousness, constipation, and sexual dysfunction.

Interactions

As noted under contraindications, the concomitant use of this class of drugs and a monoamine oxidase inhibitor may result in the development of the serotonin syndrome. Carbamazepine may increase the metabolism of the SSRIs/SNRIs and, conversely, the SSRIs/SNRIs may reduce carbamazepine metabolism. Cimetidine reduces the metabolism of the SSRIs/SNRIs. The SSRIs/SNRIs enhance the antiplatelet effects of nonsteroidal anti-inflammatory agents.

Gabapentin

Mechanism of Action

Gabapentin is an anticonvulsant that has been used to treat VMS associated with tamoxifen treatment in breast cancer patients as well as those associated with menopause. The mechanism of action of gabapentin for these purposes is unknown.

Dosage

Trials of gabapentin in postmenopausal women have utilized starting doses of 600 to 900 mg gabapentin in divided doses daily. Doses have been titrated to effect to a maximum total daily dose of 2.7 g.

Time Frame for Response

While efficacy may be appreciated at approximately 4 to 6 weeks of treatment, full effects may not be observed until as late as 12 weeks. In clinical trials, hot flash frequency was reduced by 45% and the composite hot flash score (including frequency and severity) was reduced by as much as 54% when compared to placebo.

Contraindications

Gabapentin should not be used in women with a history of hypersensitivity to gabapentin or any of its components.

Adverse Events

Somnolence, fatigue, dizziness, rash, and peripheral edema have been observed in women taking gabapentin for the treatment of VMS.

Interactions

Antacids may significantly reduce the absorption of gabapentin such that gabapentin should be dosed 2 hours after any antacids.

Clonidine

Clonidine is a centrally acting α-2 agonist used in the management of hypertension that has also been observed to treat VMS associated with menopause.

Mechanism of Action

The exact mechanism of clonidine in treating VMS is unclear but thought to be related to its central activity and potential impact on the thermoregulatory center in the hypothalamus.

Dosage

The recommended dose of clonidine for postmenopausal VMS is 0.1 mg by mouth daily.

Time Frame for Response

Improvement in VMS may be experienced following 4 to 6 weeks of clonidine treatment. Overall, clinical trial data for clonidine used to minimize VMS are lacking. What is available illustrates that clonidine is more effective than placebo but less effective than HT.

Contraindications

As clonidine is an antihypertensive agent, women with baseline low blood pressure would not be candidates for its use in managing VMS.

Adverse Events

The most common side effects noted with clonidine use include dry mouth, insomnia, drowsiness, and increased risk for hypotension.

Interactions

Clonidine may potentiate the effects of other central nervous system depressants.

Selecting the Most Appropriate Therapy

The options for managing VMS and the GUSM are varied, and there is not one regimen that fits all patients. The regimens vary in dosage formulation as well as active drug. In addition, nondrug recommendations should also be considered. Regardless, a patient-centered approach identifying the potential benefits and risks of each regimen as well as patient preference(s) and potential for regimen adherence for each patient must be considered. The choice of regimen should be arrived at by the "team" of patient and provider.

The Patient-Centered Approach

The decision of how to manage VMS or symptoms of the GUSM is one that must be reached by both patient and provider. While HT remains the most effective treatment modality, its duration of use must be limited and many women do not view its benefits to outweigh its risks, such that alternative modalities are desired. Any treatment agreed to should be in addition to the lifestyle changes identified later in this chapter. Figure 56.1 illustrates a decision tree that can be used in determining initial treatment modalities for women presenting with menopause-related symptoms. As noted, and included within the previous text of this chapter, whether or not a woman has had any history of estrogen-dependent cancer is a factor that contributes to the final management decision. Debate still exists over the short-term use of HT in women following treatment of estrogen-dependent cancers including breast, ovarian, and endometrial. One retrospective study found that in spite of being treated for an estrogen-dependent cancer, 19.5% of women chose to take estrogen for menopause-related symptoms (primarily VMS) in spite of the contraindications to its use (Sekar et al., 2013). In addition, while there appears little question or controversy surrounding the use of HT in younger women at the time of menopause as having a very positive benefit to risk profile and being the most effective treatment for VMS, the increasing evidence of the risks and benefits of HT beyond the age of 65 years makes HT as an initial treatment choice in this older population a much less clear decision. Alternative treatments to HT should be carefully considered in this population (Davies et al., 2013; Moyer, 2013).

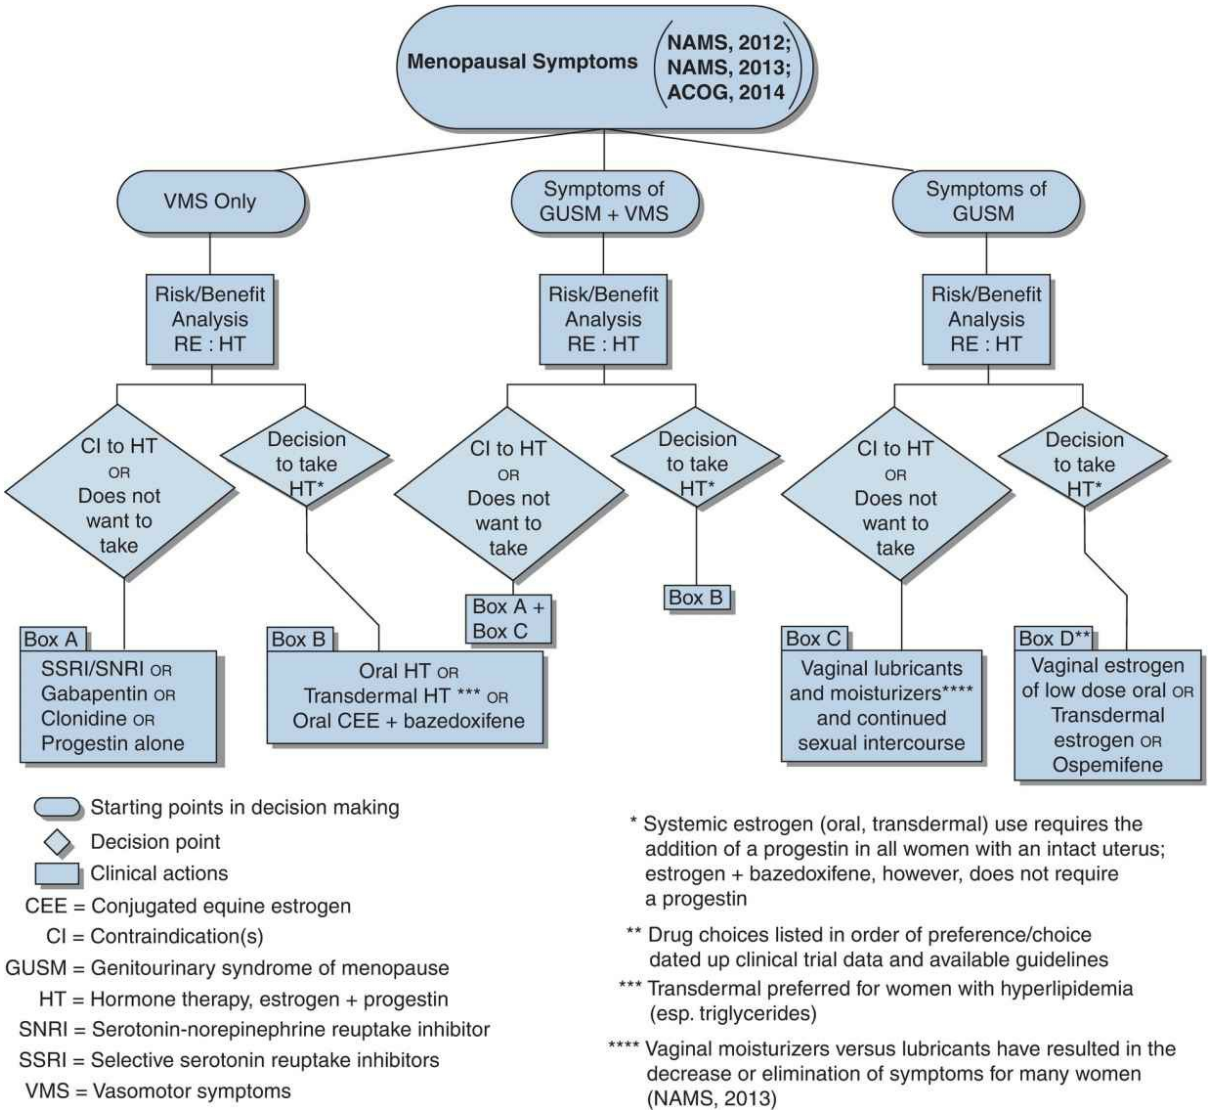

FIGURE 56.1 Treatment algorithm for menopause.

Monitoring Patient Response

The decision to continue HT should be revisited yearly, and therapy should be discontinued when symptoms resolve—usually in 1 to 3 years after menopause. And owing to an increase in breast cancer risk, its use beyond 3 to 5 years is not recommended (NAMS, 2012). The patient should be seen 4 to 8 weeks after starting therapy to evaluate response and make any necessary dosage adjustments and then in 3 to 6 months to monitor continued response to therapy, the need for any further dosage adjustments, and the occurrence of any side effects. After that, annual visits are required.

The health status of a woman on HT must be evaluated annually. Their medical history for the past year should be reviewed, including questions about vaginal bleeding. The woman should have an annual clinical breast examination and mammogram if she is older than age 40. Any woman on continuous-combined HT who has vaginal bleeding beyond the first year of treatment should be evaluated with an endometrial biopsy. The physical examination should include:

- Height and weight measurements to screen for osteoporosis and obesity
- Fasting lipid panel according to recommendations
- Blood pressure evaluation to screen for cardiovascular disease
- Clinical breast examination and review of procedures for breast self-examination
- Full pelvic examination, including a Pap smear

Prescriptions for HT should not be renewed without a full annual history and physical. Discontinuing HT should be done gradually as abrupt discontinuation may lead to a rebound of symptoms. This may be done in several ways. The patient may begin to skip more days between doses or the daily dose may be decreased at 4- to 6-week intervals.

Patient Education

Following publication of many prospective, randomized trials in the late 1990s and early 2000s, and the subsequent unbalanced media coverage that ensued, many women abruptly discontinued their HT (resulting in a plethora of women with rebounding symptoms of menopause). This only further illustrated the need for practitioners to remain current with the HT research and be able to put the clinical trial data in a balanced light for their patients. It also illustrated the need for practitioners to be more aware than ever of the alternatives that exist to HT and to effectively communicate this to their patients without overwhelming them. Menopause is a natural part of the aging process and women need to know that their providers realize the gravity of the impact its consequences may have on QoL and trust that their providers will assist them in managing this part of their life.

Drug Information

Several options are available for the postmenopausal woman with VMS. If she decides to begin HT, the decision must be an informed decision. To make an informed decision, the patient must be provided with detailed information on the risks and benefits of therapy and other options available. It is also important to understand the side effects and that there may be monthly bleeding. General key teaching points include the following:

- The patient must be aware that it may take up to 4 weeks or more (depending on treatment option chosen) before symptoms to respond to treatment. Efficacy of the treatment chosen is typically dose dependent.
- Encourage patients to be aware of and communicate with their provider the occurrence of potential adverse events as, in some instances, there may be ways to minimize them. For example, HT can be taken with food or at bedtime to prevent nausea. For other, more severe adverse events such as VTE, patients should be educated regarding the signs and symptoms and be encouraged to contact their provider in a very timely manner or seek emergency treatment as needed.
- Patients should be instructed to never, in the event of missed doses, double the next dose.
- Patients should be aware that the management of menopause-related symptoms is at the lowest necessary dose for the shortest duration as is needed; and they should be empowered to follow up with their provider regarding potential discontinuation of treatment in a timely manner.

- The North American Menopause Society: http://www.menopause.org/for-women

Nutrition/Lifestyle Changes

The reduction in intake of refined carbohydrates, caffeine, and alcohol has been reported by women to result in minimizing hot flashes. Wearing only cotton clothing and maintaining low environmental temperatures may also allow women to feel more comfortable during hot flashes. Further recommendations to reduce VMS include dressing in layers, smoking cessation, and weight loss. The latter two suggestions are also beneficial to overall good health.

For genitourinary symptoms associated with menopause, specifically the symptoms of atrophy, regular sexual activity should be encouraged.

Complementary and Alternative Medications

In women not wishing to take pharmacologically active agents to minimize the symptoms of vaginal atrophy, the use of long-acting vaginal moisturizers and lubricants is an option. Such agents may increase the vaginal pH to premenopausal levels, and their use during intercourse may reduce friction-related effects worsened by atrophy.

Women are also turning to other herbs, such as soy or black cohosh, or the phytoestrogens for managing menopausal symptoms, specifically VMS (Table 56.2). Phytoestrogens, estrogens obtained from plant sources, are marketed in oral formulations for the management of VMS. An example of this is the brand-named product Promensil. Phytoestrogens are also found in a number of common foods including soybeans and soy products, cashews, peanuts, oats, corn, wheat, flaxseeds, and sunflower seeds. While phytoestrogens appear to lack the negative effects of estrogen relative to stimulation of the breast and uterus, they must be used for 4 to 6 weeks, before any improvement may be noticed. Soy, chickpeas, and other legumes contain isoflavones, which exhibit estrogenic properties. They can provide some VMS relief, although their effectiveness in menopause is still being investigated.

TABLE 56.2 Herbal Treatment of Menopausal Symptoms

Menopausal Symptom	Herbal Treatment	Usual Dose	Adverse Events and Contraindications
Hot flashes	Black cohosh (*Cimicifuga*)	40–200 mg/d; not to be taken for >6 mo	Not to be used during pregnancy Potential side effects: GI disturbances, hypotension
	Isoflavones (soy)	20–40 mg/d	Flatulence
Mood swings	St. John wort (*Hypericum*)	300 mg tid	Do not take with any antidepressant May cause sun sensitivity

Another option is vitamin E. While vitamin E has been evaluated, the results have illustrated that the treatment group had minimal to no positive impact on daily hot flashes compared to placebo (Loprinzi et al., 2008). Some clinical trials have shown improvement of hot flashes with soy and black cohosh and some have shown no improvement (Faure et al., 2002).

And while black cohosh is also used to treat menopause, specifically purportedly inducing vaginal maturation and improving VMS, no long-term scientific data are available and concern regarding the development of hepatitis and myopathy with long-term use exists.

Case Study*

E.P., a 51-year-old Asian woman who is 68 inches tall and weighs 130 pounds, presents

complaining of amenorrhea for the past 8 months. She wakes up at least 5 times a night with hot flashes and experiences them at least 10 times a day. She is very uncomfortable and sleep deprived. At the visit, a Pap smear is done and a mammogram is negative. Her FSH level is 32 international units/mL. She has no family history of breast cancer, but her mother has osteoporosis.

1. List specific goals for treatment for E.P.
2. What drug therapy would you prescribe? Why?
3. What are the parameters for monitoring success of the therapy?
4. Discuss specific patient education based on the prescribed therapy.
5. List one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What would be the choice for second-line therapy?
7. What over-the-counter and/or alternative medications would be appropriate for E.P.?
8. What lifestyle changes would you recommend to E.P.?
9. Describe one or two drug–drug or drug–food interactions for the selected agent.

57 Osteoporosis

Virginia P. Arcangelo

Osteoporosis is a progressive systemic disease characterized by a decrease in bone mass and microarchitectural deterioration of bone tissue, resulting in bone fragility and increased susceptibility to fractures. Bone loss occurs at about 10% each 10 years after the age of 30. Each decade after 40 years is associated with a fivefold increase in the incidence of osteoporosis. Osteoporosis, or low bone mass (osteopenia), is estimated to occur in approximately 54 million Americans aged 50 years and older, 80% of whom are women (National Osteoporosis Foundation, 2014). Women are more likely than men to develop osteoporosis because of thinner, lighter bones, changes associated with menopause, and greater longevity than men.

One in four men will have an osteoporotic-associated fracture. Men develop osteoporosis because of the inability to convert testosterone into estrogen through enzyme deficiency leading to decreased bone mass. They also may develop it because of medication side effects.

Osteoporosis affects 10.2 million adults, and another 43.4 million have low bone mass; more than one half of the total U.S. adult population is currently affected (http://nof.org/news/2948, accessed 3/28/2015). Based on these statistics, it is predicted that by 2020, the number of adults over age 50 with osteoporosis is 64.4 million, and by 2030, the number will increase to 71.2 million (http://nof.org/news/2948, accessed 3/28/2015).

Bone fracture is the major cause of mortality and morbidity in patients with osteoporosis. The most common fractures are vertebral compression fractures and fractures of the distal radius and proximal femur.

Causes

The three types of osteoporosis are postmenopausal, senile, and secondary (Box 57.1). Many risk factors are associated with osteoporosis (Box 57.2).

BOX 57.1 Types of Osteoporosis

Type I: Postmenopausal Osteoporosis

Occurs in postmenopausal women between ages 51 and 75.
Decreased estrogen causes an accelerated rate of bone loss, especially trabecular bone loss.
The most common fractures are of the vertebrae and distal femur. There is also tooth loss.

Type II: Senile Osteoporosis

Occurs in men and women older than age 70.
There is a proportional loss of cortical and trabecular bone.
The most common fractures are hip, pelvic, and vertebral.

Type III: Secondary Osteoporosis

Occurs in men and women at any age.
Secondary to other conditions such as drug therapy and other diseases.

BOX 57.2 Risk Factors for Osteoporosis

Female sex
Older age
Asian or White race
Family history
Petite stature
Low body weight
Amenorrhea
Menopause (either natural or surgical) without hormone replacement
Sedentary lifestyle
Low calcium intake
Excess alcohol intake
Smoking

Excess caffeine intake
Low testosterone level in men
Drugs
  Thyroid replacement drugs
Lithium
Glucocorticoids
Anticonvulsants
Chemotherapy
Heparin
Cyclosporin
Depot medroxyprogesterone (Depo-Provera)
Tamoxifen, before menopause
  Pioglitazone (Actos) and rosiglitazone (Avandia)
Disease states
  Anorexia/bulimia
Cushing syndrome
Thyrotoxicosis
Rheumatoid arthritis
Type 1 diabetes mellitus
  Thalassemia

Skeletal growth and the majority of bone mass are achieved during the first two decades of life, with bone density peaking around age 30. Between age 30 and menopause, bone mass remains relatively stable. At menopause, women have a period of 5 or more years during which there is an accelerated rate of bone loss. Some women lose up to 5% of their bone mass per year during this time.

Pathophysiology

Two types of bone are discerned at the macroscopic level: cortical bone and trabecular bone. Cortical bone has a dense structure, whereas trabecular bone has a spongy appearance. Long bones have a thick outer layer of cortical bone and a thin inner layer of trabecular bone, whereas short bones consist of mostly trabecular bone with a thin layer of cortical bone.

The skeleton undergoes continuous remodeling throughout life. Bone remodeling involves the removal of mineralized bone by osteoclasts followed by the formation of bone matrix through the osteoblasts that become mineralized. There are three phases of remodeling: resorption, during which osteoclasts digest old bone; reversal, when mononuclear cells appear on the bone surface; and formation, when osteoblasts lay down new bone until the resorbed bone is completely replaced. Bone remodeling serves to maintain skeletal integrity and repairs microdamages in bone matrix preventing the accumulation of old bone. Additionally, it serves to maintain plasma calcium homeostasis. Bone remodeling takes place at the systemic and local level. The major systemic regulators include parathyroid hormone (PTH), calcitriol, and other hormones such as growth hormone, glucocorticoids, thyroid hormones, and sex hormones. Factors such as insulin-like growth factors (IGFs), prostaglandins, tumor growth factor-beta (TGF-beta), bone morphogenetic proteins (BMPs), and cytokines are involved as well. At the local level, there are cytokines and growth factors that affect bone cell functions. Through the RANK/receptor activator of NF-kappa B ligand (RANKL)/osteoprotegerin (OPG) system, the processes of bone resorption and formation are closely interwoven allowing bone formation to follow each cycle of bone resorption to maintain skeletal integrity.

An imbalance in bone remodeling causes osteoporosis. This can be due to numerous factors targeting both osteoblasts and osteoclasts that result in greater resorption than formation. One cause is the decreased estrogen levels during menopause causing an up-regulation of RANKL. OPG secretion is suppressed. Because of this, there is greater osteoclastogenesis and accelerated bone resorption. Because bone formation is coupled to resorption, the entire remodeling unit is activated. Bone resorption is a rapid process, taking about 2 weeks for the osteoclasts to attach and resorb matrix. Formation is much more deliberate, meaning that with the release of soluble cytokines, an imbalance in remodeling immediately occurs, and this favors bone resorption. The loss is faster than remodeling causing bone loss. Estrogen administration can prevent bone loss by enhancing OPG production as well as by suppressing RANKL expression.

Bone is in a constant state of remodeling (reforming). Osteoblasts are responsible for bone formation and osteoclasts for bone resorption. A balance is normally achieved between osteoblast and osteoclast activity. When bone resorption occurs at a faster rate than bone remodeling, osteoporosis is the result because the bones then become brittle and prone to fracture. Bone loss is greater in trabecular bone than in cortical bone.

Maximal mineral content of cortical bone occurs between the second and fourth decades of life, followed by a slow decline. In general, women have less bone mass than men, so even a small loss is more significant in women. Cortical bone loss in women is approximately 3% per decade until menopause, when the rate of bone loss accelerates to 9% per decade. Women lose approximately 15% of trabecular bone during the first 5 to 7 years after menopause. The rate returns to normal approximately 20 years after menopause. Generalized bone loss in men occurs at a rate of approximately 4% per decade throughout life.

Diagnostic Criteria

Medical history and a drug history are essential in the diagnosis. Bone mineral density (BMD) is related to bone mass at maturity and subsequent bone loss. Dual-energy x-ray absorptiometry (DEXA) scan measures BMD and is used to diagnose osteoporosis. A BMD of –1 to –2.5 standard deviations (SD) signifies osteopenia. A BMD of –2.5 SD, or lower than the mean for a normal 30- to 35-year-old woman, is diagnostic of osteoporosis. Initial screening is recommended for:

- All women older than age 65
- Younger perimenopausal or postmenopausal women and men who have any medical condition or are taking medication associated with bone loss
- Any adult older than age 50 with a fracture
- Anyone being treated for osteoporosis
- Men age 50 and older at risk

For every 1 SD decrease in bone mass, the relative risk of fracture increases by 1.5 to 3 SD.

The guidelines use fracture risk calculations derived from a new computerized model developed by the World Health Organization (WHO). FRAX, or "WHO Fracture Risk Assessment Tool," is a free online tool. It assesses the likelihood a patient will experience an osteoporotic fracture within 10 years. FRAX considers 10 risk factors in addition to the BMD T-score so it will aid in the decision-making process of who to treat. The risk factors are age, gender, fracture history, parental hip fracture history, oral steroid therapy, low body mass index, femoral neck BMD, secondary osteoporosis, current smoking, and alcohol intake. FRAX is available for download at http://www.shef.ac.uk/FRAX/.

Initiating Drug Therapy

Prevention of osteoporosis should begin early in life with adequate intake of calcium and vitamin D. Children ages 9 to 18 should consume 1,300 mg of calcium daily. Adults ages 19 to 50 need 1,000 mg of calcium per day, and those age 51 and older require 1,200 mg each day. Because it is difficult to ingest that amount, supplements are usually needed. Weight-bearing exercise enhances bone mass and thereby helps prevent osteoporosis. Alcohol intake should be minimal, and those who smoke should stop.

Drugs used for the prevention and treatment of osteoporosis decrease bone resorption. They are called resorption-inhibiting drugs and include estrogens, bisphosphonates, calcitonin, and selective estrogen receptor modulators (SERMs). When these drugs are given, the rate of bone resorption decreases within weeks and the rate of bone formation increases within months. Remodeling spaces fill in, and an increase of BMD of 5% to 10% occurs with treatment. This process takes 2 to 3 years.

The National Osteoporosis Foundation (NOF) recommends that health care providers should consider U.S. Food and Drug Administration (FDA)–approved medical therapies in patients with:

1. Low bone mass (T-score from –1.0 to –2.5 at the femoral neck, total hip, or spine) and 10-year probability of hip fracture of 3% or more or a 10-year probability of any major osteoporosis-related fracture of 20% or more
2. T-score of 2.5 or less at the femoral neck, total hip, or spine after appropriate evaluation to exclude secondary causes
3. Low bone mass (T-score from –1.0 to –2.5 at the femoral neck, total hip, or spine) and secondary causes associated with high fracture risk (such as glucocorticoid use or immobilization)
4. A hip or vertebral (clinical or morphometric) fracture
5. Other prior fractures and low bone mass (BMD T-score from –1.0 to –2.5 at the femoral neck, total hip, or spine).

Goals of Drug Therapy

The goals of drug therapy are minimizing bone loss, delaying the progression of osteoporosis, and preventing fractures and fracture-related morbidity and mortality. Once osteoporosis is diagnosed and drug therapy is started, it is continued for life. Table 57.1 provides an overview of the drugs used in treatment.

TABLE 57.1 Overview of Selected Agents Used to Prevent or Treat Osteoporosis

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Bisphosphonates			
alendronate (Fosamax) Prevention: 5 mg/d or 35 mg once a week Treatment: 10 mg/d or 70 mg once a week	GI upset, abdominal pain, gastroesophageal reflux disease, esophagitis, headache	Esophageal abnormalities, inability to be upright for 30 min, hypocalcemia, creatinine clearance <30	Swallow whole Take with 8 oz of water 30 min before eating or drinking Sit or stand for 30 min after taking (do not lie down until after eating) Calcium supplements and aluminum- or magnesium-containing antacids may interfere with absorption, so it should be given at a different time
risedronate (Actonel) 5 mg/d or 35 mg once a week	Arthralgia, GI disturbances, headache, abdominal pain, rash, edema, chest pain, bone pain, dizziness, leg cramps, infection	Same as above	Same as above This drug is more tolerable for patients with GI problems than alendronate
ibandronate (Boniva) 2.5 mg PO daily or 150 mg PO once a month or 3 mg/3 mL IV every 3 mo	Same as above	Same as above	If taken monthly, take the same day each month IV medication is given in a bolus over 15–30 s
zoledronic acid (Reclast) 5 mg/100 mL once a day	Same as above	Same as above	Infusion must be given over at least 15 min
Selective Estrogen Receptor Modulators			
raloxifene (Evista) 60 mg qd	Hot flashes, leg cramps	Pregnancy, history of thromboembolic events	Medication is to be stopped 72 h before surgery or prolonged immobilization
RANK Ligand Inhibitor			
denosumab (Prolia) 60 mg subq q 6 months	Musculoskeletal pain, infection, arthralgia, myalgia, and abdominal pain	Pregnancy, low calcium	Caution in creatinine clearance <30, immunosuppression, small bowel excision
Other			
calcitonin (Miacalcin) 200 U (1 spray) daily 100 U IM or SC daily	Rhinitis, GI upset, back pain, facial flushing (with injection)	Allergy to salmon or fish products, lactation Caution in renal deficiencies	Perform periodic nasal examinations to check for ulceration Stop if nasal ulceration results Switch nostrils each day Injection recommended at bedtime because of possible facial flushing and nausea
Hormone Modifiers			
teriparatide (Forteo) 20 mcg daily SC	Hypercalcemia, dizziness, hyperuricemia, leg cramps, nausea, arthralgia	Paget disease, previous bone radiation, skeletal malignancy, hypercalcemia, hyperparathyroidism; caution with kidney stones	Used in women with a high risk of fracture or who have failed other therapies

Calcium Supplements

There has been recent discussion about calcium supplements increasing cardiovascular risk.

Data have been analyzed and it has been determined that there is no strong evidence that calcium supplement intake increases CVD risk in women (Paik et al., 2014).

Sufficient calcium intake is necessary for the prevention of osteoporosis. Postmenopausal women should take 1,200 to 1,500 mg of calcium a day. This can be achieved through dietary intake or supplements. Calcium is absorbed most effectively when taken in small amounts throughout the day. Patients should not take calcium with meals that are high in fiber or with bulk-forming laxatives because such materials decrease absorption. The over-the-counter (OTC) antacid Tums is an excellent and inexpensive source of calcium.

Most brand-name calcium products are absorbed easily in the body. If the product information does not state that it is absorbable, how well a tablet dissolves can be determined by placing it in a small amount of warm water for 30 minutes, stirring occasionally. If it hasn't dissolved within this time, it probably will not dissolve in the stomach. Chewable and liquid calcium supplements dissolve well because they are broken down before they enter the stomach. Calcium carbonate is absorbed best when taken with food. Calcium citrate can be taken any time. Calcium, whether from the diet or supplements, is absorbed best by the body when it is taken several times a day in amounts of 500 mg or less, but taking it all at once is better than not taking it at all.

While calcium supplements are a satisfactory option for many people, certain preparations may cause side effects, such as gas or constipation, in some individuals. If simple measures such as increased fluids and fiber intake do not solve the problem, another form of calcium should be tried. Also, it is important to increase supplement intake gradually; take 500 mg/d for a week, then add more calcium slowly.

Even if calcium supplements are not taken, vitamin D intake is important. Vitamin D is responsible for the maintenance of an adequate concentration of calcium and phosphorus in the extracellular fluid. It also works with PTH to regulate calcium movement across the gastrointestinal (GI) tract. The recommendation is 800 to 1,000 international units of vitamin D_3.

LEAVE ALL OF THIS IN Estrogen administration can prevent bone loss by enhancing OPG production as well as by suppressing RANKL expression.

Bisphosphonates

Alendronate (Fosamax), risedronate (Actonel), ibandronate (Boniva), and zoledronic acid (Reclast) are bisphosphonates used for preventing and treating osteoporosis.

Mechanism of Action

These drugs inhibit bone resorption and increase bone density. They are deposited in the bone at sites of mineralization and in resorption lacunae. The bone resorption and fracture rates decline, whereas bone density increases. In studies of alendronate, an increase in bone mass was shown in the spine and hip, with a 48% decrease in the rate of vertebral compression fractures. Bone turnover increases to previous levels after 6 to 9 months when the patient takes alendronate for 6 months and then stops. If the patient takes alendronate for 6 years, no decrease in bone mass is noted for 2 years after therapy stops. These drugs have been used successfully for prevention and treatment of decreased bone mass as a result of long-term use of glucocorticoids.

In large, randomized, controlled trials, alendronate showed consistent increases in BMD irrespective of the severity of the underlying bone density levels, and it reduced the incidence of both vertebral and nonvertebral fractures (Cummings et al., 1998; Liberman et al., 1995). Among women with osteoporosis, the incidence of symptomatic vertebral fractures was decreased by 44% over 4 years and clinical fractures were reduced by 36% (Cummings et al., 1998). Risedronate similarly reduced the incidence of vertebral fractures by 41% over 3 years (Harris et al., 1999) and reduced hip fractures by 40% in elderly women who had low BMD but not in women who had risk factors alone (McClung et al., 2001).

Dosage

The dosage for alendronate is 5 mg/d for prevention and 10 mg/d for treatment. It has also been approved for use once a week at 35 mg for prevention and 70 mg for treatment. Intestinal absorption of the drug is poor, so patients should take it on awakening with 8 ounces of water and 30 minutes before consuming any food or other drink. The dosage for risedronate is 5 mg/d or 35 mg once a week for prevention and treatment. The dosage for ibandronate is 2.5 mg daily or 150 mg once a month. There is also a 3 mg/3 mL solution for intravenous (IV) use every 3 months. Zoledronic acid is an IV medication given once a year. The dose is 5 mg/100 mL.

Contraindications

Bisphosphonates are not prescribed to patients with a history of esophageal problems, gastritis, or peptic ulcer disease. Adverse events include GI disturbance, esophagitis, diarrhea, and abdominal pain. Absorption increases with intravenous administration of ranitidine. Bisphosphonates should be prescribed with caution when the patient also is

using nonsteroidal anti-inflammatory drugs. Absorption decreases when these drugs are taken with food, calcium, or iron, so patients should take the medication at different times from these substances (i.e., at least 30 minutes before or after taking food or liquid nourishment).

Adverse Events

Alendronate can cause esophagitis, usually within the first month of therapy. Ways to diminish esophagitis as well as to increase drug absorption include taking alendronate and risedronate with 8 ounces of water and remaining upright for 30 minutes after administration. Risedronate has fewer harsh effects on the GI system.

Calcitonin

Salmon calcitonin (Miacalcin) is another drug used in treating osteoporosis.

Mechanism of Action

Calcitonin works by inhibiting the action of osteoclasts. It is available in injectable form and as a nasal spray. It is not effective in preventing bone loss early in the postmenopausal period, but studies have shown that it increases bone mass in the spine and decreases the risk of vertebral compression fractures. Calcitonin also has an analgesic effect on pain associated with vertebral compression fractures.

In one study of postmenopausal women who used calcitonin daily, new vertebral fractures were decreased by 33% compared with placebo, though only a small increase was noted in BMD (Chesnut et al., 2000).

Dosage

The intranasal dosage of calcitonin is 200 U/d. The patient should alternate nostrils each day. The injectable dosage is 100 U subcutaneously or intramuscularly each day.

Adverse Events

An adverse event with the use of nasal calcitonin is rhinitis. The nasal mucosa should be inspected every 6 months for ulceration. Injection can cause local irritation. With both inhalation and injection, GI upset, flushing, rash, and back pain may occur. Recommendations are for patients to perform injections at bedtime because facial flushing and nausea may occur.

Selective Estrogen Receptor Modulators

SERMs are indicated for treating and preventing osteoporosis. They reduce the risk of vertebral fractures but do not appear to have an effect on hip fractures.

Mechanism of Action

SERMs mimic the effects of estrogen on bones without replicating the stimulating effects of estrogen on the breasts and uterus. They decrease bone resorption and bone turnover. These agents also decrease total cholesterol and low-density lipoprotein cholesterol levels.

Dosage

Raloxifene (Evista) is the only available SERM. The dose is 60 mg/d. Supplemental calcium and vitamin Dare recommended.

Contraindications

Raloxifene is contraindicated in women who are lactating or who may become pregnant. It is also contraindicated in women who have a history of thromboembolic events. The patient must discontinue the drug 72 hours before prolonged immobilization, such as surgery requiring bed rest.

Adverse Events

Adverse events include hot flashes, GI distress, flu-like symptoms, leg cramps, deep vein thrombosis, and arthralgias. When taken with cholestyramine, absorption is disrupted.

Hormone Modifiers

Hormone modifiers contain recombinant human PTH. Teriparatide (Forteo) is the only PTH recombinant currently available.

Mechanism of Action

PTH is the primary regulator of calcium and phosphate metabolism and regulates bone metabolism, renal tubular reabsorption of calcium and phosphates, and intestinal calcium absorption. It stimulates new bone formation in trabecular and cortical bone surface by preferential stimulation of osteoblastic activity over osteoclastic activity. This causes an increase in skeletal mass and an increase in markers of bone formation and resorption and bone strength.

A study showed women using teriparatide had an increased density of the spine of 10% to 14% and of the hip of 5%. In 18 months, vertebral fractures were reduced 60% to 70% and nonvertebral fractures 55% (Dempster et al., 2001). It has been shown that teriparatide can prevent back pain in women with osteoporosis for up to 18 months beyond the end of treatment.

Dosage

Teriparatide is the only agent in this class currently. It is administered subcutaneously at a dosage of 20 mcg daily. This is used in women at high risk for fracture or those who have failed to respond to or who are intolerant of other therapies.

Contraindications

Teriparatide is contraindicated in the following circumstances: Paget disease, children, previous bone radiation therapy, history of skeletal malignancy, metabolic bone disease, hypercalcemia (which is usually transient), and hyperparathyroidism. It should be used cautiously in patients with a history of kidney stones.

Adverse Events

Teriparatide may increase calcium levels and increase the risk of digoxin toxicity if used together. Common adverse events include dizziness, nausea, leg cramps, arthralgia, and hyperuricemia.

RANK Ligand Inhibitor

Denosumab (Prolia) is a RANK ligand inhibitor.

Mechanism of Action

RANK ligand is an essential mediator of osteoclast activity. In postmenopausal osteoporosis, decreased estrogen leads to increased RANK ligand, an essential mediator of osteoclast activity. Increased osteoclast activity leads to increased bone loss and fracture risk. A RANK ligand inhibitor targets and binds to RANK ligand, inhibiting osteoclast formation, function, and survival, keeping osteoclasts from resorbing bone.

Dosage

The dosage is 60 mg subcutaneously every 6 months.

Contraindications

Denosumab is contraindicated in pregnancy and hypocalcemia, Caution should be used if the creatinine clearance is greater than 30, immunocompromised patients, and those who have had small bowel excision.

Adverse Events

Denosumab can cause musculoskeletal pain, infection, arthralgia, myalgia, and abdominal pain.

Selecting the Most Appropriate Agent

The patient needs an intake of calcium and vitamin D in addition to any other drug selected. Results of the DEXA scan guide the provider's decision in selecting therapy for osteoporosis. If the T-score is less than −1 SD from the norm, the patient is said to have no osteoporosis or osteopenia, but calcium intake and weight-bearing exercise are encouraged. A T-score below −1 SD or less than −2.5 SD from the mean indicates osteopenia, and treatment with calcium and vitamin D should begin. Also, the practitioner should consider preventive resorption-inhibiting therapy. The risk of fracture almost doubles for each BMD decrease of 1 SD. The DEXA scan should be repeated in 2 years or sooner if the patient experiences menopause. The NOF recommends pharmacologic treatment if the T-score is below −2 SD from the mean, if the T-score is −1.5 with other risk factors for osteoporosis or fracture, and if the woman is older than age 70 with multiple risk factors, especially previous fractures (Figure 57.1).

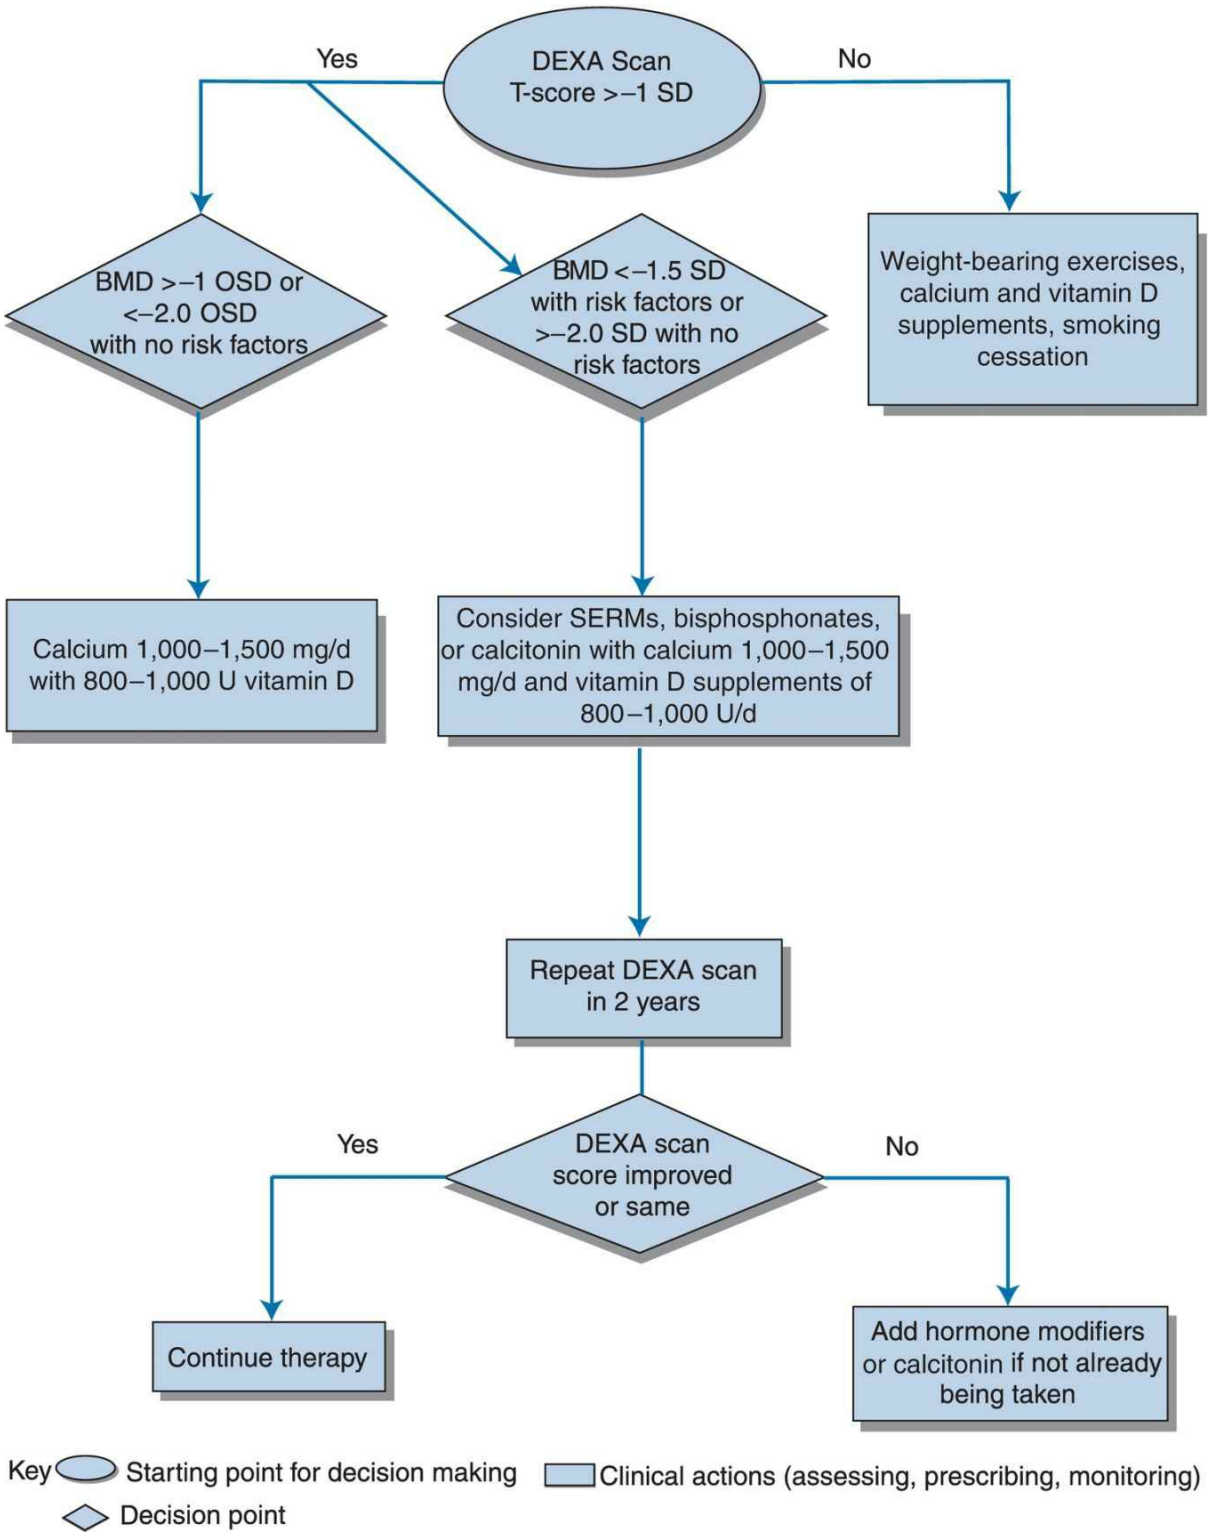

FIGURE 57.1 Treatment algorithm for osteoporosis.

First-Line Therapy

Raloxifene or bisphosphonate therapy is used for prevention; bisphosphonates are used for treatment (Table 57.2). Patients should have calcium and vitamin D supplementation.

Treatment decisions are based on patient history. For instance, if the patient has a history of esophagitis, alendronate is not the best choice; if the patient has a history of thromboembolic disease, raloxifene is not the appropriate therapy.

TABLE 57.2 Recommended Order of Prevention and Treatment for Osteoporosis

Order	Agents	Comments
First line	Prevention: raloxifene, alendronate, ibandronate, zoledronic acid, or risedronate plus calcium and vitamin D Treatment: raloxifene, alendronate, risedronate, ibandronate, zoledronic acid, or calcitonin	Treatment may be lifelong.
Second line	Addition of hormone modifiers or calcitonin if not being taken	

Second-Line Therapy

Calcitonin, a hormone modifier or RANK ligand inhibitor, is recommended for second-line therapy in women who have failed to respond to first-line therapy or who cannot tolerate hormone replacement therapy, bisphosphonates, or SERMs.

Monitoring Patient Response

The DEXA scan should be repeated every 2 years. Measurement of the density of the proximal femur is most helpful in predicting fractures, and measurement of the density of the lumbar spine is most effective in measuring the response to therapy. Within 2 years, resorption-inhibiting drugs increase the BMD of the lumbar spine by 5% to 10% in women with postmenopausal osteoporosis, causing the incidence of fractures to decrease by 50% (Cummings et al., 1998; Melton et al., 1993). Follow-up is recommended 1 to 2 months after the start of therapy and then every 3 to 6 months if the patient has osteoporosis. Follow-up is necessary every year if the therapy is prophylactic

Even if the medication is stopped, its positive effects can persist. That's because after taking a bisphosphonate for a period of time, the medicine remains in your bone. Because of this lingering effect, there is a belief by the experts that it is reasonable for people who are doing well during treatment—those who have not broken any bones and are maintaining bone density—to consider taking a holiday from bisphosphonate after taking it for 5 years.

Patient Education

Drug Information

Bisphosphonates should be taken with 8 ounces of water, and the patient should remain upright for 30 minutes after administration. Information about osteoporosis can be obtained from the NOF Web site (http://www.nof.org) or the National Institutes of Health Osteoporosis and Related Bone Disease National Resource Center (http://www.osteo.org).

Lifestyle/Nutritional Changes

A well-balanced diet is important, as are weight-bearing exercises. Safety strategies are necessary, such as removing unstable rugs and keeping items that could cause a fall out of the way. Smoking cessation is essential. Excessive alcohol intake should be avoided.

Complementary and Alternative Therapy

Supplemental calcium and vitamin D are important adjuncts to therapy. Patients without osteopenia or osteoporosis should ingest 1,200 mg of calcium a day, and those with osteopenia or osteoporosis should ingest more—1,500 mg calcium daily and 800 to 1,000 U of vitamin D to facilitate the absorption of calcium.

Case Study*

J.S., a 72-year-old woman of Asian descent, has just transferred to your practice. She had a hysterectomy 8 years ago and has not been on hormone replacement therapy. She is 5 ft 2 inches tall and weighs 102 lb. She has had a sedentary lifestyle (she was a secretary and retired 2 years ago). She drinks four glasses of wine a day. Her mother died at age 62 from complications of a hip fracture. J.S.'s sister was just diagnosed with metastatic breast cancer. You prescribe a DEXA scan, and the T-score is –2.6 SD.

Diagnosis: Osteoporosis

1. List specific goals of therapy for J.S.
2. What drug therapy would you prescribe? Why?
3. What are the parameters for monitoring the success of the therapy?
4. Discuss specific patient education based on the prescribed therapy.
5. List one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What OTC or alternative medicines might be appropriate for this patient?
7. What dietary and lifestyle changes might you recommend?
8. Describe one or two drug–drug or drug–food interactions for the selected agent.* Answers can be found online.

58 Vaginitis

Virginia P. Arcangelo

Vaginitis is one of the most common gynecologic complaints. The most common causes of vaginitis are vulvovaginal candidiasis (VVC), bacterial vaginosis (BV), and *Trichomonas vaginalis*. The presentation is often vaginal or perineal itching, burning, vulvar or vaginal irritation, and abnormal vaginal discharge. Many women may be asymptomatic. Other causes of vaginal irritation or inflammation include allergic reactions and atrophic changes in the vaginal mucosa.

Causes

Candidiasis

Most vaginal yeast infections are caused by *Candida albicans*, although other organisms, such as *Candida tropicalis* and *Candida glabrata*, are seen, especially in recurrent candidiasis. Colonization of Candida at other sites, such as the oral mucosa and the gastrointestinal (GI) tract, may be associated with recurrent vaginitis. Candidal vaginitis is often accompanied by vulvitis, so the term *vulvovaginal candidiasis* may better describe this disorder.

Behavioral factors may cause VVC. Sexual factors, in particular orogenital sex, may contribute to the introduction of microorganisms or cause microtrauma to the vulva and vestibule. Contraceptive practices may contribute to VVC; oral contraceptives, use of a diaphragm and spermicide, and the use of an intrauterine device are associated with an increased risk of infection.

Bacterial Vaginosis

BV is a polymicrobial vaginal infection that occurs when the hydrogen peroxide–producing *Lactobacillus* normally present in the vagina diminishes, allowing other bacteria to proliferate. Bacteria, such as *Gardnerella vaginalis*, *Prevotella* species, *Mobiluncus* species, and *Mycoplasma hominis*, are responsible for BV. Although the cause of BV is not well understood, some studies suggest that causes may include complications of pregnancy and infections associated with gynecologic procedures, pelvic inflammatory disease, and cervical intraepithelial neoplasia. It is unclear whether BV is only sexually transmitted.

Although BV in the past frequently has been ignored, it is considered the most common form of vaginitis and affects approximately 30% of women. The prevalence of BV among U.S. women aged 14 to 49 is about 29% (Koumans et al., 2007).

Because most women who have BV exhibit no or minor symptoms, there is a tendency to overlook this condition. Sociodemographic factors associated with BV include younger age, being non-Hispanic Black or Mexican American, having less than a high school education, living at or near the federal poverty level, and douching. Sexual risk factors, such as being sexually active, age of first sexual intercourse, and having multiple male lifetime sexual partners, particularly multiple over the past year, all are risk factors for BV. In lesbian women, female partners of women who have BV have a higher incidence of BV. Despite the sexual risk factors associated with BV, however, BV is considered sexually associated but not sexually transmitted. While infection is rare in women who have never been sexually active, treatment of male sex partners has not proven to be beneficial in preventing recurrence.

Trichomoniasis

Trichomonas vaginalis, an anaerobic protozoan, is one of the most commonly sexually transmitted organisms. Practitioners have long recognized that some asymptomatic women may harbor the organism. The organism, which can apparently survive in the environment for several hours, may be transmitted by contact, particularly with moist objects (e.g., underclothing and towels). Increased numbers of sexual partners, a recent new sexual partner, or early initiation of sexual activity (younger than age 16) is associated with an increased prevalence. Up to 86% of trichomoniasis infections may be asymptomatic. Trichomonads can live for a limited length of time on moist surfaces and may be transmitted by fomites, such as towels or sexual toys.

Allergies and Irritants

Conditions or products that irritate the vulva or the vaginal epithelium or local allergic reactions may produce symptoms similar to those of infectious vaginitis. Examples of irritants include vaginal lubricants, condoms, spermicides, and feminine hygiene products. Women who have other atopic skin conditions may experience vaginal and vulvar manifestations as well.

Atrophy

Low levels of estrogen in a postmenopausal woman may lead to atrophy of the vaginal epithelium and subsequent irritation and inflammation, which also may predispose the woman to vaginitis.

Pathophysiology

A review of the normal physiology of the vaginal environment forms the basis for understanding the possible causes and pathophysiology of vaginitis. In postpubertal women, both anaerobic and aerobic bacteria make up the normal vaginal flora. These include potential pathogens, such as *Staphylococcus*, *Streptococcus*, and *Bacteroides* species, and nonpathogens, such as lactobacilli and diphtheroids. *Candida albicans* is a saprophytic fungus that is a normal vaginal inhabitant in 15% to 25% of women.

One of the most important factors in the defense against infection is an acidic vaginal pH, which may be influenced by the acidic by-products produced by the normal vaginal flora. Hydrogen peroxide–producing strains of lactobacilli in vaginal secretions have been associated with protection against some vaginal infections as well. Therefore, variables that alter the vaginal pH or destroy lactobacilli may predispose a woman to vaginal infection. Among these variables are pregnancy, diabetes, sexual activity, hormonal changes, antibiotic therapy, and the use of feminine hygiene products. The thickness of the vaginal epithelium may also influence antimicrobial defenses.

Diagnostic Criteria

Candidiasis (VVC)

Symptoms of VVC include intense pruritus and erythema, dysuria, and a thick, white, curdlike vaginal discharge that tends to adhere to the vaginal walls. Diagnosis is made on the basis of presenting complaints, physical findings, and observation of pseudohyphae on potassium hydroxide (KOH) wet mount slide. Gram stain and culture of the vaginal discharge are other methods that may be employed in the diagnosis of VVC. Vaginal cultures can confirm the diagnosis and identify the species of *Candida* causing infection. Since 10% to 20% of women harbor *Candida* in the vagina, it is not recommended that asymptomatic women be treated. If the vaginal pH is tested, the value in candidiasis is usually less than 4.5. *Candida* may also be identified on Papanicolaou (Pap) smears of symptomatic or asymptomatic women. VVC may be classified as complicated or uncomplicated (Box 58.1).

BOX 58.1 CDC Classification of Vulvovaginal Candidiasis (VVC)

Uncomplicated VVC
Sporadic or infrequent vulvovaginal candidiasis
or
Mild to moderate vulvovaginal candidiasis
or
Likely to be *C. albicans*
or
Nonimmunocompromised women
Complicated VVC
Recurrent vulvovaginal candidiasis
or
Severe vulvovaginal candidiasis
or
Non-*albicans* candidiasis
or
Women with uncontrolled diabetes, debilitation, or immunosuppression, or those who are pregnant

Bacterial Vaginosis

Routine cultures are not helpful in diagnosing BV because up to 50% of women who harbor *G. vaginalis* vaginally are asymptomatic. When symptomatic, a woman may complain of a fishy odor, yellow or grayish discharge, and vaginal irritation. A yellow discharge increases the likelihood of BV fourfold but also can indicate a *Trichomonas* infection. A white discharge makes BV less likely. A clinical diagnosis of BV requires three out of four Amsel criteria, which are 92% sensitive but only 77% specific. Amsel criteria are abnormal grayish homogenous discharge, vaginal pH greater than 4.5, positive amine or "whiff test" ("fishy" odor with KOH applied to discharge), and more than 20% positive clue cells (epithelial cells surrounded by adherent coccobacilli) on microscopy (Box 58.2). Treatment reduces symptoms, yet recurrences are common, with 23% at 1 month and 58% at 12 months.

BOX 58.2 Diagnostic Tests for Bacterial Vaginosis

FemExam test card (CooperSurgical, Shelton, Connecticut)
Pip Activity TestCard (Litmus Concepts, Inc., Santa Clara, California)

CDC, 2010

Trichomoniasis

Patients with vaginitis caused by *Trichomonas* organisms report a profuse, frothy, yellowish vaginal discharge, vaginal and vulvar irritation, dysuria, and dyspareunia. Microscopic identification of the motile organism on a wet mount slide usually confirms the diagnosis. *Trichomonas* organisms may also be identified on a Pap smear. Because the organism may be recovered from male partners of infected women, this form of vaginitis is considered to be sexually transmitted.

Occasionally, asymptomatic women are diagnosed with trichomoniasis by routine Pap smear, which is reported to be 57% sensitive and 97% specific. If symptomatic, trichomoniasis presents as vaginal itching, burning, vaginal discharge (frequently profuse, yellowish-green, and malodorous), or postcoital bleeding. Trichomonads often appear in motion on a vaginal secretion saline wet mount, "swimming" with the flagella in a jerking or tumbling action. The sensitivity of detecting trichomonads on saline wet mount is estimated at 62% with a specificity of 97% and a positive predictive value of 75%. Culture is very sensitive (95%) and specific (greater than 95%) but delays diagnosis and is not routinely performed.

Allergic Vaginitis

Vaginitis resulting from allergy or irritants may be characterized by pruritus, discharge, and dyspareunia. The diagnosis often relies on exclusion. Although vaginal discharge may be increased, the secretions, when examined microscopically, do not harbor candidal organisms, trichomonads, or clue cells.

Atrophic Vaginitis

Vaginitis associated with atrophy of the vaginal walls produces pruritus, discharge, dryness, and dyspareunia. Physical examination reveals thinning of the vaginal walls with a characteristic shiny-smooth appearance. Introduction of the speculum into the vaginal introitus may cause bleeding. Microscopic examination reveals no candidal organisms, trichomonads, or clue cells.

Initiating Drug Therapy

When considering pharmacotherapy for vaginitis, the practitioner explores lifestyle choices that may predispose the patient to infection or inflammation. Questions to ask regard the use of douches or other feminine hygiene products, sexual practices and partners, the possible relationship between sexual activity and appearance of symptoms, and recent antibiotic or oral contraceptive use. The practitioner should perform a thorough assessment to identify other possible irritants or complaints.

Before choosing a plan of therapy, the practitioner and patient also need to consider the issue of recurrent infection. In the case of recurrent VVC (four or more symptomatic episodes annually), the practitioner should be alert to the possibility of diabetes, and the need for screening should be discussed. In the case of recurrent trichomonal infection, sex partners should be examined and treated if they are found to be transmitting the organisms. It also is not uncommon for BV to recur.

Goals of Therapy

The primary goal of therapy in treating infectious vaginitis is eradication of the offending organism. The primary goals of therapy for allergic vaginitis include reducing inflammation and avoiding irritants. Addressing the hypoestrogenic state of postmenopausal women with hormone replacement therapy alleviates the symptoms of atrophic vaginitis. (Refer to Chapter 56 for a discussion of these treatment options.)

Another important goal of therapy is relief of symptoms. Vaginitis can cause considerable discomfort, both physically and emotionally. Women with vaginitis often experience embarrassment and even fear, particularly of the implications of a sexually transmitted disease. The frustration associated with recurrent infection may lead women to repeated attempts to self-treat, which delays proper evaluation by their primary care provider. For more information on self-treatment, see Box 58.3.

BOX 58.3 Self-Diagnosis and Self-Treatment of Vaginitis

Studies assessing the accuracy of self-diagnosis of vaginal symptoms found the incidence of misdiagnosis to be high (Ferris et al., 1996; Nyirjesy et al., 1997). In both studies, women were self-treating symptoms that they attributed to vulvovaginal candidiasis with OTC antifungals (Ferris et al., 1996; Nyirjesy et al., 1997) and other OTC alternative medicines (Nyirjesy et al., 1997).

Although misuse of these pharmaceuticals rarely causes adverse reactions, a delay in diagnosis of infections such as pelvic inflammatory disease, BV, or urinary tract infections could have significant consequences. Furthermore, repeated use of these medications unsuccessfully by women before their visit to the provider can make accurate assessment of the symptoms and physical findings difficult.

In the treatment of BV, additional goals of therapy include reduction of the risk of complications following gynecological procedures (e.g., abortion and hysterectomy) and reduction in the risk of acquiring other sexually transmitted infections. Adverse pregnancy outcomes have been associated with BV and trichomoniasis. The treatment of asymptomatic women with BV is not recommended, but some specialists recommend that women at high risk for preterm delivery be screened and treated for BV during the first prenatal visit.

Topical Azole Antifungals

Topical vaginal preparations for treating VVC include the following azoles: clotrimazole, butoconazole, tioconazole, miconazole, and terconazole. Treatment duration with these agents varies from 1 to 3 to 7 days. Response to treatment varies according to the duration of therapy. Types of topical preparations include creams, ointments, tablets, and suppositories. Oral fluconazole is also available for treatment in a one-time dose.

Time Frame for Response

The cure rates for topically applied azoles have long been established at between 80% and 90%. It can take up to 3 days to see the effect of the medications. These preparations are considered to be more effective than the antifungal nystatin (Mycostatin). Table 58.1 lists the azole drugs currently available by prescription or without a prescription. In the case of VVC, only women who were previously diagnosed with this form of vaginitis should choose to self-treat with an over-the-counter (OTC) medication. Practitioners should advise women whose symptoms persist or recur within 2 months of self-treatment to seek medical care. In general, the only contraindication to the topical antifungals is hypersensitivity to the azole or components of the cream or gel.

TABLE 58.1 Overview of Antifungal Agents

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
OTC Preparations			
butoconazole 2% cream (Femstat) 1 applicatorful intravag. qhs for 3 d	Vaginal irritation, skin rash, hives	Allergy	Oil based; might weaken latex condoms and diaphragms
butoconazole 2% cream (sustained release) 1 applicatorful qhs for 3 d	Refer to product labeling for more information		
clotrimazole 1% cream (Gyne-Lotrimin, Mycelex-G) 1 applicatorful intravag. qhs for 7–14 d	Same as above	Same as above	Same as above
clotrimazole 100-mg vaginal tablets (Gyne-Lotrimin, Mycelex-G) 1 tab intravag. qhs for 7 d or 2 tabs intravag. qhs for 3 d	Same as above	Same as above	Same as above
miconazole 2% cream (Monistat 7) 1 applicatorful intravag. qhs for 7 d	Same as above	Same as above	Same as above
miconazole 200-mg suppository (Monistat 3) 1 suppository intravag. qhs for 3 d	Same as above	Same as above	Same as above
miconazole 100-mg suppository (Monistat 7) 1 suppository intravag. qhs for 7 d	Same as above	Same as above	Same as above
tioconazole 6.5% ointment (Vagistat) 1 applicatorful intravag. qhs, single dose	Same as above	Same as above	Same as above
Prescription Preparations			
terconazole 0.4% cream (Terazol 7) 1 applicatorful intravag. qhs for 7 d	Same as above	Same as above	Same as above
terconazole 0.8% cream (Terazol 3) 1 applicatorful intravag. qhs for 3 d	Same as above	Same as above	Same as above
terconazole 80-mg suppositories (Terazol 3) 1 suppository intravag. qhs for 3 d	Same as above	Same as above	Same as above
fluconazole 150-mg tablet (Diflucan) 1 tablet orally, single dose	Headache, abdominal pain, nausea Rare: hepatic injury	Same as above	May interact with oral hypoglycemics, anticoagulants, cyclosporine, rifampin, theophylline, calcium channel antagonists, cisapride, astemizole, phenytoin, protease inhibitors, tacrolimus, terfenadine, trimetrexate

CDC recommendations, 2010.

Adverse Events

Topical azoles seldom cause systemic adverse events, although they may cause local irritation. Unfortunately, these effects may be difficult to distinguish from the conditions for which they are being used. Less common events may include penile irritation of the sex partner, abdominal cramps, or headache.

Interactions

Since these preparations are oil based, they may weaken latex condoms and diaphragms.

Oral Azole Antifungal Agents

Fluconazole, the only oral azole to be recommended by the Centers for Disease Control and Prevention (CDC) for treating uncomplicated VVC, is available by prescription in a single 150-mg dose. It is as effective as topical azoles. The findings of a study evaluating the acceptance of single-dose oral fluconazole by patients and physicians showed that most participants believed the drug to be effective in relieving or alleviating the symptoms of VVC. Oral fluconazole maintenance therapy for recurrent VVC should be extended for 6 months, but caution should be used with long-term ketoconazole therapy since hepatotoxicity may occur.

Contraindications

Contraindications to oral azole antifungals include known hypersensitivity to these azoles and the concomitant use of drugs with which they interact.

Time Frame for Response

Because patients treated with oral antifungals may not obtain relief of symptoms for 2 or 3 days, they may need to use an OTC antifungal cream for a few days. Failure to respond necessitates re-evaluation.

Adverse Events

The most commonly reported adverse events noted in patients treated with oral fluconazole are headache, nausea, and abdominal pain. Ketoconazole and itraconazole can cause GI disorders, headache, and pruritus. Hepatotoxicity may also occur, especially with ketoconazole. Liver enzyme levels may need to be monitored, especially with long-term use. Adverse effects tend to be dose related. Interactions may occur because oral azoles are cytochrome P-450 inhibitors.

Antibacterials/Antibiotics

Metronidazole (Flagyl) may be used orally or intravaginally for treating BV. Oral metronidazole 500 mg twice daily for 7 days is the standard treatment for BV, and only the oral form is effective in treating trichomonal infection. Tinidazole 2 g in a single dose is also used (see Table 58.2 for specific dosages). Topical clindamycin cream 2% (Cleocin) should be used in patients who are allergic to metronidazole. Clindamycin 300 mg twice daily may also be used orally for a 7-day course. It is contraindicated in patients with hypersensitivity to it or to other preparations containing lincomycin. Cleocin ovules intravaginally are also effective if inserted at bedtime for three nights.

TABLE 58.2 CDC* Recommendations for Treating Bacterial Vaginosis

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Recommended Regimens			
metronidazole 500-mg tablets (Flagyl) 1 tab PO bid for 7 d	Metallic taste, headache, GI distress	Allergy (no longer contraindicated in pregnancy)	Avoid alcohol during therapy and for 24 h after stopping (will cause nausea and vomiting) May potentiate the anticoagulant effects of warfarin and other anticoagulants
clindamycin 2% cream (Cleocin) 1 applicatorful intravag. qhs for 7 d Clindamycin ovules 100 g intravaginally once qhs for 3 d	Vaginal irritation, skin rash, hives	Allergy	Oil based; may weaken latex condoms and diaphragms Refer to product labeling for more information
metronidazole gel 0.75%. (MetroGel) 1 applicatorful intravag. bid for 5 d	Vaginal irritation, skin rash, metallic taste, GI distress	Same as above	Although blood levels are lower than with the use of oral metronidazole, alcohol still should be avoided
clindamycin 300-mg tablets (Cleocin) 1 tablet orally bid for 7 d	GI distress	Same as above	None

*CDC recommendations as of 2010.

Contraindications

Metronidazole is no longer thought to be teratogenic, and therefore, it is not contraindicated in the first trimester of pregnancy. It is contraindicated, however, in patients with a known hypersensitivity to it or other nitroimidazoles.

Adverse Events

Metallic taste, headache, and GI distress are common side effects of metronidazole. To avoid the disulfiram-like effect of nausea and vomiting, patients must not consume alcohol during treatment and for 24 hours after treatment stops.

Interactions

Metronidazole may potentiate the anticoagulant effect of warfarin (Coumadin) and other oral anticoagulants. Although some animal studies have linked metronidazole to cancer, no current evidence indicates that the drug has a similar effect on humans.

Estrogens

Treatment of atrophic vaginitis consists of systemic estrogen replacement or topical estrogen creams administered externally or intravaginally. Refer to Chapter 56 for a complete discussion of these therapies.

Anti-Inflammatories

Mild topical steroid preparations can be used on a short-term or episodic basis. Careful monitoring of the patient's response is advised.

Selecting the Most Appropriate Agent

First-Line Therapy: Candidiasis

In an attempt to guide therapeutic options, the CDC classifies VVC as either uncomplicated or complicated (see Box 58.2).

OTC topical antifungals are typical first-line therapy of uncomplicated VVC and can be used before the patient seeks professional treatment. Women experiencing typical symptoms such as pruritus and vaginal discharge can obtain relief of symptoms promptly without the expense of a visit to the practitioner. Appropriate therapy consists of 1 to 7 days of treatment with the topical antifungals. It is recommended that self-treatment with OTC antifungals be reserved for women who have been previously diagnosed with VVC and who have not experienced a recurrence within 2 months.

Single-dose oral antifungals are an alternative first-line therapy in uncomplicated VVC, especially because the ease of administration may ensure therapeutic adherence. Fluconazole is the oral azole of choice. The patient's sex partners need not be treated because candidiasis is not sexually transmitted. However, consideration may be given to treating male sex partners of women with recurrent infection. Male sex partners who have symptoms of balanitis may benefit from the use of topical antifungals. See Figure 58.1 and Table 58.3 for an overview of VVC treatment.

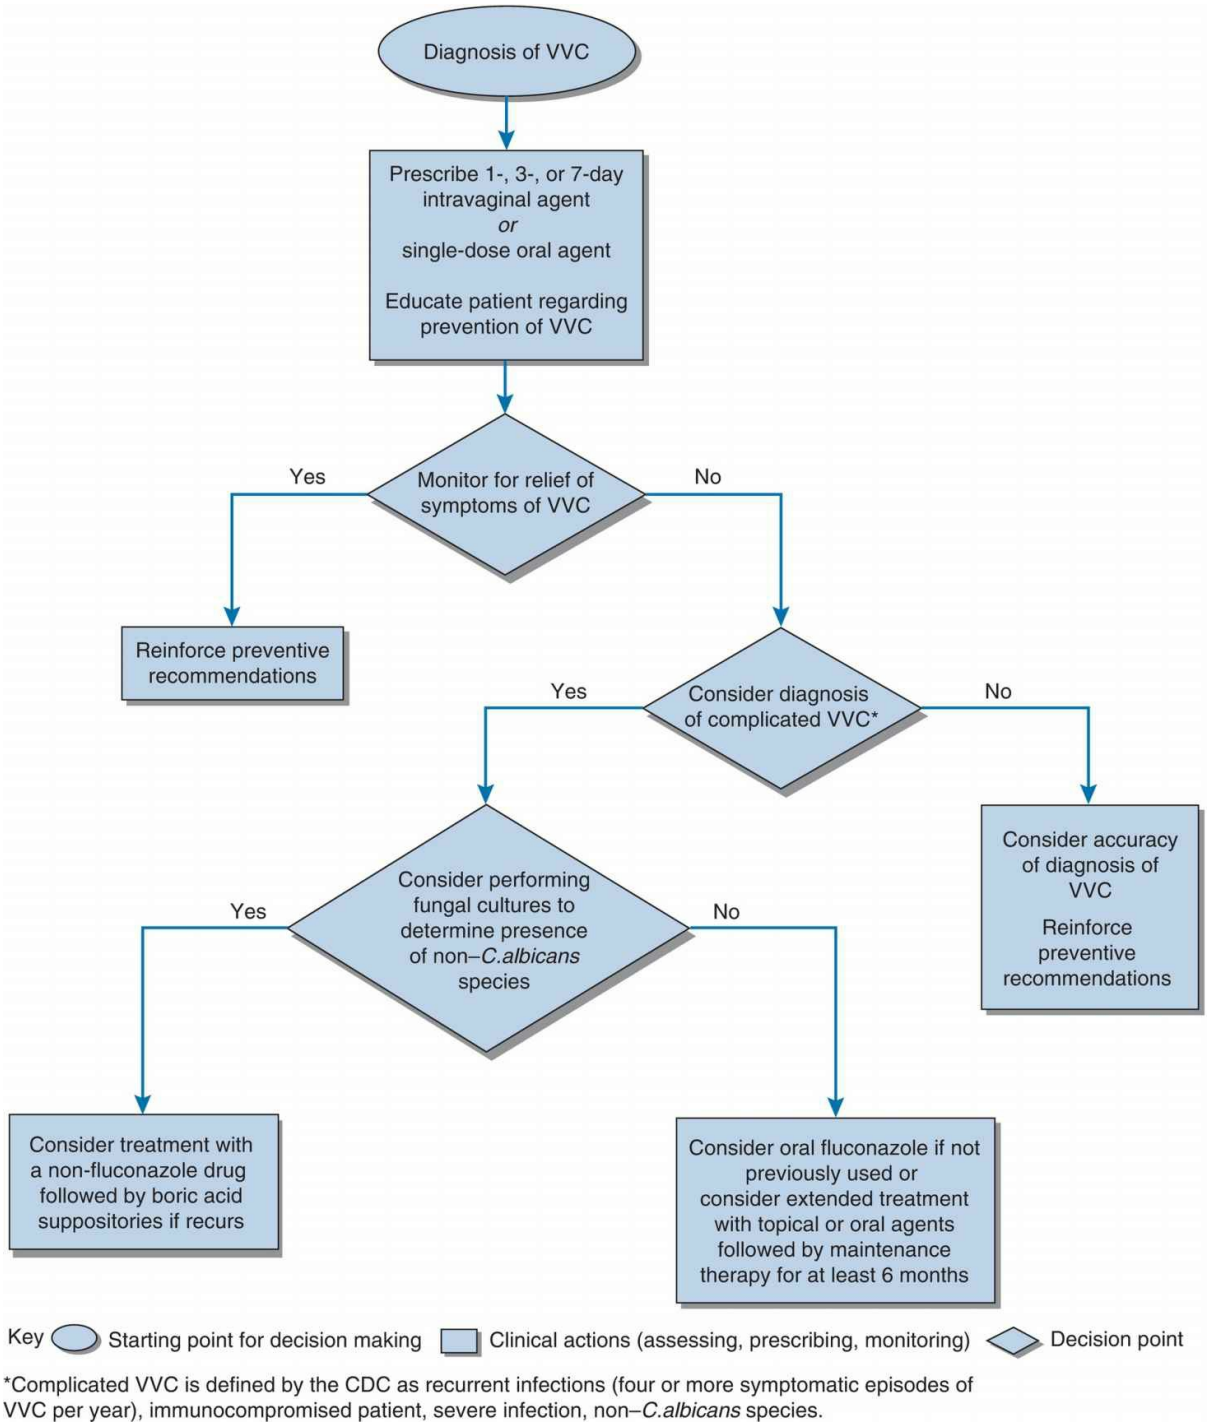

FIGURE 58.1 Treatment algorithm for vaginitis known as vulvovaginal candidiasis (VVC).

TABLE 58.3 Recommended Order of Treatment for Vulvovaginal Candidiasis

Order	Agents	Comments
First line	OTC topical antifungals *or* Single-dose oral antifungal	Patients may self-treat before visit with practitioner
Second line	Single-dose oral antifungal *or* Extend course of therapy of topical or oral antifungal *or* Maintenance therapy with an oral or topical antifungal *or* Boric acid suppositories	If not used as first line Vaginal cultures to determine presence of non-*albicans* candidiasis

Second-Line Therapy: Candidiasis

If symptoms persist beyond the recommended course of therapy with first-line agents, second-line therapy involves assessing for possible recurrent VVC or infection with non-*albicans Candida*, such as *C. glabrata*. Vaginal cultures should be obtained to confirm the diagnosis and identify the species of *Candida* involved.

If an oral antifungal was not the first-line therapy, the practitioner may opt to treat with oral fluconazole as second-line therapy or extend the course of topical or oral therapy. It has been suggested that 7- to 14-day treatment with topical agents or a 150-mg dose of oral fluconazole repeated 3 days later may achieve remission in patients with recurrent VVC. Maintenance regimens are recommended for patients with recurrent VVC and include clotrimazole (500-mg suppositories once weekly), ketoconazole (100-mg dose once daily), fluconazole (100- to 150-mg dose once weekly), or itraconazole (100-mg dose once monthly). These maintenance therapies should be continued for 6 months. Hepatotoxicity may occur in long-term treatment with ketoconazole, and these patients should be monitored accordingly.

Second-line therapy for patients with non-*albicans* VVC consists of 7- to 14-day treatment with a non-fluconazole azole drug followed by boric acid suppositories (600 mg in a gelatin capsule intravaginally once daily for 14 days), if the infection recurs. Topical flucytosine 4% and nystatin 100,000-unit vaginal suppositories are additional options in the treatment of non-*albicans* VVC. However, consultation with a specialist is recommended. Women who are immunocompromised also benefit from the prolonged therapy (7 to 14 days) with either topical or oral agents.

In complicated cases, a second dose of oral fluconazole 150 mg given at day 3 yields an 80% cure rate versus 67% with a single dose. In women who have more than four infections a year, a 7- to 14-day course of oral fluconazole may be needed to suppress the *Candida*. Suppression therapy with fluconazole 150 mg weekly for 6 months controls symptomatic episodes in 90% of women, and one half have prolonged symptom relief. A treatment failure may indicate infection with *C. glabrata*, which does not respond well to azoles. Boric acid 600-mg capsules given intravaginally for 14 days may be effective.

First-Line Therapy: Bacterial Vaginosis

Oral metronidazole (500 mg twice daily) 7-day therapy has long been considered standard first-line treatment for BV. However, the CDC (2010) also recommends topical clindamycin cream 2% (intravaginally for 7 days) or metronidazole gel 0.75% (intravaginally for 5 days) as acceptable first-line therapy. Alternative regimens for first-line therapy include clindamycin 300 mg twice daily orally for a 7-day course or clindamycin ovules 100 g intravaginally at bedtime for 3 days. Once-daily dosing with metronidazole 750-mg extended-release tablets has been approved by the U.S. Food and Drug Administration for the treatment of BV, but data are not available regarding the efficacy of this regimen (CDC, 2006). Treatment of sex partners is not recommended because clinical trials have not shown a relationship between treatment of partners and recurrence of BV. See Figure 58.2 and Table 58.4 for an overview of treatment.

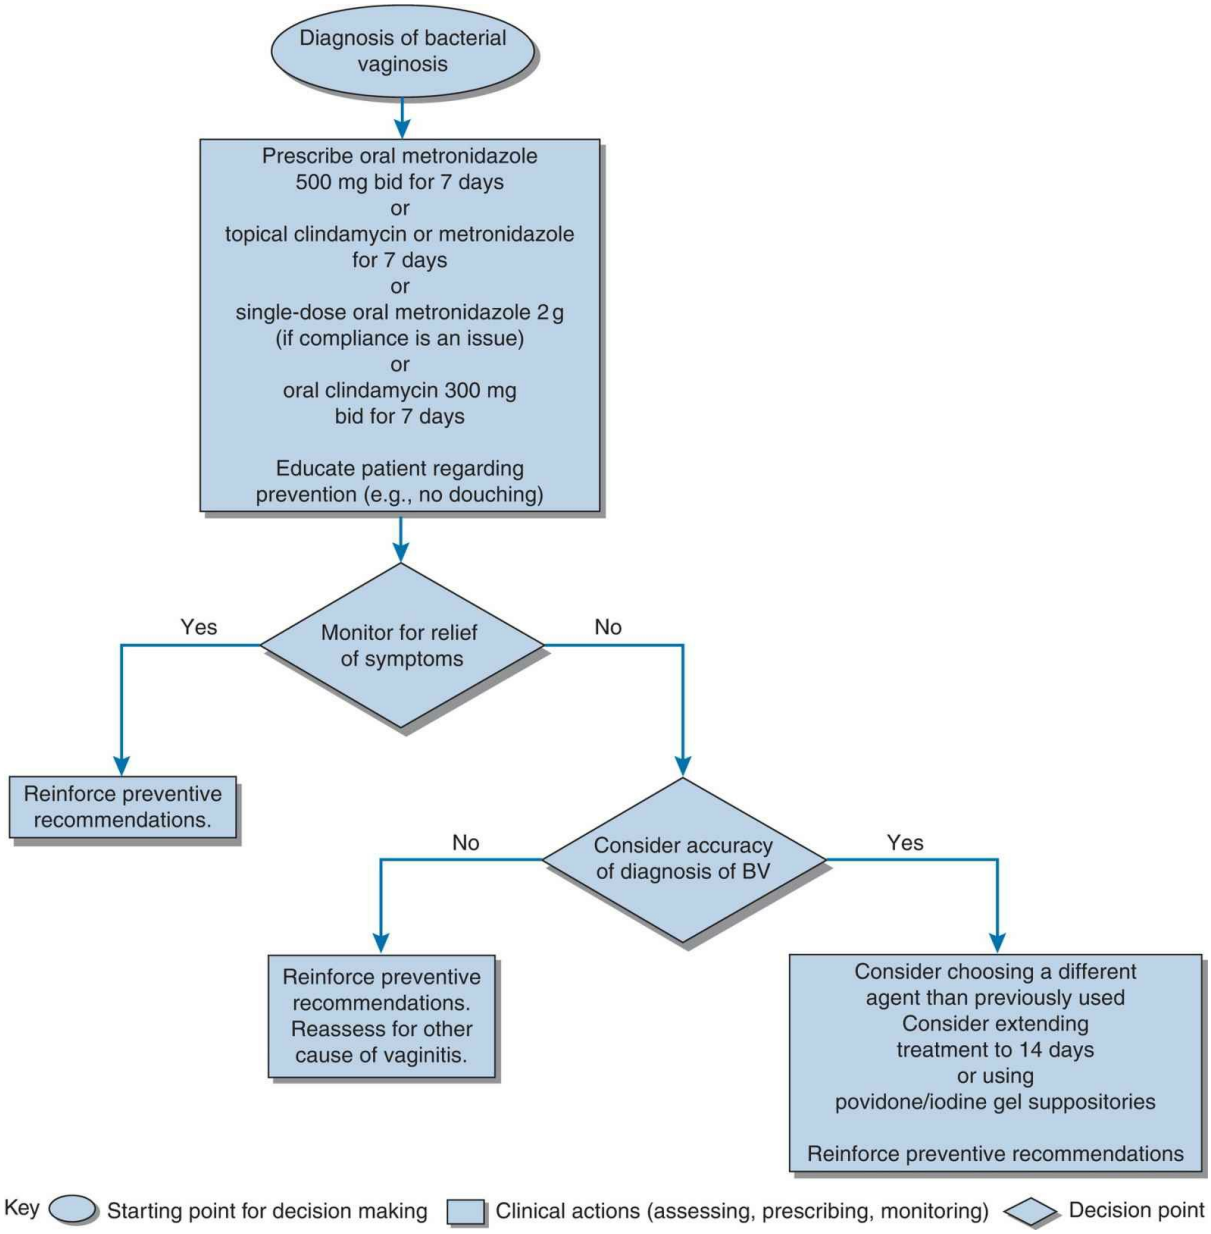

FIGURE 58.2 Treatment algorithm for bacterial vaginosis (BV).

TABLE 58.4 Recommended Order of Treatment for Bacterial Vaginosis

Order	Agents	Comments
First line	Oral metronidazole *or* clindamycin cream 2% *or* metronidazole gel 0.75% *or* clindamycin orally *or* clindamycin ovules	Traditionally used as first line
Second line	Extend duration of above agents *or* povidone–iodine gel suppositories *or* choose different agent	*May* be effective

Second-Line Therapy: Bacterial Vaginosis

Treatment reduces symptoms, yet recurrences are common, with 23% at 1 month and 58% at 12 months. Recurrent BV should be treated. One randomized trial for persistent BV indicated that metronidazole gel 0.75% twice per week for 6 months after completion of a recommended regimen was effective in maintaining a clinical cure for 6 months (Sobel et al., 2006). Clinical trials indicate that a woman's response to therapy and the likelihood of relapse or recurrence are not affected by treatment of her sex partner(s). Therefore, routine treatment of sex partners is not recommended.

First-Line Therapy: Trichomoniasis

Only one treatment regimen is considered to be clinically efficacious for trichomoniasis: metronidazole or tinidazole given as a single 2-g dose. An alternative regimen is metronidazole 500 mg twice daily for 7 days. Treatment of male sex partners (who are usually asymptomatic) is recommended, and patients and their partners should avoid intercourse until they have completed therapy and are symptom free. Patients should be cautioned to avoid alcohol, as previously described. See Figure 58.3 and Table 58.5 for an overview of treatment.

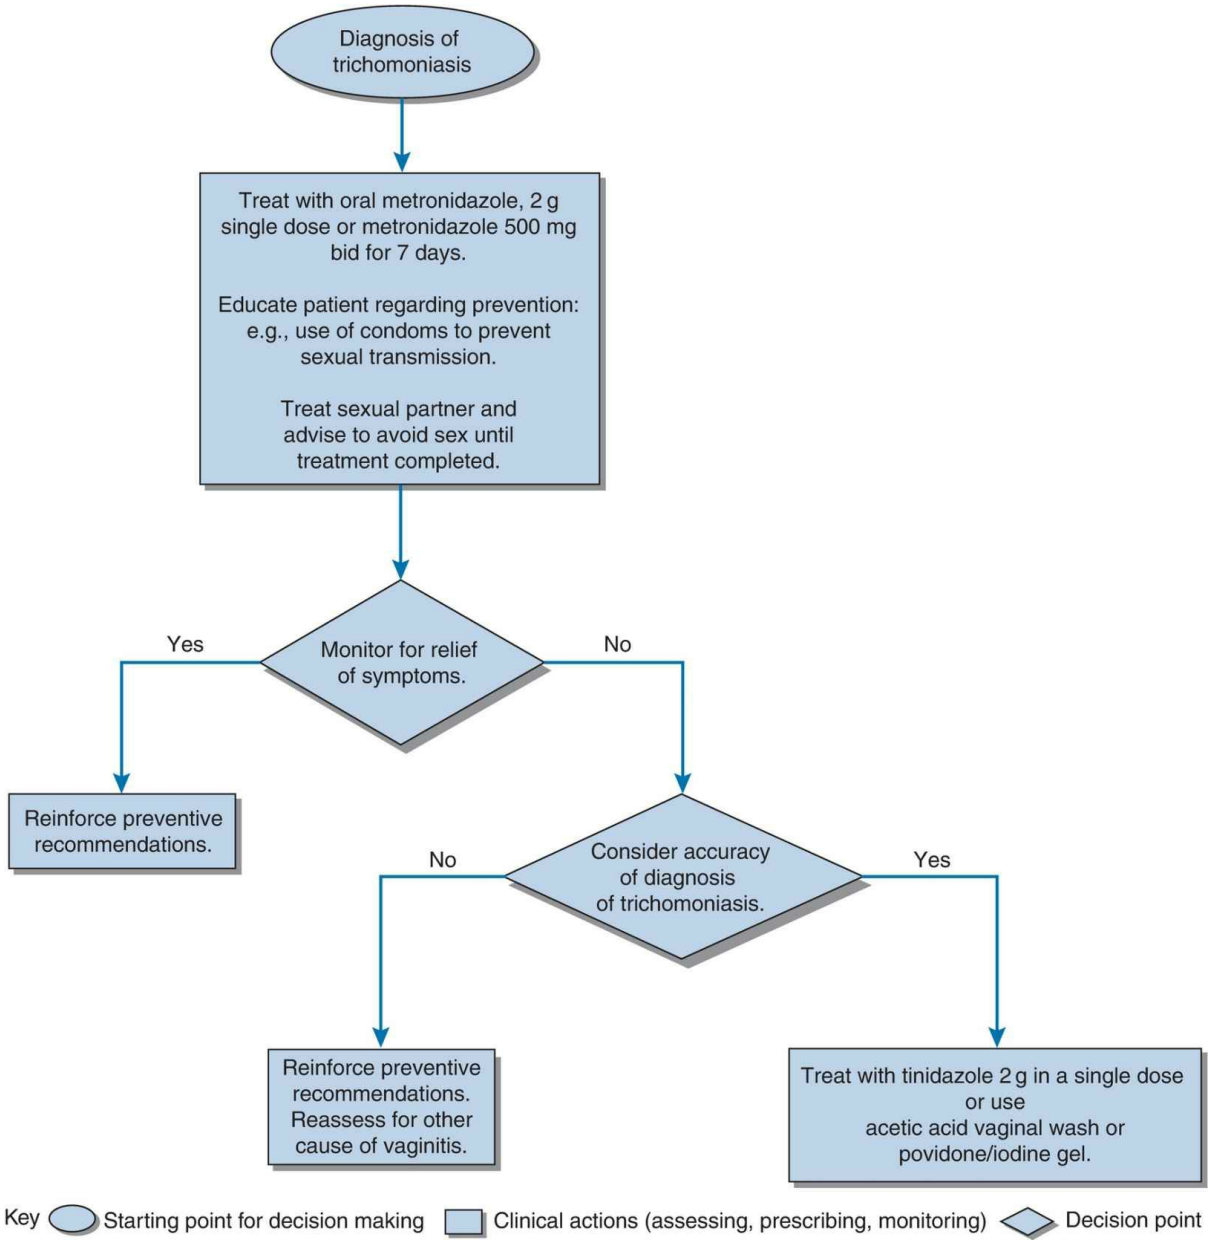

FIGURE 58.3 Treatment algorithm for vaginitis resulting from *Trichomonas* organisms.

TABLE 58.5 Recommended Order of Treatment for Trichomonal Infection

Order	Agents	Comments
First line	Metronidazole Single dose of 2 g	
Second line	Extend the course of metronidazole *or* Acetic acid vaginal wash or povidone–iodine solutions	*May* be effective

Second-Line Therapy: Trichomoniasis

Some strains of *T. vaginalis* can have diminished susceptibility to metronidazole but respond to tinidazole or higher doses of metronidazole. Tinidazole has a longer serum half-life and reaches higher levels in genitourinary tissues than metronidazole. If treatment fails and reinfection is excluded, the patient can be treated with metronidazole 500 mg orally twice daily for 7 days. For patients failing either of these regimens, clinicians should consider treatment with tinidazole or metronidazole at 2 g orally for 5 days.

Special Population Considerations

Pediatric

Before menarche, when estrogen levels are low, the vaginal epithelium is thin and the vaginal pH tends to be between 6.0 and 7.0. These conditions create a vaginal environment that is more susceptible to invading anaerobic bacteria if the child is exposed. Infections may be sexually transmitted or caused by contamination with fecal flora, and the possibility of sexual abuse must be considered. Poor hygiene and the use of vaginal irritants such as bubble baths and other products may also contribute to infections in the prepubertal child. Because of the high vaginal pH of the prepubertal child, candidiasis usually does not occur.

Postmenopausal Women

The decline in estrogen levels that occurs in the postmenopausal woman produces conditions similar to those in prepubertal children, and these conditions predispose the woman to infection and atrophy. As noted previously, the practitioner needs to be aware that atrophic vaginitis is a common cause of vaginal symptoms, and accurate diagnosis is essential.

Pregnant Women

Because vaginitis may occur during pregnancy, therapeutic goals include relieving symptoms and avoiding complications. Depending on the cause of vaginitis, therapy aims to achieve one or both of these goals. Refer to Box 58.4 for the CDC recommendations for the treatment of vaginitis in pregnancy.

BOX 58.4 CDC Recommendations for Treatment of Vaginitis in Pregnancy

Vulvovaginal Candidiasis

Topical azole therapies, *only*, for 7 days (most effective: butoconazole, clotrimazole, miconazole, terconazole)

Bacterial Vaginosis

Recommended: metronidazole 250 mg PO tid for 7 days *or* clindamycin 300 mg PO bid for 7 days

Trichomoniasis

Metronidazole 2 g orally single dose

Data are current for 2010.

Physiologic conditions of pregnancy increase the risk of VVC. For treatment of VVC during pregnancy, the CDC recommends that only topical azoles be used for a 7-day course of therapy. The most effective agents are butoconazole, clotrimazole, miconazole, and terconazole.

Because adverse pregnancy outcomes have been reported in patients with BV, it is recommended that women who are at high risk (i.e., those who have previously delivered a premature infant) and who are asymptomatic should be treated. Symptomatic BV in women at low risk (no history of premature delivery) should be treated to relieve symptoms. Oral metronidazole and clindamycin may be used in both groups (see Table 58.3).

The use of topical agents is not recommended because of reports of adverse events, such as premature birth. Although the use of oral metronidazole in pregnancy had long been controversial, multiple studies have found no relationship between birth defects and the use of metronidazole during pregnancy. Follow-up of high-risk pregnant women who have been treated for BV is recommended 1 month after completion of treatment to ensure a successful response.

Trichomonas infections have been associated with preterm delivery. Symptomatic infections during pregnancy can be treated with metronidazole. Asymptomatic pregnant women who have incidentally noted trichomonads should not be treated. The severity of a woman's symptoms needs to be balanced against the risk that metronidazole therapy may increase preterm delivery.

Monitoring Patient Response

Diagnosis and management of vaginitis can be frustrating for both the patient and the practitioner, especially in patients with chronic symptoms and recurrent infections. Symptoms may recur or persist despite adherence to prescribed therapy. The practitioner should consult an expert if the patient fails to respond to current treatment recommendations.

The use of fungal cultures to assess response to therapy and to identify the offending candidal species is beneficial in assessing and treating patients with recurrent VVC. Fungal cultures play a role in detecting non-*albicans* candidal infections that may require second-line therapy.

Practitioners need to individualize the plan of care with each patient. They also need to maintain current knowledge of research regarding alternative therapies and to inform patients of findings. In many situations, yogurt and similar products may cause no harm and may provide patients with a perception of control over a frustrating condition.

Because of the increased risk of postoperative infectious complications associated with BV, some specialists suggest that before performing surgical abortion or hysterectomy, providers should screen for and treat women with BV in addition to providing routine prophylaxis. However, more information is needed before recommending treatment of asymptomatic BV before other invasive procedures. Routine treatment of sex partners is not recommended because studies have shown that treatment of partners does not reduce the incidence of recurrence or relapse.

Patient Education

Drug Information

Metronidazole and tinidazole can cause nausea and vomiting if alcohol is ingested during therapy and up to 24 to 72 hours after therapy stops. Patients should be instructed to adhere to the directions included with the product. In patients taking oral azole and oral antibiotic medications, the practitioner should reinforce the importance of following directions carefully and completing the full course of antibiotic therapy even if symptoms subside earlier.

Lifestyle Changes

The patient should avoid tight-fitting clothing, should wear undergarments that allow adequate vaginal ventilation, and should avoid douches and other feminine hygiene products that may alter the normal vaginal pH. The possibility that sexual activity may be associated with the onset of symptoms should be discussed, and the patient should be instructed to monitor these patterns. The patient should use condoms to protect against sexually transmitted disease. Because the use of antibiotics and oral contraceptives may be factors that predispose patients to vaginitis, other treatment options should be explored.

Receiving orogenital sex and using any form of contraceptive, having a high body mass index, having impaired glucose tolerance, consuming excessive sweets, and having high stress levels are some of the risk factors for recurrent vulvovaginal candidiasis.

Complementary and Alternative Medicine

Probiotics are supplements that contain live bacteria. They promote healthy normal flora. Ingesting yogurt or inserting in intravaginally (to promote vaginal recolonization) may be effective in preventing VVC. The true benefit of colonization with lactobacilli as protection against VVC or BV, however, has not been established.

Case Study*

R.S. is a 32-year-old woman who seeks treatment for a vaginal discharge that she has had for the past month. She is sexually active and has had the same partner for the past 6 months. She reports noticing an odor, especially after sexual intercourse. Her history reveals that she has been using a commercial douche on a biweekly basis during the past year for hygienic purposes in an attempt to prevent vaginal infections. She denies any other associated symptoms. The physical examination reveals a white vaginal discharge. Microscopic examination of the vaginal discharge shows clue cells, and the pH is 5.5.

Diagnosis: Bacterial Vaginosis

1. List specific goals of treatment for this patient.
2. What drug therapy would you prescribe? Why?
3. What are the parameters for monitoring the success of the therapy?
4. Discuss specific patient education based on the prescribed therapy.
5. List one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What would be the choice for second-line therapy?
7. What OTC or alternative medications would be appropriate for this patient?
8. What dietary or lifestyle changes should be recommended?
9. Describe one or two drug–drug or drug–food interaction for the selected agent.* Answers can be found online.

UNIT 15
Integrative Approach to Patient Care

59 The Economics of Pharmacotherapeutics

Samir K. Mistry ■ Briana L. Santaniello ■ Joshua J. Spooner

As little as 100 years ago, health insurance in the United States was scarce. Although President George Washington signed a law establishing prepaid health care in 1798, health insurance plans were slow to develop. Traditionally, patients in the United States paid health care providers and hospitals directly for their services on a fee-for-service basis. This system worked well for patients in times of good health; however, a serious injury or illness could place the patient in severe financial risk.

The goal of this chapter is to provide a fundamental understanding of the principles used by managed care organizations (MCOs) and pharmacy benefit managers (PBMs) to manage pharmacy costs while providing access to appropriate patient care. This chapter provides a brief review of pharmacoeconomic principles, educates the reader about the strategies used by MCOs and PBMs to manage health care expenditures, explains how these strategies are developed and implemented, and reviews how MCOs evaluate the performance of contracted providers. Through a better understanding of the practices, benefits, and challenges of MCOs and PBMs, practitioners can better prescribe appropriate and cost-effective medications for their patients.

Origins of Managed Care

Modern health insurance's origins can be traced to 1929, when the Baylor University Hospital in Dallas, Texas, began to offer 1,500 school teachers up to 21 days of hospital care a year for $6 per person (Starr, 1982). Other groups also entered into agreement to prepay for Baylor's services. Shortly thereafter, several other Dallas-area hospitals followed suit and offered similar plans. Other early health insurance plans included the Kaiser Health Plans (early to mid-1930s) and the Group Health Association in Washington, DC (1937). As the country slid into the depression and hospital revenues plummeted by 75% per patient, hospitals began to rely on insurance payments for a greater proportion of their operating budget (Starr, 1982).

Most health plans offered indemnity insurance (also known as *fee-for-service insurance*), in which patients paid for health care expenses out of their own pockets and then requested reimbursement from the insurer (often receiving reimbursement for 80% of incurred expenses). However, indemnity insurance did little to control health care expenditures because physicians and hospitals received payments proportional to the volume of services they provided. Concerned with the rising cost of providing health care, insurance providers sought ways to slow the increases in health care expenditures. After extensive lobbying and negotiations in Congress, President Richard Nixon signed the federal Health Maintenance Organization (HMO) Act into law in 1973. This act encouraged the growth of managed care by providing grants and loans to develop HMOs, overturned restrictive state laws regulating health providers, defined a basic package of services that HMOs were required to offer, and established procedures by which HMOs could become federally qualified.

Because HMOs could deliver cost-effective health care benefits while maintaining a reasonable quality of care, they were viewed as an attractive health insurance alternative for employers. The rate of enrollment in HMOs grew rapidly during the 1980s and 1990s, growing to rival preferred provider organizations (PPOs) as the leading source of employer-sponsored health insurance in the United States in the late 1990s. The federal government also encouraged the use of HMOs to manage the health care costs of Medicare-eligible beneficiaries; HMOs were reimbursed on a prospective basis by the government. The states soon followed suit, offering HMO-based options to Medicaid recipients. Of late, there has been a significant decline in employer-sponsored HMO enrollment, with a shift in favor of other health insurance plan types (Kaiser Family Foundation, 2014).

Overview of Pharmacoeconomics

When MCOs make decisions related to what medications are covered and placed on formularies, those decisions could impact thousands of members. Applying economic principles to analyze the impact of a medication on the MCO's overall health care cost and disease management of the patient population is essential to appropriate decision making. *Pharmacoeconomic* research assesses the "overall value" of medications in the treatment or prevention of the disease(s) they are intended to treat (Navarro et al., 2009). Because they evaluate both cost and human data, studies on pharmacoeconomics are important tools for MCOs in making drug therapy decisions. To provide an overview, some different pharmacoeconomic study designs are described in the following sections.

Cost–Benefit Analysis

A cost–benefit analysis is used to determine the overall cost of a particular intervention or protocol by evaluating all pertinent data and converting the data to a monetary end point (e.g., U.S. dollars or EU Euros). Most often, this type of analysis is used to compare two different programs that also have different units for end points because the data can then be converted to one common unit (usually the dollar). The limitation to this analysis involves the evaluation of "intangible" end points or data that cannot be equated to a monetary value.

Cost Minimization Analysis

A cost minimization analysis evaluates the cost of two or more interventions with equivalent components or end points and determines which intervention is least costly. The most appropriate use for such analyses involves situations in which every aspect of compared interventions is identical except the cost of the intervention. Because efficacy and safety are identical, the cost of each intervention becomes the differential outcome. The outcomes of these analyses are also expressed in a monetary end point.

Cost-Effectiveness Analysis

A cost-effectiveness analysis may help determine the best program or intervention, where the desired outcome is a combination of both a monetary end point and a nonmonetary end point relative to an improvement in health (e.g., life expectancy, blood glucose measurements). An example of this would be dollars per life-year saved.

Cost–Utility Analysis

A cost–utility analysis, which is closely related to a cost-effectiveness analysis, measures data in terms of quality of life. Quality of life is an assessment of a patient's well-being and social functioning, which can assist practitioners in determining a patient's response to drug therapy (Hunter et al., 2015). Along with traditional clinical results (e.g., laboratory values, blood pressure, serum glucose level), a cost–utility analysis provides a more complete evaluation of a patient's progress and compares the cost of an intervention or program in terms of more intangible end points, rather than dollars. These analyses predominantly use quality-adjusted life-years (QALYs) gained as a major outcome. The QALY is symbolic of healthy years of life and is the unit of measurement that encompasses outcomes (e.g., morbidity and mortality) in preferential sequence. This method has been very successful in evaluating various procedures compared with drug therapy in which a patient's quality of life is the chosen outcome (Hunter et al., 2015).

Pharmacoeconomic research compares cost and consequence with respect to pharmaceutical products and their impact on individuals, the health care system, and society. Such parameters are seldom analyzed in most studies.

Formularies and Pharmacy and Therapeutics Committees

An evaluation of American health expenditures identified $2.9 trillion in total health care spending in 2013 (Centers for Medicare and Medicaid Services [CMS], 2014a), which accounted for 17% of the national gross domestic product (GDP). Of this $2.9 trillion in health expenditures, $271.1 billion (9.3%) was spent on prescription drugs. Although this represents a minor portion of overall health care expenditures, it is a target for intervention by MCOs due to large annual increases in prescription drug spending. Prescription drug spending in the United States increased 13.1% in 2014, driven by demand for newer treatments for cancer, multiple sclerosis, and hepatitis C (IMS Health, 2015).

Formularies

One of the most effective methods by which an MCO can improve the quality of care provided to patients and mitigate the increasing costs of providing a prescription benefit is by implementing a formulary. Also known as a *preferred drug list*, a medication formulary is simply a list of preferred medications approved for use within an HMO, third-party payer, or PBM (Navarro et al., 2009). Formularies are usually organized by therapeutic area and medication class, with the formulary status and reimbursement category listed for each medication.

Formularies encourage the use of medications considered to be safer, more clinically effective, or more cost-effective than other medications within the same therapeutic category. When an MCO wants to limit the use of a drug for a specific reason (safety, efficacy, or cost), the formulary allows the flexibility to implement restrictions or limitations on utilization. Examples of such restrictions include prior authorizations, step therapies, quantity limitations, and tiered copayments.

Evolution of Formularies

The use of formularies can be traced back to 1925, when the physicians and pharmacists of Syracuse University Hospital collaborated to establish a formulary system to monitor drug use and reduce therapeutic duplication (the unnecessary use of two or more medications to treat the same condition) in its drug therapy program (Sonnedecker, 1976). By the 1960s, formularies were being implemented in hospitals throughout the country with the guidance of the *American Hospital Formulary Service*, a prominent set of formulary development materials published by the American Society of Hospital Pharmacists. Following the HMO Act of 1973, many HMOs adopted the hospital formulary to monitor medication use. Formularies were initially used by managed care as an inventory control mechanism for staff model HMOs (Navarro et al., 2009), but they have evolved into effective tools for monitoring and regulating medication utilization for all types of MCOs.

Structure of Formularies

Although formats may differ among plans, a formulary usually contains the same fundamental information. Formularies usually begin with a basic plan summary and detailed key points of reference and then proceed to the list of drugs. The drugs are most often categorized within their respective therapeutic classes with the therapeutic classes listed in alphabetic order. The order of the drugs within each therapeutic class can vary but are often listed alphabetically, either in complete alphabetical order (generic and brand drugs intermixed) or generic drugs listed before brand-name drugs. Additional information usually detailed for each drug includes the brand/generic status; the drug's relative cost, which is most often symbolized by relative $ signs; copay tier; and any potential utilization management programs. An example of a formulary is shown in Table 59.1. A "formulary

medication" is a drug that is covered (reimbursed) by the health plan; formulary medications can be subdivided into different groups such as preferred and nonpreferred agents. "Preferred" agents are drugs that the health plan would prefer the practitioner to prescribe, due to safety, efficacy, and/or relative cost. "Nonpreferred" drugs are not the preferred drugs of the health plan but will nonetheless be covered by the plan at a higher out-of-pocket cost to the patient. Most formularies have different tiered copays for preferred and nonpreferred drugs, in which preferred drugs have a lower-cost tiered copay than the nonpreferred drugs. "Nonformulary medications" are drugs that are excluded from the formulary; health plans generally do not publish nonformulary medications on their formularies. Prescribers must usually provide exception justification for a patient to receive reimbursement for nonformulary medications.

TABLE 59.1 Example of a Formulary

Drug Name	Brand/Generic	Relative Cost	Tier	Edits
Drug A	Generic	$	Tier 1	
Drug B	Generic	$	Tier 1	QL
Drug C	Brand	$$	Tier 2	QL, ST
Drug D	Brand	$$	Tier 2	
Drug E	Brand	$$$	Tier 3	ST
Drug F	Brand	$$$$	Tier 3	PA
Drug G (specialty injectable)	Brand	$$$$$	Tier 4	QL, ST

Key: PA, prior authorization; QL, quantity limits; ST, step therapy; Tier 1, generic; Tier 2, preferred brand drug; Tier 3, nonpreferred brand drug; Tier 4, specialty injectable.

Formularies can be grouped into three different categories: closed, open, and tiered formularies. Closed formularies limit clinicians to prescribing from a limited list of preferred agents (Edlin, 2015). Open formularies usually do not involve a preferred group of agents; instead, they allow the prescriber to select any covered medication. Tiered formularies are essentially the compromise between closed and open formularies. Tiered formularies are open formularies that set different copay tiers for generic, preferred, and nonpreferred medications (Edlin, 2015).

Impact of Formularies on Patients

The price that consumers pay for prescription medications varies from plan to plan.

Patients are commonly required to pay a portion of the cost of the prescription, also known as the *copayment*, or *copay*. Copay amounts can differ from plan to plan and by geographic region. Closed and open formularies usually only have two copays: one for generic drugs and brand drugs, respectively. Tiered formularies have more than two copays, and each tier is related to a copay amount. Tiered formularies usually have three tiers: generic drugs, preferred brand drugs, and nonpreferred brand drugs.

Most copays are set to cover up to a 1-month supply of medication (28 to 34 days of therapy, depending on the health plan). Thus, a patient who received a prescription for a 7-day course of therapy of prednisone for an acute allergic reaction would likely have the same copayment as a patient who received a prescription for a 30-day course of therapy of prednisone for chronic use.

Some plans may allow patients to get more than a 1-month supply of medication at a time for a maintenance medication (medications used for chronic conditions). For maintenance medications, most health plans allow patients to receive a 90-day supply of medication. Health plans usually charge patients three copays for a 90-day supply (three 1-month supply copays). For example, if a patient paid a $10 copay for a 1-month supply, then the 90-day supply would cost $30. Health plans often offer reduced copayments as an enticement for patients to order their maintenance medications from a mail-order pharmacy service; a 90-day supply of medication might only cost the patient one or two copayments instead of three.

In the rigid formulary systems utilized in the 1990s, a two-tiered prescription copayment system was used by most health plans and pharmacy benefits manager (PBM); the lower copayment tier was used for generic medications, whereas the higher copayment tier was used for formulary brand-name medications. Nonformulary medications were rarely covered by health plans or PBMs without prior approval; if granted, the prescription would fall into the higher copayment tier. Nonformulary medications that were not approved by the health plan were not covered; either the patient paid the full retail price for the prescription or the prescription was switched to a formulary agent by the prescriber.

Fueled by unsustainable prescription cost increases, MCOs abandoned the two-tiered formulary system in favor of higher tiered formulary designs, ranging from three-tiered systems up to the more recently used four- to six-tiered systems. Within the generally utilized three-tiered formulary system, the first two tiers are set up the same as the previous two-tiered system, with the first (lowest) tier copayment reserved for generic products and the second-tier copayment reserved for preferred brand-name products. Agents in the third tier are the nonpreferred brand-name products; the copayment is substantially higher than the second-tier copayment. Some plans include a fourth tier to their formulary for high-cost specialty medications with the highest prescription copayments. Three- and four-tiered formularies have introduced value considerations to patients: Do they value a specific third-tier or fourth-tier product enough to pay the higher copayment or will a second-tier product (with a lower copayment) be suitable for their needs? The multiple-tiered copayment has been proven to successfully move patients to products in the first and

second tiers of the formulary without restricting access to prescription products (Edlin, 2015).

Functions of Formularies

Formularies have been used to promote the prescribing of safe, efficacious, and cost-effective medications. Formularies' main functions are to promote the use of less costly and equally efficacious medications (which are most often generic medications). For brand-name medications, formularies financially incentivize the use of preferred brand drugs over nonpreferred brand drugs or place barriers that prevent nonpreferred branded medications from being covered by the MCO. MCOs also implement policies or programs with their formularies to promote appropriate drug utilization and the use of generic drugs and preferred brand drugs prior to nonpreferred and nonformulary drugs. Examples of such policies or programs include generic substitution, therapeutic interchange, prior authorization, step therapy, medical necessity, and dispensing limitations around quantity, duration of therapy, age and gender.

Generic Substitution

A highly effective method of reducing the cost of the pharmacy benefit is generic substitution. Generic substitution is the process of dispensing an appropriate generic equivalent of a prescribed brand-name drug. Prescribing generic products can reduce the cost of providing prescription medications for patients; generic medication use reduced prescription drug expenses by an estimated $239 billion in 2013 (IMS Health, 2014). Generic substitution has been supported by cost minimization analyses; as the brand and generic agents are considered identical in composition and activity, cost becomes the contributing factor for an agent's selection.

A generic medication is considered equal, or bioequivalent to its parent brand-name medication, and must undergo stringent safety and equivalency testing and comply with specific criteria established by the U.S. Food and Drug Administration (FDA). The FDA has set certain therapeutic equivalence evaluation codes to show the relative bioequivalence of generic agents to the brand-name drugs (FDA, 2014). There are two basic rating codes: A and B. The "A" rating indicates that the drug is considered therapeutically equivalent to other pharmaceutically equivalent products. The "B" rating indicates that the agent is not therapeutically equivalent to other pharmaceutically equivalent agents. Both A- and B-rated drugs are further differentiated based on dosage form. An "AB" rating states that the product's bioequivalence problems have been resolved, and evidence exists supporting the bioequivalence to pharmaceutically equivalent agents.

An example of generic substitution is dispensing the diuretic furosemide when the prescriber writes the prescription for Lasix, and the prescriber has not indicated that the brand-name product is medically necessary. In such a situation, the pharmacist is filling the prescription with an FDA-approved, bioequivalent form of the brand-name drug. Some insurance plans may allow the patient or prescriber to request the brand-name agent, but this often results in a higher copayment for the patient (Navarro et al., 2009). The increase

in copayment may be as large as the difference in cost to the health plan between the brand and generic agents.

To maximize generic substitution, plans may use restrictive strategies such as "dispense as written" (DAW) blocks. A DAW code describes the rationale for the drug's selection and is entered into the prescription claim by the pharmacist before it is transmitted to the health plan for adjudication. There are DAW codes for "substitution permissible" (DAW 0), "dispense as written" (DAW 1), "patient requests brand" (DAW 2), as well as other choices to provide a rationale for the chosen agent. A health plan can require that the patient receive an acceptable generic substitution for a brand-name product unless a suitable DAW code has been entered. A DAW code of 7 is used for products with a narrow therapeutic index. Due to the risk of disrupting the level of drug in the patient's blood, drugs with a narrow therapeutic index may not have to be automatically substituted for an equivalent generic agent. A DAW of 7 informs the health plan that the physician, pharmacist, or patient has elected to continue use of the brand-name product. Drugs in this category include warfarin (Coumadin) and levothyroxine (Synthroid).

Therapeutic Interchange

Therapeutic interchange is defined as the procedure of dispensing prescribed medications that are chemically different but deemed therapeutically similar to the medication prescribed (Holmes et al., 2011). In general, therapeutic interchange involves the substitution of drugs that are different chemical compounds but are considered to exert the same therapeutic effect and have similar toxicity and side effect profiles (e.g., HMG-CoA reductase inhibitors: substitution of generic atorvastatin [Lipitor] for Crestor). The use of therapeutic interchange has increased significantly because of a large influx of new medications that do not offer any therapeutic advantages over existing therapies but are priced much higher than the established products. These medications are commonly known as *me too drugs*. Some popular examples of therapeutic categories that contain me too drugs include proton pump inhibitors (PPIs), HMG-CoA reductase inhibitors (statins), angiotensin receptor blockers, and bisphosphonates.

Pharmaceutical manufacturers offer rebates to health plans to compete for preferred status on formularies, which lowers the prescription benefit cost. Controversies tend to arise when discounts are used to exchange one drug over another when the drugs are in different classes. If a therapeutic interchange involves two drugs of the same therapeutic class, it can be considered an example of therapeutic minimization because the only difference between the two agents is cost (assuming that the relative safety/efficacy data for the two agents are similar).

Therapeutic interchange is used for reasons other than controlling costs, including promoting the use of agents associated with fewer drug–drug interactions (e.g., substitution of fluconazole for ketoconazole) or of agents with a more convenient dosing schedule (e.g., once-daily enalapril instead of two- to three-times daily captopril). These interventions may

prevent unnecessary drug–drug interactions or enhance medication compliance, which could, in turn, improve care and decrease overall health care costs.

In the outpatient pharmacy setting, therapeutic interchange must be verified and accepted by the prescribing practitioner. In the institutional setting, therapeutic interchange does not necessarily require a prescriber's approval if the institution's pharmacy and therapeutics (P&T) committee approves the specific interchange protocol. The American Medical Association (AMA) endorses the practice of therapeutic interchange in settings that have an organized medical staff and a functioning P&T committee (AMA, 1994).

Drug-Dispensing Limitations

Limitations regarding dispensing drugs are developed and implemented to promote appropriate prescribing of medications and are often structured around FDA-approved labeling and evidence-based medical data. Examples of drug limitations include drug quantity limits, duration of therapy limits, age limits, and gender limits. Drug quantity limitations are used to promote the appropriate quantity of medication that should be prescribed. There are two main types of quantity limits: quantity per filled prescription and quantity per days. Quantity per filled prescription limits are implemented for drugs that are prescribed for short-term use, such as analgesics and antibiotics. An example of such a quantity limit would be limiting the prescribing of addictive, high-potency narcotic analgesics indicated for acute pain to 10 tablets per prescription. Quantity per days limits are utilized for chronically used (maintenance) medications. An example of this type of quantity limit would be limiting the prescribing of simvastatin to one tablet per day. Duration of therapy limits are implemented to manage how long a drug should be used, especially for medications that are not considered maintenance medications. An example of a duration of therapy limit would include a 3-month duration of therapy limit for the prescribing of PPI agents. Age limitations prevent the use of medications either above or below what is recommended by the FDA. An example of an age limit would be to prevent the use of barbiturates in members greater than 65 years of age. Gender limits prevent the use of medications for a gender when prescribing would not be safe and/or appropriate; an example of which would prevent prescriptions of oral contraceptives for males.

Prior Authorization and Step Therapy Programs

Prior authorization refers to the approval process that health plans may require for certain medications before they will be covered. The primary purpose of a prior authorization process is to control the use of and prevent the overuse of nonformulary, hazardous, or inappropriately prescribed medications. Prior to the recent move by health plans toward increasingly open formularies with three and four tiers of copayments, health plans would require prior authorizations for most nonformulary drugs, expensive drugs, newly approved drugs, and drugs with less expensive alternatives (Navarro et al., 2009). Over 80% of commercial health plans used prior authorization programs in 2014 (Takeda

Pharmaceuticals, 2014), and prior authorizations are used by a majority of the states in their Medicaid programs (National Conference of State Legislatures, 2010).

The criteria for approval of each drug undergoing the prior approval process will depend on the drug, the patient, the disease state involved, and the prescribing practitioner. Some prior authorizations may require a diagnosis along with pertinent laboratory values, whereas others may require a patient to fail therapy with certain drugs that are indicated to treat the same disease as the restricted agent. Other criteria may include patient demographics, such as age or gender limits, or prescriber limits, where only specific specialty types are allowed to prescribe for certain medications (e.g., only allowing dermatologists to prescribe isotretinoin).

The usual chain of events involving prior authorization starts with a patient presenting a pharmacist with a prescription for a newly prescribed medication. The pharmacist, after submitting a claim and having it rejected, learns that the medication requires prior authorization (often from a message sent with the rejected claim). The pharmacist or patient then contacts the prescriber, tells the prescriber that the medication requires prior authorization, and requests that the prescriber contact the MCO to explain why the patient requires that medication. Either prescribers can decide to contact the MCO and pursue prior authorization or they may choose not to pursue prior authorization and select an alternative agent. MCOs often accept prior authorization requests from practitioners by mail, fax, telephone, or Internet. Completing the prior authorization process may result in the drug's approval for use in that patient, or the MCO may again reject the claim and offer a list of alternative medications that are covered by the plan.

If the prescriber knows that the drug requires prior authorization, the necessary paperwork can be completed to have the drug approved for the patient before the patient enters the pharmacy. Problems arise when the patient and prescriber are unaware of which agents on the MCO's formulary require prior authorization. This confuses many patients, possibly leading them to think that the prescriber ordered the wrong medication or the pharmacist made an error in filling the prescription (Bendix, 2013).

Step therapy programs are utilization management programs that are a version of prior authorization, in which they promote the use of one drug before another (Navarro et al., 2009). There are two main types of step therapy programs: those driven by cost-effectiveness and those that promote more clinically effective medications before less effective medications. The cost-effectiveness step therapy programs promote the use of cost-effective generic medication before the use of an expensive branded medication. They can be implemented using drugs within the same therapeutic class or different categories. An example of a step therapy within a therapeutic class would be to require the use of a generic HMG-CoA reductase inhibitor, such as atorvastatin, before the approval of a branded HMG-CoA reductase inhibitor like Crestor. An example of a step therapy using different categories would be to require the use of metformin before the approval of DPP4 inhibitors like sitagliptin and saxagliptin. Step therapy programs implemented for the purpose of promoting clinical effectiveness are usually based on practice guidelines or evidence-based

medical data. An example of this type of program would be to require the use of nasal corticosteroids or nonsedating antihistamines before the approval of leukotriene inhibitors for the treatment of allergic rhinitis.

MCOs have increased their efforts to prospectively review prescriptions requiring prior authorization during the claim adjudication process. When a pharmacy sends a claim for a prior authorization drug to the PBM for adjudication, the PBM can review the patient's prescription claim history and the claim itself to determine if the prior authorization criteria have been met. This step can decrease the number of rejected prescription claims and minimize the time and efforts of prescribers, pharmacists, and patients in obtaining prior authorizations. When initiated effectively by informing practitioners of the drug's status and the preapproval process, prior authorization can become a very efficient mechanism for controlling costs and drug use.

Medical Necessity

Some MCOs use the term *medical necessity* interchangeably with *prior authorization*. In most settings, a medication considered a medical necessity is a nonformulary drug that is usually extremely expensive and usually has less expensive generic and branded alternatives or is considered a relatively unsafe medication compared to available alternatives (Navarro et al., 2009). Some MCOs make medical necessity drugs available only after failure of drug therapy with a drug requiring prior authorization. MCOs carefully evaluate drugs before classifying them as medical necessity drugs, knowing that the drugs will be restricted if they are covered. Like the criteria for medications requiring prior authorization, the criteria for coverage vary from drug to drug.

Pharmacy and Therapeutics Committee

Structure and Function

A P&T committee is a group that meets periodically to review and revise the organization's formulary. The committee is composed primarily of physicians and pharmacists and may also include nurses, nurse practitioners, physicians' assistants, and members of the organization's administration. The physicians on the committee often comprise a diverse group from various fields of practice, with general practitioners and multiple specialists represented. The committee should be a well-balanced mix of practitioners who can view health care policies from different perspectives and provide sound recommendations.

Formulary Management

The main responsibilities of a P&T committee are to develop and revise the formulary, create and implement medication use policies, and provide education for practitioners. Formulary reviews include evaluating new medications for formulary consideration, periodic drug class reviews, and utilization analyses. A major goal of the P&T committee is to provide cost-effective, clinically safe, and effective therapy. Frequent formulary revisions are needed for several reasons: the introduction of new products into the marketplace, modifications to a product's labeling to include new treatment indications, emerging research indicating a previously unknown benefit or risk of therapy, changes in consensus disease treatment guidelines, and changes in the brand/generic status of a product or other pricing concerns.

The inclusion and exclusion of agents are time-intensive processes for P&T committees. As such, many P&T committees elect to delay their consideration of a new product until it has a sufficient body of evidence to perform a review and/or it has been on the market for a sufficient length of time (e.g., 1 year) to provide an opportunity for any adverse events undetected in clinical trials to be noticed. P&T committees may consider a wide variety of information when evaluating a new product, including peer-reviewed clinical trials, adverse event/safety data, patient-oriented health outcomes (e.g., the ability of an antihypertensive to reduce the risk of myocardial infarctions, not merely to lower blood pressure), the FDA-approved product labeling for the new agent, quality-of-life research, and pharmacoeconomic data (Box 59.1). The committee must consider the issue of bias when evaluating results provided by any research sponsored by the pharmaceutical manufacturer. Literature that includes data comparing the new agent with an agent currently used to treat the same disorder is prized by P&T committees for its utility in comparing one drug with another. If the new agent offers a clinical, safety, or economic advantage to existing formulary agents, the P&T committee may place the agent on the formulary and can do so by adding the new product with or without removing an existing product or products. Further, committees can add the drug to the formulary unconditionally or may recommend implementation of certain restrictions on the coverage (prior authorization, quantity limitations, step therapy) of the new agent to allow its inclusion in the formulary.

BOX 59.1 Information Considered by a Pharmacy and Therapeutics Committee When Reviewing a Product for the Formulary

1. FDA-approved indications
2. Pharmacology/mechanism of action

3. Pharmacokinetic/pharmacodynamic data
4. Dosing and administration, including special monitoring or drug administration requirements
5. Adverse effect profile, warnings, precautions, contraindications, and black box warnings
6. Drug interactions (with other drugs, foods, or medical conditions)
7. Clinical evidence: clinical trials, health outcomes research, retrospective database analyses, quality- of-life research
8. Risks versus benefits regarding clinical efficacy and safety of a particular drug relative to other drugs with the same indication
9. Pharmacoeconomic data and modeling
10. Off-label uses
11. Cost comparisons against other drugs available to treat the same medical condition(s)
12. Source of supply and reliability of manufacturer and distributor

Because of the increase in prescription drug spending by health plans, cost now plays a more significant role in formulary status, although many organizations claim that cost is considered only after safety and efficacy data have been evaluated. Pharmacoeconomic modeling allows an organization to estimate the impact of a formulary change on both the health outcomes experienced by their members and total prescription drug and health care spending. To improve the likelihood of a drug's addition to a formulary, pharmaceutical manufacturers may offer prescription volume-dependent rebates to MCOs as incentives.

Development of Disease Management Programs or Treatment Protocols

Another responsibility of a P&T committee is to develop or approve disease management programs or treatment protocols for the organization. These programs and protocols provide useful recommendations for practitioners treating various diseases. They may be based on current consensus practice guidelines, or they may be developed by the P&T committee using current clinical data. A main purpose of guidelines or algorithms is to minimize treatment variations and improve patient outcomes while reducing costs (Navarro et al., 2009).

Ensuring Formulary and Practice Guideline Compliance

One of the primary reasons that MCOs develop formularies and practice guidelines is to help lower the cost of the prescription drug benefit. Unfortunately, merely printing and distributing formularies and algorithms often are not enough to alter prescribing practices. Patients and pharmacists may also be wary of the formulary system, failing to understand both its necessity and utility. While educational programs (including seminars, newsletters, provider peer-to-peer communications, and one-on-one meetings) are useful, these tools alone do not ensure improved formulary compliance. MCOs have developed a variety of payment and reimbursement strategies to improve compliance. The following sections describe the ways that MCOs evaluate formulary and treatment guideline compliance and how MCOs use different levels of payments to improve compliance.

Prescriber Incentives for Compliance

MCOs can monitor compliance to the formulary and treatment protocols with a variety of tools. Many MCOs use the level of peer compliance to determine the amount of a prescriber's or practice's year-end incentives. Prescribers can be eligible for financial incentives if their compliance to the formulary or treatment protocols meets the threshold established by the MCO (Navarro et al., 2009).

Some MCOs may tie a portion of a provider's compensation to the level of compliance. If a practitioner fails to follow treatment protocols closely and inexplicably high prescription costs result, an MCO may withhold a portion of the provider's compensation. In a capitated plan, the provider receives a fixed, predetermined, per-member payment by the MCO to provide services for members, regardless of how much or how frequently a member uses service. Providers can reap financial reward if they can provide services at a cost lower than their level of payment but are responsible for all costs if expenses should rise above their level of payment. While capitation remains a frequently utilized tool by MCOs to manage medical costs (Kaiser Family Foundation, 2010), few (if any) health plans utilize a capitated pharmacy benefit.

Evaluating Compliance: Percentage Formulary Compliance

The simplest way for an MCO to evaluate formulary compliance is to determine the prescriber's percentage of prescriptions for generic and branded formulary products. Although this method is useful for determining formulary compliance (e.g., the use of generic and branded formulary angiotensin receptor blockers (ARBs) compared with nonformulary-branded ARBs), it does not evaluate the quality of prescribing; just because a formulary agent is prescribed does not make the prescription appropriate. It may be more important to determine if the prescriber is following consensus disease treatment guidelines. A prescriber who prescribes a formulary agent but is not following treatment guidelines may have the same percentage formulary compliance as a prescriber who uses a different and potentially less expensive or more appropriate formulary medication by following treatment guidelines. Also, prescribers who use medically necessary or appropriate nonformulary drugs are penalized in this system. Many MCOs have initiated programs to evaluate the quality of prescriber by implementing practitioner profiling programs, where MCO clinicians evaluate questionable prescribing with the provider.

Because of the aforementioned limitations with percentage formulary compliance, MCOs also use another tool to evaluate compliance: per-member–per-month (PMPM) reports.

Health Care Trend Reporting

When analyzing health care trends for an MCO, many variables are reviewed and factored in to evaluate and justify the trends during any particular year. The PMPM reports are a

unit of measure related to each enrollee for each month. When used to evaluate prescribing practices, average PMPM prescription costs are determined for each provider. Theoretically, prescribers who adhere to formulary and practice guidelines will achieve lower PMPM prescription costs than their peers who do not. This is not a foolproof method to evaluate compliance because a small number of patients requiring expensive therapy (e.g., chemotherapy, antipsychotics) can substantially increase a prescriber's PMPM amount. More frequently, MCOs use PMPM reports to evaluate prescription costs for a specific disease. An example of a disease-specific PMPM report appears in Table 59.2. Although prescriber A is responsible for the highest dollar expenditure on antihyperlipidemics, his or her PMPM prescription cost is close to the average of the prescriber's peers. On the other hand, despite prescriber C's low overall dollar expenditure on lipid agents, his or her PMPM prescription cost is the highest.

TABLE 59.2 Per-Member–Per-Month (PMPM) Prescription Costs for Patients Receiving Antihyperlipidemic Therapy

Prescriber	Number of Member Months	Lipid Prescription Costs ($)	PMPM Prescription Costs ($)
A	561	45,183	80.54
B	240	18,818	78.41
C	285	25,639	89.96
D	496	36,248	73.08
E	357	30,780	86.22
F	489	40,223	82.31

Another factor that is considered in evaluating health care trends is drug cost. Monitoring the rate of increase in drug cost has become a significant factor in overall health care spending. As the prices of prescription medications increase, MCOs are adjusting their overall plan designs to compensate for that increase. These adjustments may include changes in product status on drug formularies, implementation of prior authorization and step therapy programs for expensive products, increases in member copayments, or increases in member premiums.

Improving Formulary Compliance

In addition to prescribers, MCOs have an opportunity to improve formulary and practice guideline compliance by providing financial incentives or disincentives to other players: the prescription dispenser (pharmacist) and the prescription recipient (patient). These financial incentives include bonuses, differential reimbursement rates, and different levels of prescription copayment.

Pharmacist Reimbursement

An MCO can influence pharmacists as a secondary step in limiting the use of nonformulary medications. As a part of the contracting process, MCOs may impose requirements on pharmacies if the pharmacy wishes to serve members of the plan. MCOs can require that pharmacies dispense generic products when available, unless the prescriber requires the prescription to be DAW or the medication has a narrow therapeutic index (e.g., phenytoin [Dilantin], warfarin). Many states already require automatic generic substitution when applicable. To reduce wasted or unused medication, MCOs often impose a limit on the amount of medication that a community pharmacist can dispense—usually no more than 1 month's worth at a time. Once a patient is stabilized on a maintenance dose for medications used to treat chronic illnesses (e.g., hypertension, diabetes), MCOs may require that patients receive a 3-month supply of medication from a mail-order pharmacy; this can be done at a lower expense to the MCO.

Pharmacies that are successful in increasing formulary compliance or reducing member pharmacy costs may be eligible for bonuses or they may receive a higher reimbursement rate. Alternatively, pharmacies that fail to meet the requirements of the contract may receive a lower reimbursement rate or have their contract terminated altogether. MCOs frequently audit the claims of pharmacies with a higher-than-average number of DAW orders to ensure that the prescriber does in fact require the brand-name drug be dispensed to the patient.

Patient Prescription Copayment

The impact of prescription copayment on patients was reviewed earlier in this chapter. In summary, as formularies have progressively become more open, health plans have responded by using differential copayments with significant price differentials between tiers in an effort to encourage patients to use lower-cost generic or preferred brand medications. Patients who are hesitant to pay a high prescription copayment when lower priced alternatives are available frequently ask their provider to prescribe the product with the lower copayment; the provider will often comply with the patient's request if they believe the change can be made without adversely affecting the outcome of care.

Electronic Prescribing and Electronic Health Records

Before the introduction of electronic prescribing, practitioners were faced with a variety of options by which they could prescribe medications: written orders on prescription pads, typed orders sent via fax, or verbal orders communicated through telephone calls. These prescribing options leave room for error, as there is the potential for illegible handwriting, poorly scanned images, and inaudible messages. Furthermore, these options are not exempt from tampering or fraud, as individuals can alter handwritten prescriptions, send falsified prescriptions via fax, or call in fake prescriptions over the phone. With the advent of electronic prescribing, practitioners were presented with an additional option that has the potential to save time and money, as well as reduce medication errors and fraud.

Electronic prescribing, or e-prescribing, is the process whereby a prescriber orders and submits a prescription through an application that electronically transmits the prescription to a pharmacy in real time (CMS, 2014b). A variety of e-prescribing software programs exist, and thus, there may be differences in functionality among the e-prescribing software programs available to clinicians. Ideally, the software programs should allow the prescribers to view a patient's current medication list, medication history, available pharmacy, and prescription insurance plan (Health Resources and Services Administration [HRSA], 2015).

E-prescribing software requires a user (the prescriber or an authorized representative) to log in to a secure system and verify his/her identity using a username and password combination. After authentication, the prescriber can search for and select a patient record within the e-prescribing system using patient-specific information (i.e., first name, last name, date of birth, etc.). The prescriber can then choose to review the patient's records and begin to enter and edit a prescription (HRSA, 2015).

After entering the intended prescription information, the prescriber can send the order to the transaction hub, which links the prescriber to both the pharmacy and the PBM. This interoperability allows for the verification of patient eligibility for prescription coverage by submitting the prescription information to the PBM before the e-prescription arrives at the pharmacy. Once the information has been submitted, the PBM determines if the drug is a covered benefit for the member. The prescriber then receives a message regarding the drug's coverage status. If the drug is covered, the prescriber may choose to send the prescription to the pharmacy for it to be filled. On the other hand, if the drug is not covered, the prescriber has the option of ordering a different medication or contacting the PBM for prior authorization of the drug (HRSA, 2015).

The ability of prescribers to directly transmit prescriptions from the office to the pharmacy eliminates the need for the patient to take it to the pharmacy to be filled. Since patients are not required to take electronically transmitted prescriptions to the pharmacy, there are increased chances that the prescriptions actually arrive at the pharmacy.

Surescripts, an e-prescribing software vendor, released a report that showed that e-prescribing increases the number of first fills of prescriptions that actually reach the pharmacy by 11.7% and the number of prescriptions picked up at the pharmacy by 10% (Surescripts, 2012).

E-prescribing has also been shown to reduce prescribing errors. Researchers at Weill Cornell Medical College found 37 errors for every 100 prescriptions written by hand, but only 7 errors for every 100 prescriptions ordered via e-prescribing software (Kaushal et al., 2010). These benefits, along with the potential for time and cost savings, explain the rationale behind the "meaningful use" incentive payments program offered by the Centers for Medicare and Medicaid Services (CMS), which began in 2009 and ended in 2013 (CMS, 2014c).

E-prescribing represents only one part of a greater change to the health care system: electronic health records. Electronic health records, or EHR, are digital versions of patient-centered medical records, which can be updated in real time (HealthIT, 2013). In 2009, the American Recovery and Reinvestment Act (ARRA) authorized CMS to offer financial incentives to providers and hospitals that exhibit "meaningful use" of EHR technology (AMA, 2014). With the recent advances in technology, many providers have already adopted the software necessary to maintain electronic health records. However, these systems can impart challenges to smaller practices because of the significant cost to upgrade technology and the operational changes needed to use the system. Aside from the large costs associated with the purchase of EHR software, the universal implementation of EHR represents an opportunity for enhanced interoperability, improved continuity of care, and medical error reduction.

Current Issues in Managed Care

One cause of discontent among health care purchasers is the cost of insurance premiums, which began to rise at a rate greater than that of inflation starting in the mid-1990s. The average family's annual premium costs were nearly $17,000 in 2014, with covered workers paying 29% of the premium (Kaiser Family Foundation, 2014). A portion of the price increase is attributed to increased costs of medications, which increased an average of 9.9% a year during the 10-year period ending in 2007 and increased 13.1% in 2014 (Aitken et al., 2009; Kaiser Family Foundation, 2014). The increase in expenditures for prescription drugs is the effect of three factors: price inflation, increased utilization, and the increased availability of high-cost specialty medications. If prescription drug spending continues to increase at the 5.7% annual rate forecast for the next decade as projected (Sisko et al., 2014), MCOs will be forced to modify the extent to which they cover prescription drugs through coverage limits, establish more rigid formulary systems, and increased cost shifting to consumers.

In March 2010, the U.S. Congress passed the Affordable Care Act, commonly known as either the Healthcare Reform Bill or "ObamaCare." The premise for the act was to ensure accountability of MCOs, lower health care costs, improve quality of care, and provide improved consumer choice for health care services (U.S. Department of Health & Human Services, 2010). Components of the Affordable Care Act include provisions requiring insurers to provide coverage for individuals with preexisting conditions, allowing individuals under the age of 26 years to remain on a parent's insurance plan, an elimination of lifetime and annual dollar limits for essential health benefits, and requirements for specific preventive services (e.g., colorectal cancer screening for adults over 50, breast cancer mammography screening for women over 40, vision screening for children) without having to pay a copayment or coinsurance when delivered by a network provider (U.S. Department of Health & Human Services, 2015). A mandate written into the act requires individuals not covered by an employer-sponsored health plan or a public insurance plan to obtain an approved private insurance policy or pay a penalty. This individual mandate provision of the act was upheld by the U.S. Supreme Court in June 2012 as a constitutional action under Congress's taxation powers (National Federation of Independent Businesses vs. Sebelius, June 28, 2012). The act established health insurance exchanges to facilitate the purchase of health insurance by citizens; the rollout of the federally operated exchange in October 2013 to serve the citizens of the 36 states that opted not to establish their own state-specific exchanges was marred by technological issues that took several months to resolve. The act continues to face legal and legislative challenges in its funding and implementation, and the regulations and provisions noted here may be modified or eliminated in the future.

Despite its critics and shortcomings, managed care is likely to remain the leading manner of financing and delivering health care in the United States. Through more

effective communication and cooperation, practitioners and MCOs may someday resolve their conflicting issues. It is imperative for practitioners and MCOs to understand each other's role in health care. Although practitioners and MCOs have quite different responsibilities in health care, both groups share a common goal: the delivery of high-quality care to patients.

60 Integrative Approaches to Pharmacotherapy— A Look at Complex Cases

Virginia P. Arcangelo Andrew M. Peterson Jennifer A. Reinhold Veronica F. Wilbur

The cases presented in each of the disorders-focused chapters were designed to help the learner think through the process of evaluating patient-specific drug therapy needs. The cases were simple ones, typically involving a single problem related to the disorders discussed in the chapter. This chapter, however, uses cases involving patients with multiple problems, which encourages the learner to assess the problems and prioritize them. When managing multiple problems in a single patient, the practitioner must evaluate possible medication therapies and select the best patient-specific option. This level of complexity is reflective of real-life situations and requires a systematic approach to the patient to manage the complexities.

The Complexity of Patients

The reality of life is that patients are complex individuals with multiple competing issues and priorities. Patients have economic, social, emotional, and cultural issues that affect their medical conditions.

Chronic medication therapy can be costly, even in instances when patients are prescribed generic medications exclusively. Nearly two thirds of elderly patients use medications on a daily basis with an average of eight prescription medications per person. The average yearly cost for a single generic drug in 2013 was more than $280, which can be cost prohibitive for some patients, particularly those on multiple medications. In the same year, the average annual cost associated with brand name medications was more than 10 times higher than that of generic medications (Schondelmeyer & Purvis, 2014). The selection of treatment options must include consideration of the cost, because if patients cannot afford the treatment, they will not follow the plan.

In addition, the social and emotional impact of a diagnosis must be considered. Patients requiring insulin injections to maintain adequate blood glucose levels need assistance in making the lifestyle change necessary to incorporate the injections as well as the monitoring into their daily routine. The emotional reminder of "illness associated with chronic medication-taking behavior" must be addressed at the initial and subsequent visits. Last, culturally accepted treatment options are important considerations; injectable medications containing human blood products (e.g., albumin) may not be acceptable to patients who are of the Jehovah's Witness faith. Asian cultures view illness as an inevitable consequence of life and, as a result, may not seek care or may refuse treatment.

General Overview of Methods for Assessing Patients and Drug Therapy

One of the more common methods for organizing medical information is the problem-oriented medical record (POMR). Each of the patient's medical problems is identified and prioritized in order of importance. The order of the problems depends on the acuity and severity of the situation. Typically, the most severe and acute problems are listed first, followed by the chronic conditions, and then problems requiring preventive measures (e.g., smoking cessation).

In addition to the prioritized problem list, the POMR system uses the "SOAP" note technique for organizing information associated with each problem. The acronym *SOAP* stands for (S)ubjective, (O)bjective, (A)ssessment, and (P)lan. The subjective and objective components are the data that support the identification of the prioritized problem. The subjective data refer to information provided by the patient (or other individual) that cannot be independently verified. The objective data often are laboratory data or health assessments (e.g., blood pressures) performed or observed by the practitioner.

The information needed in this part of the SOAP note includes the chief complaint, history of the present illness, past medical history, family and social history, medication history, the results of the review of systems, and physical examination and laboratory results. This data collection is key in the assessment of the patient.

The assessment section of the SOAP note integrates the subjective and objective information and is where the practitioner delineates the potential diagnosis related to the problem. The rationale for the diagnosis should be included as well as an indication of the severity and acuity of the problem. The last portion of the note is the therapeutic plan. In this section, the practitioner may include additional diagnostic tests necessary to confirm or rule out the suspected diagnosis. This diagnostic plan may also include referral to other practitioners as necessary. The other portion of the plan section should include information about changes in therapeutic plans such as adding or discontinuing drug therapy, identifying therapeutic goals, and establishing monitoring parameters.

Anticipating Problems

One of the key elements of a good practitioner is the ability to plan for unintended consequences. A patient may become noncompliant with a medication due to an adverse event and not report the event or the noncompliance before your next scheduled visit. The result is the patient forgoes treatment for an identified problem for an unknown period of time. When addressed, the patient will admit to the noncompliance but may indicate unawareness of the severity of self-discontinuing drug therapy. Proactive discussions regarding potential consequences (adverse reactions, noncompliance) will help reduce the frequency of these types of encounters. As a practitioner, one should always consider what to do if the patient has an adverse drug reaction, takes an interacting drug, or even stops taking the drug.

Other Information Needed Before Prescribing

When taking a medication history, the practitioner needs to assess specific information related to drug therapy. An inventory of patient-reported allergies is vital to a good medication history. These allergies include an assessment of drug allergies. A patient may report a symptom as an allergy, but the clinician must assess the validity of the report. For example, a patient may report abdominal discomfort as an allergy to erythromycin, but in reality, the reported symptom is an adverse effect of the drug. This type of report is not a true allergy and would not preclude the patient from receiving that drug or a related drug. However, the practitioner must consider the impact the symptom has on the patient's willingness to take a prescribed medication. If the patient was prescribed a medication that would cause distress, the patient is less likely to take it.

Food allergies are also important to assess. Reports of allergies to shellfish or other iodine-containing foods are important to know when prescribing medications such as intravenous contrast dyes.

Further, within this section of the patient history, the practitioner must not only assess prescription medication use but also obtain a good history of nonprescription and complementary and alternative medication use. In 2012, 33.2% of adults used complementary and alternative products as part of their personal treatment plan (U.S. Department of Health and Human Services, 2015), representing a decrease as compared to 2002 through 2007 and 2007 through 2012. The most commonly used products were fish oil; glucosamine/chondroitin products are consistently among the most popular. As compared to previous years' trends, there was a meaningful increase in the use of melatonin and a meaningful decrease in the use of echinacea. The potential for drug–drug and drug–disease interactions with these and other agents exists and must be considered as part of the treatment plan.

Questions

As noted earlier, each disorder chapter had a simple case with a series of questions designed to help you work through the pharmacotherapeutic approach to the patient. These nine questions are indicative of a thought process that should be followed when developing the pharmacotherapeutic aspect of the care plan. The following real-life cases are more complex than those in the disorder chapters and are designed to help the learner integrate the treatment plan for patients with multiple disorders and multiple medication needs. We use the same nine questions, in varying forms, to illustrate the thought process. The answers provided may not be the only "correct" answers. Other choices of drug therapy may clearly be available, or as time progresses, we may learn that there are better choices due to new drug development and new research on existing drugs. We encourage you to use this process to help you think through the problem, not solely finding the answer.

Depression/Anxiety/Rheumatoid Arthritis

J.R. is a 48-year-old Caucasian male who is employed as a college professor and has been diagnosed with depression and anxiety in the last year. At the time of diagnosis, the Hamilton Depression Rating Scale score was 18 (moderate depression), and the Hamilton Anxiety Rating Scale score was 20 (moderate anxiety). Though he had vague complaints of mood disturbances and sad mood, he resisted medication therapy. His past medical history is also significant for rheumatoid arthritis, which has been managed with weekly methotrexate (7.5 mg every week). Recent personal issues (divorce, a new boss) have prompted J.R. to seek some assistance with his depressed and anxious symptoms. Currently, J.R. complains of staying awake at night worrying, lack of pleasure or joy in daily activities, decreased desire to socialize and lack of interest in his hobbies, and increase in napping during the weekends. In addition, J.R. complains about an increase in his normal daily pain rating (normal for J.R. = 2/10, but in the last few weeks, it has consistently been 4/10).

Weight: 250 lb (an increase of 20 lb since his last visit 6 months ago)

Height: 64 inches

BP: 140/80 mm Hg

Pulse: 72 bpm

Current medications:

Methotrexate: 7.5 mg every Friday
Naproxen: 500 mg bid, as needed

Lab values:

Glucose: 107 mg/dL (fasting)
HbA_{1c}: 6.5%
Total cholesterol: 250 mg/dL
LDL: 169 mg/dL
HDL: 30 mg/dL
Triglycerides: 290 mg/dL
Creatinine: 1.0 mg/dL
BUN: 14 mg/dL
AST: 15
ALT: 20
Urine microalbumin (–)

Issues: J.R. has an established diagnosis of rheumatoid arthritis that had been previously controlled with drug therapy. In addition to complaints of less optimal pain control, J.R. also has had an exacerbation of his mood and anxiety symptoms, which has prompted him to seek help. Some new metabolic issues have also emerged as he has gained a significant amount of weight in a short time and his blood glucose and HbA_{1c} are no longer at goal. The challenge will be to determine which complaints and lab abnormalities are independent problems and which are potentially consequences of another issue.* Answers can be found online.

List specific goals for treatment for J.R.

There are two distinct types of outcomes that should be expected for J.R.; clinical and quality of life related. The current complaints are primarily related to depressed mood and anxiety, which consequently impact his social and occupational quality of life. The rating scales that would be used to measure response to treatment will yield quasiobjective information, which can be considered a clinical outcome. Additional clinical outcomes related to the anxiety and depression would be prevention of serious outcomes (suicidality, worsening depression, or anxiety). J.R.'s pain complaint is a subjective parameter. The abnormal lab values are suggestive of an emerging metabolic problem, and the related goals would be clinical. An important consideration in this case is determining whether to treat all problems as independent or to approach treatment systematically, assuming that the weight gain and associated metabolic changes as well as the increase in pain rating may be a result of the worsened depression and anxiety. It is also a reasonable possibility that the increase in pain is also elevating his blood pressure.

Specific goals of therapy would reasonably include:

- HAM-D response (a ≥50% reduction in HAM-D score = 9)
- HAM-A response (a ≥50% reduction in HAM-A score = 10)
- Return to baseline function (subjective)

- Improvement in quality of life (subjective)
- Reduction in pain level (subjective)
- BMI: 18.5 to 24.9
- Blood glucose (fasting): less than 100 mg/dL
- Reduction in 10-year cardiovascular risk (no longer driven by LDL goals)

What drug therapy would you prescribe? Why?

One approach to drug therapy would be to treat the depression and anxiety first and then evaluate the impacts on the other problems (weight gain, metabolic disturbances, pain). An alternate and possibly less conservative approach would be to initiate medication therapy for the blood glucose, lipids, and pain. Though, starting multiple drug therapies simultaneously for problems that are likely dependent on one another is probably not optimal. Targeting the mood and anxiety first is recommended. In the absence of contraindications, a medication from the SSRI or SNRI class is recommended as first-line drug therapy for depression as well as anxiety. This patient has no contraindications; therefore, he is a candidate for these drug classes. One possible choice would be duloxetine (Cymbalta) 30 mg. The rationale would be that it is indicated for both depression and anxiety and also for neuropathic pain. J.R.'s pain results from rheumatoid arthritis and would not be classified as neuropathic; however, some patients report improvement in pain rating regardless of the etiology. There is a risk of weight gain with almost all of the medications in the SSRI and SNRI class, with a few exceptions. This risk does exist with duloxetine, but it is potentially less so as compared to other medications. There is less of a risk of increases in blood pressure as compared to venlafaxine (Effexor); the other SNRI indicated for anxiety. Sertraline (Zoloft) is a weight neutral SSRI, but the risk of sexual dysfunction is higher than that of the SNRIs, and though the patient is divorced, adding an additional potential life stressor may not be in his best interest. Bupropion (Wellbutrin) would have been a great choice secondary to its alerting properties and potential weight loss, but the patient has comorbid anxiety and bupropion may worsen it.

What are the parameters for monitoring success of the therapy?

Assuming that the anxiety and depression are treated first, and then any additional potentially remaining problems are treated after resolution of the psychiatric complaints, the HAM-A and HAM-D would be the most likely instruments. After 4 to 8 weeks of drug therapy with duloxetine (or alternate SSRI or SNRI), the patient should be reevaluated using both of these rating scales. A response to drug therapy is defined (based on these rating scales) as a 50% or greater reduction in baseline score. This equates to a nine or less on the HAM-D (baseline was 18) and a 10 or less on the HAM-A (baseline was 20).

Discuss specific patient education based on the prescribed

therapy.

Adherence is especially important in the context of depression and anxiety medication therapy. Discussion regarding the importance of taking the medication daily and not skipping doses should occur. In addition, there needs to be explanation about the expected delay to therapeutic effect. These medications generally take four or more weeks to exert a therapeutic effect and it's important (particularly with regard to adherence) to let patients know that they should not expect to feel "better" within the first few weeks of therapy. Once patients do feel a therapeutic effect, it is important that they do not self-discontinue the drug and assume that they are "cured." Drug therapy typically extends for 6 to 12 months beyond symptom resolution. Duloxetine can cause weight gain. All SSRIs and SNRIs carry warnings for worsening depression and risk of suicidality; therefore, the patient needs to be told to report any worsened or emerging symptoms to the provider.

List one or two adverse reactions for the selected agent that would cause you to change therapy.

Any significant worsening of depressive or anxious symptoms or any change in personality or thoughts of suicide would warrant a change in therapy.

What would be the choice for second-line therapy?

In the event that duloxetine failed to produce a therapeutic effect after an appropriate trial (8 to 12 weeks), then another medication from the SSRI or SNRI class would be appropriate.

What over-the-counter and/or alternative medications would be appropriate for J.R.?

There are no nonprescription products that have been shown to be safe and effective in the treatment of depression or anxiety.

What lifestyle changes would you recommend to J.R.?

Seeking counseling or therapy would be an appropriate treatment option in addition to drug therapy. J.R. should also increase his physical activity to 30 or more minutes most days of the week while also limiting high-fat and processed foods.

Describe one or two drug–drug or drug–food interaction for the selected agent.

Other medications that are serotonergic (other SSRIs or SNRIs, TCAs) should not be used in combination with duloxetine. Some over-the-counter products, like St. John's wort, are known to interact with duloxetine as both are serotonergic.

Seizure Disorder/Headache/Insomnia

R.M. is a 32-year-old female who presents with a 6-week history of brief periods of "blanking out" and having a bilateral, rhythmic, mild "jerking" of her arms. These episodes, which have occurred approximately six times, last from 30 seconds to about 1 minute, and consciousness is not lost. She worries that she might be hypoglycemic and is seeking help. Her past medical history is significant for migraine headaches and insomnia. R.M. has been self-managing her infrequent migraines with ibuprofen (doses as high as 800 mg once and then repeating in 4 hours up to three times) but reports that they are now increasing in frequency with approximately 4 to 5 per month. She is currently not treated for her insomnia, which she categorizes as difficulty staying asleep. Though in the office R.M.'s EEG is normal (as would be expected since it would only be abnormal during an actual seizure), her provider diagnoses her with complex partial seizures, as her complaints are consistent with this diagnosis. There are no metabolic abnormalities that could explain the seizure activity.

Weight: 140 lb

Height: 68 inches

BP: 112/76 mm Hg

Pulse: 68 bpm

Current medications:

Ibuprofen as needed for migraine (usual doses during headache are 800 mg two to three times)

Issues: R.M. is newly diagnosed with complex partial seizures and requires initiation of drug therapy. She has two additional diagnoses; migraine headaches (which are increasing in frequency) and insomnia, which are not formally treated with prescription drug therapy. She currently manages her migraines with over-the-counter ibuprofen at higher than recommended doses for self-treatment. There are no additional medications or lab abnormalities that complicate this clinical picture. There is an opportunity to minimize the pill burden for R.M. as there is some overlap in terms of the drug therapy that can be used for at least two of her complaints.* Answers can be found online.

List specific goals of treatment for R.M.

- Reduce seizure frequency, ideally to zero seizures.
- Reduce the number of migraine headaches per month to zero.
- Minimize adverse effects and drug interactions.
- Improve sleep quality and maintain sleep through the night.

What drug therapy would you prescribe? Why?

There are a number of medications that are indicated for the treatment of complex partial seizures. Monotherapy is recommended, and therefore, a medication indicated as monotherapy should be considered. Since the efficacy of most antiepileptic medications is comparable, adverse effects, drug interaction potential, and practical considerations (the need to monitor blood levels, frequency of administration, etc.) are at the forefront of selecting drug therapy for seizures. Considering that based on the frequency of her migraine headaches, R.M. is also a candidate for prophylactic therapy for her migraines. Both topiramate and valproic acid are indicated for the monotherapy treatment of complex partial seizures as well as the prophylactic treatment of migraine headaches; these two drugs should be considered possible options. A rationale to initiate topiramate instead of valproic acid is that valproic acid needs to be monitored and topiramate does not. Also, though most seizure medications are contraindicated or strongly not recommended in pregnancy, valproic acid is the medication that is associated with the most risk of fetal harm. The patient is not pregnant currently but she is of childbearing age. An appropriate starting dose of topiramate would be 50 mg daily for 1 week with a weekly increase by 50 mg daily up to 200 mg once daily (maximum of 400 mg daily). This plan is driven by the dosing for seizures and not migraine prophylaxis. If R.M. had been on interacting medications or if she has existing metabolic issues, the drug initiated could be different (e.g., if she had risk factors for kidney stones or a history of kidney stones, topiramate would not be the best choice).

Topiramate may cause unwanted sedation initially, which could ultimately be beneficial given the presence of insomnia. But since topiramate can be sedating, initiating a medication for insomnia at this time would not be recommended. Once R.M. was stable on her chronic topiramate dose and was no longer experiencing daytime sedation (assuming that this occurs), and if her insomnia complaint persists, then drug therapy could be initiated. Since her insomnia complaint involves waking in the middle of the night, a medication with a longer duration of action is warranted. Zolpidem ER 5 mg would be an appropriate choice since it is a first-line medication and it would be expected to exert an effect through the night.

What are the parameters for monitoring success of the therapy?

After approximately 1 week, topiramate dosing can be adjusted so 1-week postinitiation of medication therapy would be an appropriate time for a follow-up. At 1 week, an assessment of seizure frequency is made. Ideally, there have been no additional episodes of complex partial seizures by this time. Assuming that there has been no seizure activity and the medication has been well tolerated, the dose should be titrated upward as detailed above. Absence of seizure activity will remain the parameter by which success of therapy is measured. If a drug that needs to be monitored had been chosen, then therapeutic level

would also be part of the monitoring plan for efficacy.

Discuss specific patient education based on the prescribed therapy.

Adherence to drug therapy for seizure disorder is critical, as noncompliance is the most common reason for treatment failure and subsequent seizure activity. Topiramate is a pregnancy category D (according the current rating structure) and is not recommended during pregnancy. If R.M. decides to start a family, she needs to inform her provider. Additionally, if she is in a sexual relationship with a male partner, she must be counseled on what constitutes effective contraception.

List one or two adverse reactions for the selected agent that would cause you to change therapy.

Topiramate is associated with a risk of nephrolithiasis and metabolic acidosis. Baseline and periodic monitoring of serum bicarbonate, electrolytes, and ammonia are recommended. Emergence of nephrolithiasis or metabolic acidosis may warrant a change in drug therapy.

What would be the choice for second-line therapy?

Assuming that the plan remained to treat the seizure disorder and provide migraine prophylaxis with a single drug, then valproic acid would be the next best choice. Periodic monitoring of the level is required (50 to 100 mg/L), and the risk of fetal malformation is higher with valproic acid. The dosing is weight based and should be initiated at 15 mg/kg/d and adjusted by 5 to 10 mg/kg/d at weekly intervals until therapeutic levels are achieved (maximum of 60 mg/kg/d). The initial dose for this patient would be 954 mg/d, which would be accomplished by administering a 500-mg tablet twice daily. If the migraine prophylaxis and seizure treatment were separated, then multiple other antiepileptics would be considered appropriate for this patient (e.g., lamotrigine). A new prophylactic and/or abortive therapy for the migraines would need to be initiated with this plan.

What over-the-counter and/or alternative medications would be appropriate for R.M.?

Aside from the current periodic use of ibuprofen during episodes of migraine headache, there are no additional nonprescription products that would be recommended for any of R.M.'s diagnoses.

What lifestyle changes would you recommend to R.M.?

With regard to insomnia, R.M. needs to establish a regular routine and initiate sleep hygiene measures in addition to any subsequent medication therapy that may be initiated. This should occur regardless of whether or not a drug is started. In terms of the migraines

and seizure disorder, R.M. should keep a headache and seizure diary in an attempt to capture a pattern and, especially, any triggers that may contribute to headache or seizure episodes.

Describe one or two drug–drug or drug–food interaction for the selected agent.

Topiramate may interact with other medications that depress the central nervous system and/or cause sedation. If zolpidem (or a similar medication for insomnia) is eventually initiated, this will become a very important counseling point and the zolpidem would need to be started at a lower dose (half of a 5-mg tablet). Splitting the tablet would preclude the use of the extended-release product, also. Alcohol may increase the serum concentration of topiramate and may result in increased sedation as well as toxic effects associated with higher serum concentrations of topiramate. If the patient decided to initiate the ketogenic diet for seizures (which is not recommended), her risk of kidney stones with topiramate would be increased.

Attention Deficit Hyperactivity Disorder (ADHD)/Anxiety/Asthma

C.P. is a 16-year-old high school student presenting with complaints of not being able to concentrate in class. The patient is seen with her mother who confirms the patient's concerns and narrative. The issues related to attention have been present since C.P. was about 8 years old, though they have never been problematic as her grades have always been good. This year, however, her grades have worsened considerably, and there is a possibility that C.P. may not progress to her senior year. Her main complaints include an inability to focus in class, challenges with maintaining focus while studying at home, avoidance of homework, failure to follow through on school assignments and personal obligations, forgetfulness, losing her belongings, organizational deficits, and "zoning out" while she is engaged in conversation. These symptoms also have emerged at her part-time job as well, and her supervisor has needed to speak to her about it several times. C.P. has gotten a tutor, studies in silence, and uses a calendar to help organize her responsibilities but without success. During the last 9 months, she has also begun to feel "nervous" and reports some trouble sleeping, excess worrying, restlessness, and frequent stomach upset that she can't control. C.P.'s past medical history is significant for asthma, which is currently treated with an albuterol inhaler. She also indicates that she has had to use her inhaler more frequently than in the past (once per day for an asthma exacerbation), and she is running out of her medication in 3 weeks instead of 4. The worsening of asthma symptoms began 3 months ago and has persisted ever since.

Weight: 186 lb

Height: 63 inches

BP: 118/80 mm Hg

Pulse: 72 bpm

EKG: normal

HAM-A: 12

Current medications:

Albuterol inhaler 90 mcg/actuation: two inhalations every 4 to 6 hours as needed

Issues: C.P. meets the DSM-5 criteria for the diagnosis of ADHD since she has six or more symptoms of inattention, the symptoms occur in more than one domain (home, school, work), symptoms were present before the patient was 12, and the symptoms are causing clinically significant impairment. Since she has already instituted nondrug approaches (keeping a calendar, studying in an appropriate environment, getting a tutor) without success, a medication is warranted. She also *may* meet the DSM-5 criteria for generalized anxiety disorder (6-month duration of symptoms, excessive worry, trouble concentrating, and presence of somatic symptoms). This is arguable because she has an identifiable stressor (possibility of not passing the school year, poor grades) and the symptoms emerged after the symptoms of ADHD. The HAM-A score suggests the presence of an anxiety disorder as well. This needs to be evaluated again at another time when the ADHD is controlled. The anxious symptoms may be the result of the ADHD and the associated academic and social consequences of the ADHD. C.P. has an established diagnosis of asthma, but her symptoms have worsened, and she is using her rescue inhaler (her only prescribed drug for asthma) more frequently than prescribed. C.P. is also obese, though this was not one of her complaints. At this time, this issue should not be addressed with drug therapy, but with lifestyle changes (not covered in detail in this case).* Answers can be found online.

List specific goals for treatment for C.P.

- Resolution of ADHD symptoms (no longer meeting diagnostic criteria)
- Improvement in academic, social, and occupational performance and quality of life
- Resolution of anxious symptoms (worrying, restlessness, stomach ache, trouble sleeping)
- Reduced utilization of her asthma rescue medication

What drug therapy would you prescribe? Why?

C.P. meets the diagnostic criteria for ADHD, as referenced above. As discussed, it is common for ADHD to cooccur with depression, anxiety, substance use disorders, and other psychiatric comorbidities. There is also significant symptom overlap, which may

complicate the accurate diagnosis and appropriate treatment of some patients. The anxious symptoms emerged after the onset of the ADHD symptoms, and it is reasonable to assume that the anxious symptoms are actually a product of ADHD (and the subsequent stressors of possibly not passing her classes, etc.). It is possible that a separate anxiety disorder is present, but it is more likely that it is a result of the ADHD and not independent. A diagnosis of generalized anxiety disorder is precluded when the symptoms are better explained by a different disorder. In this particular case, it is best to treat the ADHD and then reevaluate any residual anxious symptoms if they persist.

First-line drug therapy for ADHD, in the absence of contraindications, is a stimulant. This patient has no contraindications. Since the attention-related symptoms occur throughout the day, choosing a long-acting medication is optimal. This reduces the number of times per day the medication needs to be administered and improves convenience and compliance. In addition, it also minimizes the severity of the perceived onset and offset of the drug (feeling a rush when blood levels climb and feeling a "crash" when they decline). Lastly, the longer-acting drugs are less likely to be abused or diverted than the shorter-acting medications, though this risk is never truly absent.

Many of the long-acting products, which last at least 8 hours (because of the average school and workday or evening study time), would be appropriate. An example of a once-daily, long-acting medication with minimal abuse potential is lisdexamfetamine (Vyvanse). A starting dose of 20 or 30 mg is appropriate and can be titrated up to a maximum daily dose of 70 mg as needed and as tolerated.

Since C.P. is having daily symptoms of asthma, she is classified as moderate persistent and requires daily scheduled medication therapy. At this severity of asthma, she is a candidate for a low-dose inhaled corticosteroid with a long-acting beta agonist. An example of a possible product would be salmeterol 21 mcg and fluticasone 45 mcg MDI (Advair HFA): two inhalations twice daily.

What are the parameters for monitoring success of the therapy?

A 1-month follow-up period would be appropriate and that is more than adequate time for the drug to have a meaningful effect. Theoretically, there should be improvement within the first day or so of therapy, but meaningful, measurable markers of efficacy (like improved grades, reduced work tension, etc.) may take more time to emerge. By the end of the first month, however, the patient should report improvements in ability to focus, concentrate, and engage in tasks that require attention, reduced forgetfulness, and complete projects.

In terms of the asthma control, patient reports of decreased frequency of use of her recue inhaler would indicate effectiveness. In addition, in-office assessments of FEV1, FVC, and PEF would indicate whether the drug has improved her respiratory function.

Discuss specific patient education based on the prescribed therapy.

The patient needs to be educated about adverse effects and also what substances cannot be consumed concurrently with lisdexamfetamine. If the patient experiences any changes in mood or personality, the provider needs to be notified. Secondary to the ability of stimulants to cause weight loss, the patient should be encouraged to maintain a healthy diet and not skip meals (as appetite may be decreased). This patient is obese, and therefore, weight loss will not necessarily be detrimental; however, she should not use this drug for weight loss. Lifestyle changes should be encouraged, and the patient should be counseled on stimulant abuse for purposes of weight loss. C.P. can also be educated about keeping her treatment confidential, as sometimes peers may pressure patients being treated for ADHD to share or sell their medications.

C.P. should rinse her mouth after using her new daily inhaler as the steroid component may result in oral candidiasis.

List one or two adverse reactions for the selected agent that would cause you to change therapy.

Adverse effects that would warrant a change in therapy include clinically significant increases in blood pressure, panic attacks, frequent tachycardia, significant weight loss, or serious changes in sleep patterns. The baseline EKG was normal, and so the risk of the stimulant causing a conduction disturbance is minimal but not nonexistent. If tachycardia emerges or the patient feels an abnormal rhythm ("racing heart," "strange thumping pattern"), then the drug should be discontinued and a different stimulant would not be started. Significant weight loss is of concern even in an obese patient if there is no evidence to suggest that a lifestyle change resulted in the weight loss and it is purely the result of a stimulant.

What would be the choice for second-line therapy?

If lisdexamfetamine failed to produce an acceptable therapeutic effect, then another longer-acting stimulant can be chosen. Examples might include the extended-release mixed amphetamine salts or an extended-release methylphenidate product. If the lisdexamfetamine produced intolerable adverse effects or a serious adverse effect emerged, then another stimulant would be avoided, and potentially, atomoxetine (Strattera) would be next line. Atomoxetine has the added benefit of potentially alleviating anxious symptoms as well as ADHD symptoms. If there is concern about the presence of an anxiety disorder, then bupropion would not be appropriate as it can exacerbate anxiety.

What over-the-counter and/or alternative medications would be appropriate for C.P.?

There would not be any nonprescription products that are proven to be safe or efficacious for the treatment of ADHD, anxiety, or asthma.

What lifestyle changes would you recommend to C.P.?

Aside from continuing her structured studying and time management strategies, there are no additional lifestyle recommendations with regard to the ADHD. She should avoid taking pseudoephedrine due to its stimulant effects.

Describe one or two drug–drug or drug–food interactions for the selected agent.

C.P. should not take any additional stimulant products (like pseudoephedrine as mentioned above) and should obviously not ingest any illicit drug substances.

Asthma/ADHD/Allergies with Exacerbation of Allergy

N.J. is an 11-year-old boy with a 5-year history of ADHD and a 7-year history of asthma. He also experiences perennial allergic rhinitis. N.J.'s mother is bringing him into your office due to an exacerbation of this allergy. The symptoms he presents with include increased cough and runny nose and sneezing. He has no other medical history. The following is his current list of medications:

Concerta: 36 mg every morning
Albuterol inhaler, two puffs as needed (uses one to two times a day)
Singulair: 5 mg PO daily
Zyrtec: 5 mg PO daily* Answers can be found online.

List specific goals of treatment for N.J.

The obvious goal is to decrease the coughing and other allergic symptoms. However, it is not clear if the cough is a secondary manifestation of the uncontrolled asthma or as a result of the rhinorrhea associated with the allergies. Therefore, an additional goal would be to improve the asthma control. Specific goals related to asthma would be a decrease in the frequency of use of the albuterol inhaler.

What drug therapy would be appropriate for N.J.? Why?

The National Asthma Education and Prevention Program update of 2007 recommends that all persons with persistent asthma be prescribed a low-dose inhaled corticosteroid

controller balancing the availability on the patient's formulary and the convenience of administration (bid vs. qid). He should also remain on the Singulair daily and the albuterol as needed.

What are the parameters for monitoring success of the therapy?

For the allergies, a reduction in the rhinorrhea and, if appropriate, a decrease in the cough would be good clinical markers of success. For the asthma, the primary indicator of stable asthma would be a decreased use of the short-acting beta agonist to less than twice weekly as well as improved lung function such as improved peak flow readings or improved exercise tolerance.

Discuss specific patient education based on the prescribed therapy.

An investigation of the potential changes in the household or other environmental changes should be part of the workup. Discussion with the mother and child regarding triggers is a key to preventing these exacerbations.

Finally, the patient needs to be educated about the use of this agent as a long-term controller and not a symptom reliever. The inhaled corticosteroid is not intended to relieve acute symptoms of asthma. The clinician should also observe N.J.'s use of the inhaler to assure proper technique.

List one or two adverse reactions for the selected agent that would cause you to change therapy.

When considering alternative therapy, a thorough review of the use of short-acting β_2 agonists must also be considered because these will also produce palpitations, chest pain, and tachycardia. Further, an increasing need for short-acting β_2 agonists or a perceived lack of benefit of short-acting β_2 agonists may be a sign of seriously worsening asthma, and the patient should notify the clinician immediately.

What would be the choice for the second-line therapy for treating N.J.?

If N.J.'s symptoms are not resolved, a second-line therapy would be to move up to moderate-dose corticosteroid with or without the Singulair. Alternatively, a long-acting beta agonist such as salmeterol can be added to the regimen.

What over-the-counter or alternative medications would be appropriate for N.J.?

For treating the rhinorrhea, over-the-counter antihistamines may be used additively, but the sedating effects need to be taken into consideration.

What dietary and lifestyle changes should be recommended for N.J.?

Avoidance of allergen triggers should be considered one of the primary lifestyle changes. Removal of carpets from the bedroom, keeping pets out of rooms in which N.J. spends time, and washing sheets/linens in hot water weekly are some of the strategies for reducing environmental allergens. Exposure to second-hand smoke should also be minimized.

Depression/Gastroesophageal Reflux Disease (GERD)

M.M. is a 60-year-old African American man who presents with a 3-month history of lack of sleep because he awakens every 2 hours and cannot get back to sleep. He lacks desire to do anything that he previously enjoyed, has an increased appetite, and does not want to leave his house. It is an effort for him to go to work every morning. Additionally, he says that when he eats anything, he gets burning in his stomach and esophagus and is awakened at night with indigestion.

Social history: Married for 35 years to the same woman. Two grown children. His 15-year-old dog died 3 months ago. He took the dog everywhere with him. He smokes 1/2 pack of cigarettes a day.

BP: 126/80

Pulse: 76

Weight: 204 lb

Height: 67 inches

Rest of physical exam: WNL

Labs:

TSH: 3.4
PSA: 0.6
Cholesterol: 212 mg/dL
LDL: 128 mg/dL
HDL: 40 mg/dL

Issues: M.M. has symptoms of depression. Insomnia is an issue. He also has the symptoms of new-onset GERD.* Answers can be found online.

List specific goals for treatment for M.M.

The goals of therapy for M.M. relate to quality of life as well as clinical goals. Relieving the depressive symptoms should help M.M. enjoy life and feel better, but the time frame for response is 4 to 6 weeks, provided the initial therapy works. This should be discussed with M.M. as therapy is initiated. A depression scale, such as the Hamilton Depression Scale (HAM-D), might be given to determine a baseline level of depression and as a means of monitoring progress as treatment continues. A specific goal might be a 50% decrease or better from the baseline HAM-D score.

However, relief of indigestion and providing adequate sleep are more immediate goals that should be achievable within the first week of therapy. Progress on these short-term goals is likely to help M.M. continue with the therapy for relieving the long-term problem of depression. Therefore, specific goals are:

- Relief of symptoms of depression
- Provision of adequate sleep
- Relief of reflux symptoms
- Smoking cessation.

What drug therapy would you prescribe for M.M.? Why?

Paroxetine is a good choice because it promotes better sleep. It is best to give this agent in the evening due to slight sedative effects. If another agent is on formulary at a substantially lower cost, such as sertraline, it can be prescribed and taken in the morning. Typically, a sleeping aid is prescribed in patients such as M.M., but the sedative effects of paroxetine might be sufficient. If the insomnia persists after 4 to 6 weeks, an additional hypnotic may be considered. A proton pump inhibitor (PPI) would be a reasonable choice for relief of his GERD now, and if it persists after 3 months, endoscopy would be indicated.

What are the parameters for monitoring success of the therapy?

Follow-up history is the best way to monitor therapy for depression. Readministration of a depression scale with an improved score would indicate successful therapy. Also, indication of 8 hours of sleep a night demonstrates successful therapy. Patient-reported frequency and severity of GERD episodes is a good tool to determine success of therapy for GERD.

Discuss specific patient education based on the prescribed therapy.

The overall premise is the promotion of "good sleep habits," which include setting a routine bedtime, instituting regular exercise habits, using the bed for sleeping only, and getting in bed only when ready for sleep. Occasional completion of a sleep log is an

important tool for the clinician to evaluate the effectiveness of therapy.

Lifestyle changes are as important as drug therapy in managing GERD. Discussion with the patient and family should cover the following important dietary changes: avoidance of excess alcohol and food intake; decreased amounts of chocolate and spicy, fried, or fatty foods; and avoidance of the recumbent position for at least 3 hours after meals. Because these recommended changes involve many activities or foods that are pleasurable for the patient, they should be eliminated gradually—one at a time. A nutritionist can be consulted to help the patient learn to choose and prepare less problematic foods.

Additional measures include teaching the patient to elevate the head of the bed approximately 4 to 6 inches (using blocks); to avoid tight, restrictive clothing; and to lose weight if necessary.

The patient needs to be counseled on the risks of continued smoking. The patient's readiness for change must be ascertained, and he needs to be educated on the poor health consequences associated with continued smoking.

List an adverse reaction for the selected agents that would cause you to change therapy.

If M.M. complains of decreased libido from the paroxetine, then consideration should be given to lowering the dose or changing to a nonselective serotonin receptor inhibitor. This is particularly important if it becomes upsetting to him because he and his wife have a very satisfying sexual relationship.

What would be the choice for second-line therapy?

Lowering the dose of paroxetine might help with the side effects. However, if this is not possible, bupropion is an appropriate choice for second-line therapy for the depression, particularly as it relates to sexual side effects.

What over-the-counter or alternative medications would be appropriate for M.M.?

Some patients, especially those with delayed sleep phase insomnia, may benefit from the administration of exogenous melatonin; however, further study is necessary.

Aloe vera juice may help in the healing of gastrointestinal tract irritation. Other herbs, such as catnip, fennel, ginger, and marshmallow root, as well as papaya juice, may help stop heartburn. Licorice is used to treat both heartburn and stomach and esophageal ulcers.

What lifestyle changes would you recommend to M.M.?

Lifestyle modifications are essential for the patient with GERD. Although drug therapy will

help reduce the level of acid in the stomach and promote healing, lifestyle changes will aid in preventing the symptoms from returning. These lifestyle changes include dietary changes, such as avoiding irritating foods like caffeine, alcohol, and spicy foods. Further, refraining from eating at least 3 hours before bedtime and elevating the head of the bed by at least 6 inches will help reduce nighttime symptoms. Weight loss will also reduce the frequency of GERD symptoms. Lastly, smoking cessation will reduce the frequency of GERD symptoms.

The overall premise is the promotion of "good sleep habits," which include setting a routine bedtime, instituting regular exercise habits, using the bed for sleeping only, and getting in bed only when ready for sleep. Occasional completion of a sleep log is an important tool for the clinician to evaluate the effectiveness of therapy.

Describe one or two drug–drug or drug–food interactions for the selected agents.

Paroxetine is an inhibitor of the cytochrome P-450 (CYP) 2D6 system and might increase the serum concentrations of cough suppressants such as dextromethorphan and codeine, so care must be taken when using these agents during cough/cold season. The PPIs omeprazole, lansoprazole, and pantoprazole are inhibitors of the CYP2C19 system and would increase levels of drugs such as diazepam, phenytoin, or amitriptyline.

List specific goals for treatment for J.F.

The cold appears to be viral in nature. Symptoms of a cold consist primarily of clear nasal discharge, sneezing, nasal congestion, cough, low-grade fever (below 102°F), scratchy or sore throat, mild aches, chills, headache, watery eyes, tenderness around the eyes, full feeling in the ears, and fatigue. Symptoms usually resolve in approximately 1 week, but they may linger for 2 weeks.

Specific goals are:

- Relief of symptoms
- Reduction of the risk of complications
- Prevention of spread to others

The fact that J.F. has an elevated blood pressure is concerning, especially in light of his family history. At this time, clearance for the gym cannot be given until there is further cardiac testing completed.

There are other issues that need to be addressed, such as his alcohol intake and multiple sexual partners.

Acute Care Visit Scheduled for a Cold;

Discovered to Have Hypertension

J.F. is a 41-year-old white male who presents with a cold that he has had for about 4 days. He has a runny nose, cough that is annoying, and periodic headache. He has not tried any over-the-counter medicines. He wants an antibiotic for the cold because he is going skiing this weekend.

While in the office, he says he needs a note saying he is well enough to use the gym. He has no known health problems but has not seen a health professional in over 4 years.

Social history: Single. Elementary school teacher. Multiple sexual partners. Strong family history of heart disease. His father and uncle died before age 50 of an acute myocardial infarction. Does not smoke. Drinks socially but may have 10 beers on the weekend.

Physical exam:

BP: 150/100
Pulse: 70 RRR
Weight: 250 lb
Height: 70 inches
Nasal mucosa: red and swollen
Ears: normal
No lymphadenopathy
Lungs: clear to auscultation

Issues: J.F. presents with symptoms of a viral upper respiratory infection. He wants antibiotics for a quick fix. He also wants clearance for the gym. Physical exam shows that he is overweight and has hypertension. He also has a strong family history of heart disease at an early age.* Answers can be found online.

What drug therapy would you prescribe for J.F.? Why?

Nonpharmacologic alternatives to treating the common cold are the first line. For example, rest allows the body to gain strength and be more effective in defending itself against the pathogen. The body can then dictate the increase in activities. An alternative to decongestants and expectorants is increasing water or juice intake. This assists in liquefying tenacious secretions; making expectoration easier; soothing scratchy, sore throats; and relieving dry skin and lips. Saline gargles also are effective for soothing sore throats.

Coughing caused by chest congestion can cause a muscular chest pain. Menthol rubs can soothe this ache and open airways for some congestion relief. Menthol lozenges also have been effective in soothing scratchy throats and clearing nasal passages. Saline nasal flushes are also effective for clearing nasal passages without the rebound side effect. Petrolatum-based ointments for raw and macerated skin around the nose and upper lip ease

the drying effects of dehydration and the use of multiple tissues.

Other measures, such as drinking chicken soup, taking a hot shower, or using a room humidifier, may prove helpful. Inhaling warm, moist heat helps raise the temperature of the nasal mucosa to at least 37 °C, a temperature at which the virus does not replicate so readily.

Expectorants, including water, increase the output of respiratory tract fluid by decreasing the adhesiveness and surface tension of the respiratory tract and by facilitating removal of viscous mucus. The effect is noted within 1 to 2 hours.

J.F.'s symptoms appear viral in nature so an antibiotic is not indicated at this time. Decongestants are not recommended for J.F. because of his elevated blood pressure.

What are the parameters for monitoring success of the therapy?

Follow-up is the best way to monitor therapy. Acute sinusitis often results from progression of the common cold (5% to 10% of cases). J.F. should be seen back in 1 week to evaluate symptoms. At that time, his other issues, such as blood pressure, multiple sexual partners, and alcohol intake, need to be addressed.

If the infection has failed to resolve or improve after 7 to 10 days, he may have sinusitis. Major symptoms include facial pain, pressure, congestion, fullness, obstruction, blockage, or discharge with a temperature greater than 38°C. Purulent drainage in the middle meatus may be a strong indicator of acute sinus disease; however, nasal purulence does not differentiate viral from bacterial infection. Symptoms may include headache, fatigue, dental pain, halitosis, otalgia, or cough. Other symptoms include toothache and a poor response to decongestants. There is usually edema of the mucous membranes upon examination and tenderness over the sinus areas upon percussion.

Characteristic signs are purulent, green or yellow nasal discharge and abnormal sinus illumination. Acute bacterial sinusitis is a consideration in patients who report cold symptoms lasting more than 8 days or with prolonged nasal obstruction or a cold that seems to have gotten better but returns with more severe symptoms.

Discuss specific patient education based on the prescribed therapy.

J.F. needs to be educated not to take decongestants that might increase his blood pressure. He should increase fluids and humidity for symptom relief. If symptoms do not get better within 1 to 2 weeks, he needs to follow up. Education should be included as to how to prevent spread of germs.

However, J.F. needs to schedule a visit within 1 to 2 weeks to address his other issues. He needs a cardiac workup and probably an antihypertensive. Since his hypertension is presumed to be stage 1, the recommended antihypertensive is a thiazide diuretic.

List one or two adverse reactions for the selected agent that would cause you to change therapy.

Adverse reactions from expectorants include drowsiness, headache, and GI symptoms. Decongestants are not used because they can increase blood pressure.

What would be the choice for second-line therapy?

An antibiotic would be considered if symptoms do not resolve in 1 to 2 weeks since it has probably become sinusitis.

The recommended length of antibiotic therapy for acute bacterial sinusitis is at least 14 or 7 days beyond the resolution of symptoms, whichever is longer. Amoxicillin is appropriate for the initial treatment of acute, uncomplicated, mild sinusitis in patients with no recent antibiotic use. Antimicrobial agents with more broad-spectrum activity may be indicated as initial therapy for patients who have more severe infection, comorbidity, or risk factors for bacterial resistance or who have not responded to amoxicillin therapy. These agents include amoxicillin and clavulanic acid, the newer quinolones (e.g., levofloxacin, gatifloxacin, moxifloxacin), and some second- and third-generation cephalosporins (cefdinir, cefuroxime axetil, and cefpodoxime proxetil). Patients who are allergic to penicillin may be treated with a macrolide, trimethoprim–sulfamethoxazole, tetracyclines, or clindamycin.

If J.F.'s blood pressure is not controlled on the diuretic, it is recommended to start a second antihypertensive agent in addition to the diuretic.

What over-the-counter or alternative medications would be appropriate?

Increased humidification is recommended. Also, J.F. should increase fluid intake to loosen secretions. A hot shower helps to relieve sinus congestion.

What dietary and lifestyle changes should be recommended?

J.F. needs to decrease sodium intake because of his elevated blood pressure. He needs to lose weight and increase physical activity after a cardiac evaluation.

J.F. needs counseling in safe sexual practices, such as the use of condoms. These issues can be handled at another visit when he follows up.

Adolescent with Dysmenorrhea/Acne and Sexually Active

S.S. is a 16-year-old presenting with severe dysmenorrhea. She began menstruating at age 13. Her periods have been irregular. Each month she misses a day of school because of severe cramps and heavy bleeding with her menses. She also has a moderate case of acne, which is very disturbing to her. She has tried topical preparations and antibiotic therapy for the acne without results. She has no history of gallbladder disease, migraine headaches, or chest pain.

Social history: S.S. is a sophomore in high school. She is sexually active but does not use condoms. She has had two sexual partners, although now she is in a monogamous relationship with a senior at her high school. She lives with her mother and younger brother. She does not smoke or drink.

Issues: S.S. has dysmenorrhea that affects her quality of life. In addition, she has acne, which is disturbing to her self-image. S.S. is sexually active and does not use condoms. This puts her at risk for pregnancy and sexually transmitted infections (STIs).* Answers can be found online.

List specific goals for treatment.

Goals of treatment for S.S. relate to quality of life as well as clinical goals. Relief of dysmenorrhea is paramount. It will decrease absences from school and improve overall well-being. Additionally, treatment of acne is important because that affects her self-image.

Another goal is prevention of pregnancy and STIs. Therefore, specific goals are:

- Relief of dysmenorrhea
- Treatment of acne
- Prevention of pregnancy
- Prevention of STIs.

What drug therapy would you prescribe? Why?

NSAIDs can be used for treatment of dysmenorrhea. However, oral contraceptives (OCs) are the drug of choice for S.S. since she is sexually active and has acne unresponsive to other treatment. OCs prevent pregnancy and reduce the risk of endometriosis, ovulatory pain, dysmenorrhea, ovarian cysts, benign breast disease, premenstrual syndrome, premenstrual dysphoric disorder, and ovarian and endometrial cancer. They also might improve acne. The improvement occurs secondary to an increase in the level of sex-hormone–binding globulin, which reduces circulating free testosterone and ameliorates many androgenic effects. It is reasonable to prescribe a generic monophasic OC pill containing 30 to 35 mcg of estrogen.

In addition, S.S. should receive quadrivalent human papillomavirus (HPV) vaccine. This provides protection against the four types of HPV most commonly associated with clinical diseases. It is recommended for females ages 13 to 26. It is a series of three doses.

Ideally, vaccine should be administered before potential exposure to HPV through sexual contact. The second dose is administered 1 to 2 months after the first dose, and the third dose is administered 6 months after the first dose.

What are the parameters for monitoring success of therapy?

Follow-up history is the best way to monitor success of the OCs for dysmenorrhea. Resolution of acne can be determined by examination of the skin.

Discuss specific patient education based on the prescribed therapy.

OCs can have either a day 1 start or a Sunday start regimen. Women who follow a day 1 start regimen begin the contraceptive agent on the first day of their period, regardless of the day of the week. Likewise, women who follow Sunday start regimens begin the OC pill pack on the Sunday directly after the onset of menses. This means that the woman will not menstruate on a weekend, which is desirable to many patients. S.S. may experience some breakthrough bleeding for the first 3 months of therapy.

OCs should be taken at the same time every day. It can be recommended to place them with S.S.'s toothbrush so she takes them when she brushes her teeth. If a pill is missed, S.S. should follow this regimen:

One pill	Take missed pill as soon as possible and resume schedule; backup method of contraception is not necessary.
Two 30- to 35-mg pills	Take missed pill as soon as possible and resume schedule; backup method of contraception is not necessary
Two 20-mg pills	Follow directions for more than two pills
More than two pills	Take pill and continue taking a pill daily
	Use condom or abstinence for 7 d
	If missed in week 3, finish active pills in current pack and start a new pack the next day (skip current inactive pills)
	If missed pills in first week and had sex, use emergency contraception (EC) and then resume taking pills the next day after EC

It is imperative to discuss the use of condoms to prevent STIs. OCs prevent pregnancy, but not STIs.

List adverse reactions for the selected agent that would cause you to change therapy.

If S.S. had prolonged breakthrough bleeding, a change in hormone content would be considered. In the first half of the menstrual cycle, breakthrough bleeding is likely due to insufficient estrogen; in the second half of the cycle, it is likely due to insufficient progesterone. Therefore, changing to a new regimen with higher estrogen or progesterone is recommended.

Dizziness, Insomnia, Stress

A.E. is a 56-year-old white female who presents ongoing symptoms of dizziness, inability to sleep, and recent increase in stress. She reports that these symptoms have been present off/on for at least 6 months, but worsening the last 3 weeks. The dizziness is really an off-balance sensation, and she feels weak at times going down steps. Currently sleeps only 6 hours nightly, but with many awakenings. Also, reports some ringing in her ears at times. Last full physical was 2 years ago.

Past medical history: None

Social history: Married for 30 years but recently separated from her husband. Relationship has been verbal abuse for many years, but worse recently. Current smoker of 30 pack years. Denies alcohol. Not currently working and has just moved up to live with her sister. Has three grown children, one who is disabled.

Physical exam:

BP: 140/82
Pulse: 70 RRR
Weight: 150 lb
Height: 66 inches

Alert, oriented × 3 in NAD. Eyes, PERRLA 3 mm without nystagmus, remainder. Ears, clear but some fluid present and bulging slightly. Remainder of HEENT unremarkable. CV, regular, rate, rhythm, no murmurs, rubs, gallops. Lungs, clear. Neuro, no focal deficits, negative Romberg, pronator drift, able to tandem walk, no cerebellar signs. Psych, appears anxious and fatigued. Poor self-esteem evident in conversation.

Issues: A.E. presents with symptoms of vertigo that could be caused by a variety of problems including stress reaction, acoustic neuroma, and eustachian dysfunction. She also has sleep disturbance issues that could be related to the stress.* Answers can be found online.

What drug therapy would you prescribe for A.E.? Why?

The vertigo-type symptoms A.E. is experiencing could be something as simple as eustachian dysfunction. A trial of oral high-dose guaifenesin (Mucinex) could be helpful to improve mucous drainage from the eustachian tubes. Decongestants are not recommended for A.E. because her blood pressure is slightly elevated.

Concomitantly, there is a need to address the stress level of A.E. for pharmacologic therapy. She has been treated in the past for anxiety. Selecting an agent that addresses anxiety and depression may be helpful. A good selection for this patient is escitalopram (Lexapro), which has a minimal side effect profile. It does not causes further neurologic impairment such as drowsiness, and reports are minimal to none for worsening of suicidal ideation.

What are the parameters for monitoring success of the therapy?

Close follow-up is the best method of monitoring for success. The guaifenesin will likely help with the eustachian dysfunction in 10 to 12 days. However, the escitalopram can take up to 6 weeks for any noticeable response; however, some patients report a slight change within 2 weeks. The anticipated change is that she will feel less "off balance" and have more energy.

Discuss specific patient education based on the prescribed therapy.

A.E. needs to be educated to take the guaifenesin consistently for at least 10 to 12 days. Also, she should be advised to not to take decongestants that might increase her blood pressure until it can be ascertained that she is not truly hypertensive. Education about healthy diet, smoking cessation, and exercise will help with her overall mood.

However, A.E. needs to schedule a visit within 2 to 3 weeks to evaluate the tolerance to treatment. Appropriate bloodwork should be ordered prior to screen for other disease processes such as diabetes and hyperlipidemia.

List one or two adverse reactions for the selected agent that would cause you to change therapy.

Adverse reactions from expectorants include drowsiness, headache, and GI symptoms. Common side effects from the escitalopram can include nausea (usually only initially), dry mouth, increased sweating, and dizziness (more related to missed doses).

What would be the choice for second-line therapy?

Change to another within this class of antidepressant, such as paroxetine, which also treats for anxiety.

What over-the-counter or alternative medications would be appropriate?

Guaifenesin (Mucinex) is an over-the-counter drug. While A.E. is on escitalopram, she should not take any alternative medications advertised for depression/insomnia such as St. John's wort or valerian root due to interactions.

What dietary and lifestyle changes should be recommended?

A.E. needs to evaluate her sleep habits including temperature of the room, darkness, and activities before bedtime. Also, counseling is highly desirable to help her find coping strategies for her abusive relationship and self-esteem.

Fatigue, Hypertension, Obesity, and Seasonal Allergies

D.E. is a 64-year-old white female who presents ongoing symptoms of heart racing, heat intolerance, and weight loss. She has some sleep problems, but these have occurred in most of her life. She reports that these symptoms have been present off/on for at least 6 months, but worsening the last 3 weeks. Her allergy symptoms generally affect her in the fall.

Past medical history: Hypertension, obesity, seasonal allergies

Social history: Married for 35 years. Current smoker of 20 pack-years. Denies alcohol. Has three grown children.

Medications: Lisinopril 10 mg, HCTZ 25 mg, loratadine 10 mg

Physical exam:

BP: 152/82
Pulse: 110
Weight: 192 lb down from 210 lb without trying
Height: 66 inches

Alert, oriented × 3 in NAD. HEENT unremarkable. Neck, supple, no thyromegaly or nodules. CV, regular, tachycardic, rate, rhythm, no murmurs, rubs, gallops. Lungs, clear. Neuro, no focal deficits. Skin, no rashes, lesions, slightly dry but warm.

Issues: D.E. presents with symptoms of tachycardia that could be caused by a variety of problems including hyperthyroidism, hypothyroidism, infection with fever, and/or

cardiac arrhythmias. Her hypertension could also be a component of the fast heart rate.* Answers can be found online.

What drug therapy would you prescribe for D.E.? Why?

The rapid heart rate and other symptoms D.E. is experiencing must be evaluated further; however, adding a beta-blocker would help assist with slowing the heart rate and subsequent work of the heart. Atenolol is a good choice since it controls heart rate for 24 hours along with hypertension. It is well tolerated with a potential side effect profile of bradycardia, dizziness, and hypotension in those who do not have underlying coronary disease. A baseline 12-lead EKG is necessary before implementing treatment. If the EKG shows atrial fibrillation, D.E. needs more immediate follow-up in the emergency room. If the presentation is due to a transient thyroiditis, institution of antithyroid medications is not indicated at this time; the need is control the symptoms until bloodwork (TSH, T_4) is obtained.

What are the parameters for monitoring success of the therapy?

Close follow-up is the best method of monitoring for success. Rechecking D.E. in 3 to 4 days is necessary to evaluate for success of decreasing the heart rate and blood pressure.

Discuss specific patient education based on the prescribed therapy.

D.E. needs to be educated to take the medication routinely and not miss any doses, especially the atenolol; beta blockers should not be abruptly discontinued. If she experiences any worsening of the tachycardia as therapy is initiated, she should go to the emergency room. Education about healthy diet, smoking cessation, and exercise will help with her overall mood.

List one or two adverse reactions for the selected agent that would cause you to change therapy.

Post marketing, some patients have experienced elevated liver enzymes and/or bilirubin; hallucinations; headache; impotence; Peyronie disease; postural hypotension, which may be associated with syncope; psoriasiform rash or exacerbation of psoriasis; psychoses; purpura; reversible alopecia; thrombocytopenia; visual disturbance; sick sinus syndrome; and dry mouth. Atenolol, like other beta blockers, has been associated with the development of antinuclear antibodies (ANA), lupus syndrome, and Raynaud phenomenon.

What would be the choice for second-line therapy?

Since the tachycardia may be related to hyperthyroidism, verapamil would be a good second choice. It treats both the fast heart rate and also the hypertension. Lisinopril should still be maintained due its effect on the renin–angiotensin-activating system.

What over-the-counter or alternative medications would be appropriate?

No medications are appropriate, but the patient should avoid foods with high caffeine and OTC cold and cough products.

What dietary and lifestyle changes should be recommended?

Even though D.E. has lost weight, she is still very overweight. Ongoing counseling about dietary intake and exercise will help to enhance appropriate weight loss. Additional counseling on tobacco cessation is also important.

Type 2 Diabetes Mellitus, Hypertension, Hyperlipidemia

M.A. is a 45-year-old African American male who presents for follow-up on his diabetes. Reports to have lost a few pounds but is finding it difficult to control his diet. Performs home glucose monitoring periodically, but only at the same time of day in the morning. The results are consistently 180 to 200 mg/dL. Otherwise, he feels generally healthy. Reports taking all his medications routinely and has no problem with obtaining the drugs.

Past medical history: Type 2 diabetes mellitus × 10 years, hypertension, obesity, hyperlipidemia

Social history: Married for 20 years. Current smoker of 20 pack years. Socially drinks beer on the weekends. Has three children: one adolescent and two younger children. He does not routinely exercise. Works at the USPS in maintenance of vehicles.

Medications: Metformin 1,000 mg bid, lisinopril 10 mg, HCTZ 25 mg, simvastatin 40 mg

Physical exam:

Pertinent recent lab work: HgA_{1c} 8.0%, FBS 192, Chol 178 mg/dL, HDL 45 mg/dL, LDL 70 mg/dL, eGFR 98 mL/min/1.73 m^2
BP: 132/82
Pulse: 70
Weight: 220 lb
BMI: 30.9%
Height: 71 inches

Alert, oriented × 3 in NAD. HEENT unremarkable. Neck, supple, no thyromegaly or nodules. CV, regular, tachycardic, rate, rhythm, no murmurs, rubs, gallops. Lungs, clear. Neuro, no focal deficits. Skin, no rashes, lesions, slightly dry but warm.

Issues: M.A. presents for routine maintenance of his diabetes, hypertension, and hyperlipidemia. His lab works show uncontrolled diabetes but without current complications of CKD. Blood pressure is within normal expected range with appropriate medications. Cholesterol is well controlled with the simvastatin. Addressing his blood sugar control is the most urgent priority today.* Answers can be found online.

What drug therapy would you prescribe for M.A.? Why?

At this point, it may be appropriate to prescribe INVOKANA (canagliflozin) tablets. Sodium–glucose cotransporter 2 (SGLT2), expressed in the proximal renal tubules, is responsible for the majority of the reabsorption of filtered glucose from the tubular lumen. Canagliflozin is an inhibitor of SGLT2. By inhibiting SGLT2, canagliflozin reduces reabsorption of filtered glucose and lowers the renal threshold for glucose (RTG) and thereby increases urinary glucose excretion (UGE). M.A.'s kidney function meets the criteria for administration.

What are the parameters for monitoring success of the therapy?

Decrease in HgA_{1c} to ≤7.0%, 45% of those taking 100 mg daily within 26 weeks. This means that daily blood sugar monitoring would have a decrease on average to 130 mg/dL.

Discuss specific patient education based on the prescribed therapy.

M.A. needs to be educated to take the medication routinely with the first meal of the day. Canagliflozin will cause sugar to be excreted in the urine. In some cases, the medication can cause hypoglycemia, so routine blood sugar monitoring, especially with hypoglycemic symptoms, is important. M.A. needs to continue all other medications for his hypertension and hyperlipidemia. Caution should be exercised with administration of diuretics, phenytoin or phenobarbital, digoxin, rifampin, or ritonavir.

List one or two adverse reactions for the selected agent that would cause you to change therapy.

This class of drug can cause hyperkalemia, mycotic infections, urinary tract infections, and renal insufficiency. The mycotic infections are more common in women than men. Monitoring of renal function is a necessity as the drug must be stopped for decreasing glomerular filtration rate. Elevation in potassium would also be another indication to

change therapy.

What would be the choice for second-line therapy?

Starting basal insulin would be a second-line therapy given the persistent elevation in blood sugar and HgA_{1c}. Using any of the insulin glargine preparations (Levemir, Lantus, etc.) with a bedtime dose.

What over-the-counter or alternative medications would be appropriate?

There are no OTC medications for diabetes. Although there are some small studies with cinnamon, they have proven small increases in blood sugar control. Therefore, taking cinnamon daily would not be harmful.

What dietary and lifestyle changes should be recommended?

M.A. needs to continue to watch his carbohydrate intake. Instructions of carb counting and calorie control, with continual reinforcement at each visit. Daily exercise is beneficial for helping blood sugar control and overall well-being.

Conclusion

These are just a few examples of the decision-making process involved in prescribing medications. Most patients do not present with just one diagnosis and are taking several medications, and these factors must be considered in deciding on the best pharmacologic approaches. The intent of these examples is to help the reader understand *possible* solutions to some common problems. With advances in pharmacotherapy and in evidence-based medicine, the potential approaches to these cases are expected to change. The complexity of patients requires the practitioner to prioritize problems, develop a systematic approach to resolving the problems pharmacotherapeutically, and anticipate how to manage the plan prospectively.
